The patient's complete surgical history is important to note. Particularly relevant are surgical procedures impacting the respiratory system. For example, patients who have had a lobectomy have absent lung sounds over the affected area. A patient with a history of laryngectomy does not breathe through the mouth or nose; instead, the opening to the respiratory system is through the neck. Also important is that the nurse should assess if there is a history of respiratory complications following surgery (i.e., pulmonary embolism or atelectasis).

### Family History

A family history of respiratory illnesses may increase the patient's genetic predisposition for illnesses (i.e., cystic fibrosis). Also, close contact with family members with infectious respiratory illnesses or respiratory irritants may be the cause of noted respiratory dysfunction. For example, patients who live in close contact with an individual diagnosed with TB need to be evaluated for the disease.

### Occupation and Area of Residence

Certain occupations and areas of residence may contribute to or worsen respiratory disease processes. For example, patients who work in dusty environments may have respiratory symptoms in response to dust or other environmental allergens. Patients may be exposed to carcinogenic substances such as asbestos in their work environment. Patients who report occupational hazards or exposure to toxic substances need to be educated regarding the risks of their occupation and the importance of safety equipment to prevent complications.

### Smoking History

Tobacco can be inhaled in the form of cigarettes or cigars or chewed in the form of chewing tobacco. Patients who report current or previous use of tobacco should be asked the type of tobacco used, amount or packs per day, number of years of use, and the quit date, if relevant.

### Social History

The patient's social history, including alcohol and illicit drug use, should be evaluated for frequency of use, amount, route (for drug use), and number of years of use. Many illicit drugs can be smoked or inhaled, making the patient susceptible to respiratory illnesses.

### Recent Travel History

Recent travel out of the country, especially to impoverished areas, may put the patient in contact with infectious respiratory disease processes such as TB. Symptoms that started after travel may assist in the diagnosis of the respiratory condition.

## Physical Assessment

### Inspection

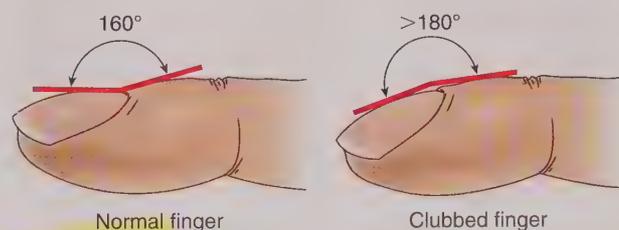

Inspection is the first step in the assessment of the respiratory system. Abnormalities in the patient's level of consciousness and orientation status may indicate hypoxia. During inspection, the nurse should also assess the patient's speech. Patients should be able to speak freely and in full and complete sentences. Patients in respiratory distress may have difficulty speaking because of shortness of breath. The characteristics of the patient's fingernails may also indicate chronic respiratory dysfunction. Clubbing of the fingernails (Fig. 23.11) is a sign of chronic hypoxia and is a common assessment finding in patients with COPD.

The nose should be inspected to assess for symmetry and size. Each naris should be inspected for discharge, bleeding, masses, and/or swelling. The mucous membranes of the nares should be inspected for color. Pale or cyanotic mucous membranes may indicate tissue hypoxia.

The mouth should be inspected for open sores, bleeding, and/or masses. During inspection, the nurse should note the color and consistency of the mouth. The mucosa of the mouth should be pink and moist. Dry, cracked, or sticky mucous membranes may indicate dehydration. Mucous membranes that are pale or cyanotic may indicate tissue hypoxia.

The neck should be inspected for symmetry, skin discoloration, masses, cyanosis, and swelling. The position of the trachea (midline or any deviation to the right or left) should also be visualized during inspection of the neck.

The thorax should be inspected for skin integrity while identifying any scars, masses, lesions, or skin discoloration. The nurse should check for **retractions** on inspiration. Retractions occur when muscles pull inward during inspiration, sometimes causing the skin to pull in around ribs. This signifies increased work of breathing and respiratory distress. The nurse should also check for chest symmetry on inspiration and compare the thorax left to right and anterior to posterior (AP). Normally, the AP diameter when compared to the lateral diameter should be 1:2, whereas patients with chronic respiratory diseases such as COPD will have a ratio of 1:1. The nurse should inspect the spine while evaluating

**FIGURE 23.11** Clubbing of the fingernails indicating chronic hypoxia.

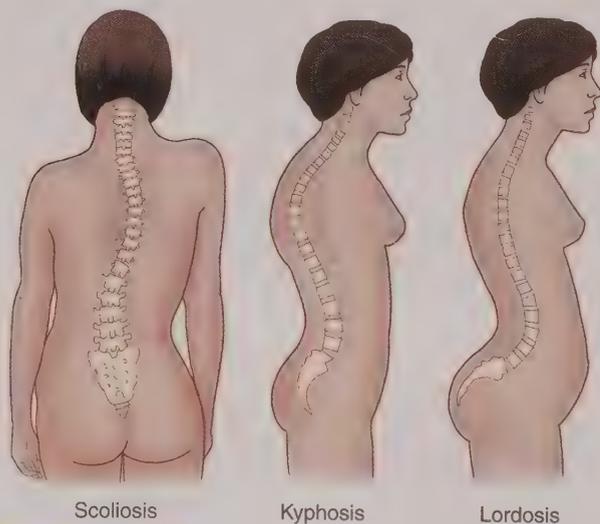

the posterior thorax. Spinal deformities such as kyphosis, scoliosis, or lordosis can have an impact on the respiratory system (Fig. 23.12).

Vital signs, specifically the patient's respiratory pattern, rate, depth, and effort, should be assessed. The patient should be unaware that the nurse is obtaining the respiratory rate because patients tend to increase their respiratory rate if they know they are being observed. In order to take the respiratory rate, the nurse can count respirations and observe the chest wall while obtaining the patient's radial pulse. Respiratory rates greater than 20 are defined as **tachypnea**, whereas respiratory rates less than 12 are described as **bradypnea**. **Apnea** is defined as absent respirations. While the respiratory rate is obtained, signs of retractions, nasal flaring, and the use of accessory muscles can be observed. In addition, the **pulse oximetry** reading should be obtained. Pulse oximetry is discussed later in the chapter.

### Palpation

The nurse should lightly palpate the trachea to ensure that it is midline and nontender. Following palpation of the trachea, the nurse can palpate the anterior and posterior thorax to assess for pain, crepitus, masses, and deformities. **Crepitus** occurs when air is trapped under the skin and is best described as a crackling feeling. Crepitus can be caused by a pneumothorax or trauma to the chest.

During palpation of the thorax, the nurse can assess for equal expansion of the lungs by placing both hands on the posterior thorax and having the patient inhale and exhale. As the patient breathes, both hands should rise equally during inspiration and return at the same rate during expiration. The nurse should also assess for tactile fremitus (vibration intensity) by placing hands on the patient's posterior thorax and having the patient say "ninety-nine." As the patient is speaking, the nurse should assess the vibration felt. Differences in vibrations between the right and left sides of the thorax may indicate conditions such as pneumonia or pleural effusions.

**FIGURE 23.12** Spinal abnormalities that may impact breathing: scoliosis, kyphosis, and lordosis.

### Percussion

Assessment of percussion between the ribs should be performed following palpation. The normal percussion sound heard over lung tissue is resonance. Table 23.1 describes the characteristics of each percussion sound and where it is heard normally. Table 23.2 details the respiratory conditions associated with each percussive sound when heard over lung tissue. Figure 23.13 demonstrates the appropriate sequence for percussion of the lungs.

### Auscultation

The diaphragm of the stethoscope is used during auscultation of the respiratory system. The nurse should compare the sounds auscultated between the right and left lungs during inspiration and expiration. Careful attention should be given to ensure that the patient does not become dizzy or lightheaded during the assessment. See Figure 23.13 for the appropriate sequencing for auscultation.

Normal lung sounds can be divided into three types: bronchial, bronchovesicular, and vesicular lung sounds. Table 23.3 details the characteristics of each lung sound and the normal location for each sound.

Abnormal or adventitious lung sounds are crackles (rales), wheezes, rhonchi, and pleural friction rubs. Table 23.4 details the characteristics of adventitious lung sounds and the possible respiratory conditions associated with each adventitious sound.

**Safety Alert** Dyspnea is a subjective finding and, as such, will vary between patients. Patients who are reporting dyspnea and have any of the following assessment findings should be referred for immediate medical intervention:

- Unable to speak or able to speak only a few words
- Use of accessory muscles
- Retractions
- Adventitious lung sounds
- Tachypnea
- Pulse oximetry readings below baseline
- Abnormal percussion sounds
- Cyanosis
- Change in level of consciousness

### Connection Check 23.3

Which of the following indicates an abnormal assessment finding of the respiratory system?

- A. Symmetrical chest expansion
- B. Muscle retractions with inhalation
- C. The sound of resonance with percussion of lung tissue
- D. Pink mucosa of the mouth and nares

**Table 23.1 Percussion Sounds**

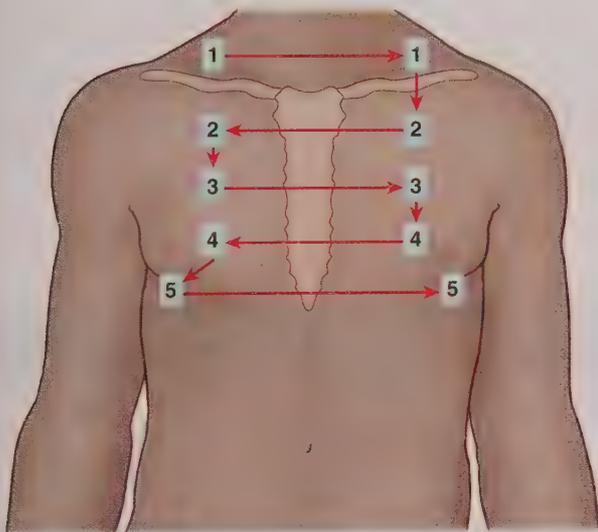

Percussion Sound	Duration	Quality	Pitch	Normal Body Location for Percussion Sound
<b>Resonance</b>	Long	Hollow	Loud	Lung tissue
<b>Flat</b>	Short	Dull	High	Bone
<b>Dull</b>	Medium	Thud	Medium	Liver, heart, kidney, diaphragm
<b>Tympany</b>	—	Drumlike	Loud	Stomach
<b>Hyperresonance</b>	Longer than for resonance	Boom	Louder than for resonance	Sound not normally heard during assessment

**Table 23.2 Percussion Sounds and Associated Respiratory Conditions**

Percussion Sound	Potential Respiratory Conditions
<b>Flat</b>	Pleural effusion
<b>Dull</b>	Pneumonia, atelectasis, mass
<b>Tympany</b>	Large pneumothorax ✓
<b>Hyperresonance</b>	Emphysema, chronic asthma, pneumothorax ✓

**Table 23.3 Normal Lung Sounds**

Sound	Characteristic	Normal Auscultation Location
<b>Bronchial</b>	<ul style="list-style-type: none"> <li>Described as hollow</li> <li>Loud intensity</li> <li>Longer during expiration than inspiration</li> </ul>	<ul style="list-style-type: none"> <li>Neck/trachea</li> </ul>

<b>Vesicular</b>	<ul style="list-style-type: none"> <li>Described as a gentle breeze</li> <li>Soft intensity</li> <li>Longer during inspiration than expiration</li> </ul>	<ul style="list-style-type: none"> <li>Below the second intercostal space and peripheral lung fields</li> </ul>

**FIGURE 23.13** Sequencing for auscultation and percussion of the anterior chest.

## DIAGNOSTIC STUDIES

### Arterial Blood Gases

#### Description and Rationale

Arterial blood gas values include the partial pressure of carbon dioxide ( $\text{PaCO}_2$ ), pH, bicarbonate ( $\text{HCO}_3^-$ ), and partial

pressure of oxygen ( $\text{PaO}_2$ ) levels. Blood gases are used to assess acid-base balance. They can be used to determine oxygenation status because  $\text{PaO}_2$  is the most accurate assessment, but pulse oximetry (discussed later in the chapter) is an easier, noninvasive way to assess oxygenation. Abnormal or low  $\text{PaO}_2$  levels indicate hypoxemia. This does not indicate an acid-base imbalance; however, the body's compensatory mechanism of increasing the respiratory rate in response to hypoxemia decreases the  $\text{PaCO}_2$  value, impacting the acid-base balance. An arterial blood gas sample is

**Table 23.4 Abnormal or Adventitious Lung Sounds**

Adventitious Sound	Characteristic	Respiratory Condition
<i>Fine crackles (fine rales)</i>	<ul style="list-style-type: none"> <li>Described as rubbing of hair follicles together</li> <li>Cause: inflation of previously deflated lung tissue</li> <li>Present during inspiration (early or late)</li> </ul>	<ul style="list-style-type: none"> <li>Fibrosis</li> <li>Bronchitis</li> <li>Pneumonia</li> <li>Chronic obstructive pulmonary disease (COPD)</li> </ul>
<i>Coarse crackles (coarse rales)</i>	<ul style="list-style-type: none"> <li>Described as a popping/coarse sound</li> <li>Cause: fluid or secretions in lower airways</li> <li>Auscultated during early inspiration or expiration</li> </ul>	<ul style="list-style-type: none"> <li>COPD</li> <li>Sputum in airway</li> <li>Pneumonia</li> <li>Pulmonary edema</li> <li>Congestive heart failure</li> </ul>
<i>Rhonchi</i>	<ul style="list-style-type: none"> <li>Described as snoring</li> <li>Cause: obstruction, sputum, or secretions typically in upper airways</li> <li>Present during inspiration and expiration</li> <li>May clear with coughing/suctioning</li> </ul>	<ul style="list-style-type: none"> <li>Pneumonia/bronchitis</li> <li>Masses (malignant or nonmalignant)</li> <li>Foreign body</li> </ul>
<i>Wheezing</i>	<ul style="list-style-type: none"> <li>Described as a squeaky musical instrument</li> <li>Cause: bronchoconstriction and inflammation</li> <li>Present during inspiration, expiration, or both</li> </ul>	<ul style="list-style-type: none"> <li>Asthma</li> <li>COPD</li> </ul>
<i>Stridor</i>	<ul style="list-style-type: none"> <li>Described as a high-pitched sound during inspiration</li> <li>Cause: airway obstruction of the throat or upper airway or spasms of the airway</li> </ul>	<ul style="list-style-type: none"> <li>Allergic reaction</li> <li>Epiglottitis</li> <li>Laryngitis</li> </ul>
<i>Pleural friction rub</i>	<ul style="list-style-type: none"> <li>Described as grating or squeaking</li> <li>Cause: inflammation of pleural space</li> <li>Typically present during inspiration and expiration</li> </ul>	<ul style="list-style-type: none"> <li>Pneumonia</li> <li>Lung malignancy</li> <li>Pleurisy</li> </ul>

obtained directly from an artery through an arterial line or peripheral needle puncture.

### Significance of Abnormal Results

The following are normal values for an arterial blood gas analysis:

PaO<sub>2</sub>, 80 to 95 mm Hg  
 PaCO<sub>2</sub>, 35 to 45 mm Hg  
 pH, 7.35 to 7.45  
 HCO<sub>3</sub><sup>-</sup>, 22 to 26 mEq/L

Table 23.5 lists some respiratory conditions that cause acid-base abnormalities.

### Patient Preparation

If the arterial blood gas specimen is being obtained through a peripheral needle puncture, the patient should be prepared for pain during the insertion of the needle. Because of the difficulty in puncturing the artery, the patient should be advised to remain still; any movement may cause difficulty in

**Table 23.5 Respiratory Conditions That Cause Acid-Base Abnormalities**

	Arterial Blood Gas Results	Associated With
<i>Respiratory acidosis</i>	PaCO <sub>2</sub> : greater than 45 mm Hg  pH: less than 7.35	<ul style="list-style-type: none"> <li>Chronic obstructive pulmonary disease</li> <li>Pneumonia</li> <li>Respiratory failure</li> </ul>
<i>Respiratory alkalosis</i>	PaCO <sub>2</sub> : less than 35 mm Hg  pH: greater than 7.45	<ul style="list-style-type: none"> <li>Hyperventilation</li> <li>May be associated with early asthma or pneumonia</li> <li>Anxiety</li> </ul>

obtaining a specimen. The patient may notice bruising and tenderness at the puncture site after specimen collection.

### Nursing Implications

Prior to obtaining the specimen, the nurse should assess the patient's pulses and select a site that has a palpable pulse. The radial arteries are the most common site for obtaining peripheral arterial blood gas specimens. If the nurse elects to utilize the radial artery, assessment of the ulnar circulation needs to be evaluated utilizing the Allen test. The Allen test is done by asking the patient to clench his or her fist while compressing both the ulnar and radial arteries. Upon unclenching the fist, the hand should appear pale. Adequate ulnar circulation is indicated by the return to normal color after releasing pressure on the ulnar artery.

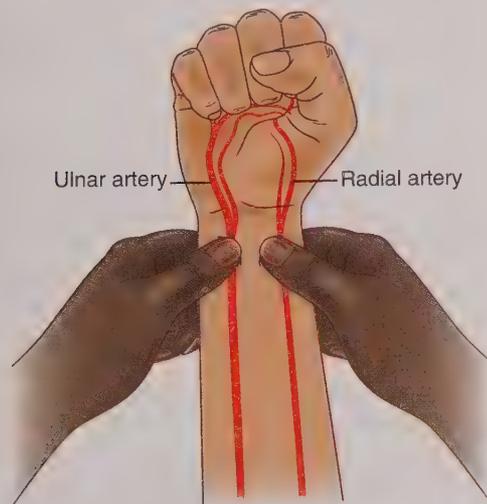

See Figure 23.14 for the appropriate technique for performing the Allen test.

After ulnar circulation is assessed, the nurse should confirm that all supplies are at the bedside, including a syringe designed for blood gas analysis and a cup of ice. Prior to insertion of the needle, the nurse preps the site with alcohol. If the patient's blood pressure is within normal limits, blood should enter the syringe immediately upon insertion of the needle into the artery. Once the specimen has been obtained, it should be promptly placed on ice. Direct pressure should be applied to the puncture site for several minutes, and then a pressure dressing is applied. The nurse should assess the puncture site to ensure that no bleeding is noted. Perfusion of tissue distal to the puncture site should also be assessed.

## Pulse Oximetry

### Description and Rationale

Pulse oximetry utilizes wavelengths of light to measure the saturation of hemoglobin with oxygen. It is a noninvasive way to monitor changes in the patient's oxygenation status.

**FIGURE 23.14** The Allen test to assess for adequacy of ulnar artery circulation.

Typically, pulse oximetry is obtained by placing a probe on a patient's finger, although some devices may be applied to the ear, toes, or forehead. Normal pulse oximetry readings are between 95% and 99%. Patients with chronic respiratory diseases may have baseline pulse oximetry readings below 95%. Pulse oximetry readings may be inaccurate if there is poor perfusion in the extremity being monitored. Poor perfusion can be caused by hypothermia, shock, cardiac arrhythmias, carbon monoxide poisoning, edema, peripheral vasoconstriction, tourniquets, and inflated blood pressure cuffs.

### Significance of Abnormal Values

Pulse oximetry readings below 95% indicate that a patient may be experiencing hypoxemia. Abnormal pulse oximetry readings should be confirmed with arterial blood gases, especially when the patient's symptoms and pulse oximetry reading do not correlate. Pulse oximetry readings between 91% and 94% indicate mild hypoxemia, readings between 86% and 90% indicate moderate hypoxemia, and pulse oximetry readings of less than 85% indicate severe hypoxemia.

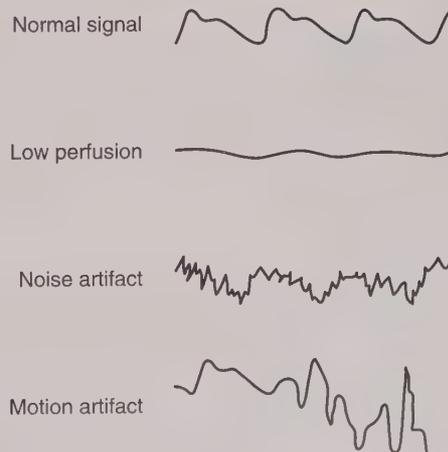

### Patient Preparation

In order for a patient to have an accurate pulse oximetry reading, the fingernails need to be warm and free of nail polish. The patient should be asked to limit the movement of the finger the probe is placed on to ensure an accurate reading.

### Nursing Implications

The nurse must confirm the accuracy of oximetry readings by evaluating the waveform (Fig. 23.15) and ensuring the pulse obtained through pulse oximetry correlates with the patient's heart rate. Without correlation, the accuracy of the reading should be questioned. It is also important to recognize that other conditions can affect the meaningfulness of the pulse oximetry reading. For example, the patient experiencing

### Pulse Oximeter Waveform

**FIGURE 23.15** Pulse oximetry waveforms.

carbon monoxide poisoning may have a pulse oximetry reading of 100%, but the hemoglobin is saturated with carbon dioxide, not oxygen. Also, a patient with a pulse oximetry reading of 100% with a decreased hemoglobin level will still not have adequate tissue oxygenation.

## Capnography and Capnometry

### Description and Rationale

**Capnography** continuously monitors the PaCO<sub>2</sub> in the airway during inhalation and exhalation and provides a written tracing. **Capnometry** measures the amount of CO<sub>2</sub> exhaled without continuous tracing. Devices typically used for capnometry are sensor devices that provide a one-time reading of CO<sub>2</sub> levels. The most valuable CO<sub>2</sub> reading is the end-tidal CO<sub>2</sub> level. End-tidal CO<sub>2</sub> measures the maximal partial pressure of CO<sub>2</sub> obtained at the end of an exhaled breath. Normal end-tidal CO<sub>2</sub> readings are 2 to 5 mm Hg less than PaCO<sub>2</sub> readings for healthy patients.

### Significance of Abnormal Values

Abnormal capnography and capnometry values indicate dysfunction of the respiratory system in expelling CO<sub>2</sub>. Increases in end-tidal CO<sub>2</sub> levels may be from an increase in cellular metabolism, resulting in an increase in CO<sub>2</sub> production or hyperventilation that causes an increase in the excretion of CO<sub>2</sub> from the lungs. Disease processes that result in increased CO<sub>2</sub> levels are hyperthermia, trauma, burns, and sepsis. Decreases in the end-tidal CO<sub>2</sub> levels result from inadequate ventilation, respiration, or pulmonary perfusion. Conditions that cause this are slow cellular metabolism, resulting in less CO<sub>2</sub> production; hypoventilation, resulting in a decrease in the excretion of CO<sub>2</sub> from the lungs; and finally, conditions that cause an increase in alveolar dead space and shunt, which causes inadequate pulmonary capillary perfusion. This limits the diffusion of CO<sub>2</sub> into the alveoli, resulting in lower end-tidal CO<sub>2</sub> levels. Disease processes that result in lower end-tidal CO<sub>2</sub> levels are hypothermia, sedation, pulmonary embolism, hypoperfusion of the pulmonary system, endotracheal tube placement in the esophagus, systemic hypotension, and cardiac arrest.

### Patient Preparation

Capnography and capnometry are both noninvasive and not uncomfortable unless attached to an artificial airway (endotracheal tube or tracheostomy) because the artificial airway may cause discomfort. The equipment and procedure should be explained to the patient.

### Nursing Implications

Capnography measuring devices can be applied to the end of an artificial airway or noninvasive oxygen delivery devices such as a nonrebreather mask. If the device is utilized on a mechanically ventilated patient, care must be taken not to disrupt the artificial airway, ventilator tubing, or capnography device. Prior to using the device, the nurse should ensure that the capnography equipment is calibrated and zeroed.

Capnometry is typically utilized to confirm endotracheal tube placement after intubation. It is applied to the end of the endotracheal tube. The device will show a color change to blue, indicating the presence of CO<sub>2</sub> and intubation of the trachea. Endotracheal tube placement should also be confirmed by auscultation and chest x-ray. Continuous capnometry or monitoring of the end-tidal CO<sub>2</sub> level is also recommended for use during cardiopulmonary resuscitation (CPR) to evaluate the effectiveness of compressions. A value equal to or greater than 20 mm Hg indicates adequate compressions.

## Connection Check 23.4

You are caring for a patient who is currently receiving continuous pulse oximetry. Which of the following findings might indicate inaccurate readings?

- The patient has a core body temperature of 94°F (34.5 °C).
- The heart rate obtained through pulse oximetry correlates with the electrocardiogram heart rate.
- The patient has the probe attached to her earlobe.
- The patient's pulse oximetry is 95%, and the patient denies shortness of breath.

## Sputum Analysis

### Description and Rationale

A sputum analysis is done to check for microorganisms and/or abnormal cell growth. If microorganisms are identified, then a sensitivity test is performed to determine an effective antibiotic therapy. If abnormal cells are identified, analysis to determine if the cells are malignant or nonmalignant is indicated.

### Significance of Abnormal Values

A sputum analysis positive for microorganisms indicates the presence of an infectious process such as TB or pneumonia. The presence of abnormal cells may indicate malignancy.

### Patient Preparation

There are two methods for collecting a sputum culture. Patients with a natural airway will be given a sterile collection device and asked to cough and deposit expectorated sputum into the container. Prior to collection, patients should rinse the mouth to limit the contamination of normal mouth flora in the culture. In addition, patients should be instructed to collect sputum as early in the morning as possible because secretions accumulate overnight, increasing the volume of sputum collected and increasing the potential to identify microorganisms. During collection of the sputum, the patient should be instructed to deeply inspire and expire, with the patient coughing during expiration.

Patients with an endotracheal tube or tracheostomy will have the sputum culture collected by suctioning the airway

and placing the contents into a sterile collection device. Suctioning may cause some discomfort to the patient, although the discomfort will be temporary.

### **Nursing Implications**

Patients who require suctioning for the collection of a sputum sample will require hyperoxygenation prior to suctioning. Once the patient is hyperoxygenated, the nurse inserts the suction catheter connected to suction into the tracheostomy or endotracheal tube utilizing sterile technique. During the procedure, the nurse monitors the patient's respiratory rate and heart rate. If vital sign abnormalities are noted, the procedure is stopped, and the patient is hyperoxygenated until the vitals return to baseline.

## **Chest X-rays**

### **Description and Rationale**

Chest x-rays are diagnostic studies of the thorax that may identify problems with the lungs, heart, and pleural space. Chest x-rays are normally a first-line diagnostic test for patients with respiratory complaints because they are widely available and relatively inexpensive.

### **Significance of Abnormal Values**

Chest x-rays will show if there are abnormalities of the heart or lungs. For the heart, chest x-rays are able to identify only abnormalities involving the size, shape, or placement of the heart. If abnormalities of the heart are noted during a chest x-ray, additional diagnostic tests are indicated. For the lungs, chest x-rays can identify masses, air or fluid in the pleural space, pneumonia, atelectasis, and possible TB infections. Many times, additional diagnostic tests are needed to confirm chest x-ray results. For example, a chest x-ray may identify possible TB, which is confirmed with a positive sputum culture.

### **Patient Preparation**

Patients should remove any necklaces or jewelry that covers the neck or thorax prior to radiography. Female patients should remove their bra prior to having a chest x-ray. Any metal objects will obscure the view of the chest and thus the x-ray image.

### **Nursing Implications**

The nurse or x-ray technician should drape all body areas not being x-rayed in a lead shield to minimize radiation exposure. For women of childbearing age, pregnancy status should be confirmed prior to the test. Women who are pregnant should receive education regarding the risk to the fetus prior to undergoing x-ray, and the test should be performed only if the benefits of the x-ray exceed the risks to the fetus.

## **Pulmonary Function Test**

### **Description and Rationale**

Pulmonary function tests evaluate lung volumes to determine the functioning of the lungs. The patient is asked to inspire

and exhale into a mouthpiece. During the test, the patient is given instructions to alter his or her breathing patterns, allowing for different tests to be obtained. Before the test is started, normal values based on gender, weight, height, and smoking history are calculated to ensure the accuracy of the readings. See Table 23.6 and Figure 23.16 for a summary of normal pulmonary function results for a healthy adult male.

### **Significance of Abnormal Values**

Pulmonary function values aid in the diagnosis of respiratory conditions. Table 23.7 discusses some possible causes of abnormalities related to the results of pulmonary function tests.

### **Patient Preparation**

Prior to a pulmonary function test, the patient needs to refrain from smoking and eating for 8 hours. Also, the patient should abstain from bronchodilators (beta-2 agonists) for 4 to 6 hours prior to the test. The person administering the test should provide clear instructions to avoid unnecessary repetition.

### **Nursing Implications**

The patient should be carefully monitored during the test to avoid any complications such as shortness of breath or bronchospasm.

## **Bronchoscopy**

### **Description and Rationale**

A bronchoscopy allows for direct visualization of the respiratory tract down to the level of the secondary bronchi. The two types of bronchoscopy are flexible and rigid. Flexible bronchoscopies are used to take tissue specimens or replace an endotracheal tube. Rigid bronchoscopy is used to remove obstructions or large amounts of secretions from the respiratory tract.

### **Significance of Abnormal Values**

Abnormal findings on bronchoscopy assist in the diagnosis of respiratory conditions. Tissue specimens are analyzed to determine the presence of infectious processes or cellular abnormalities.

### **Patient Preparation**

Because of the invasive nature of the procedure, patient consent should be obtained. Because of the need for sedation and the risk for aspiration, patients should not eat (should remain NPO) for at least 8 hours prior to the procedure.

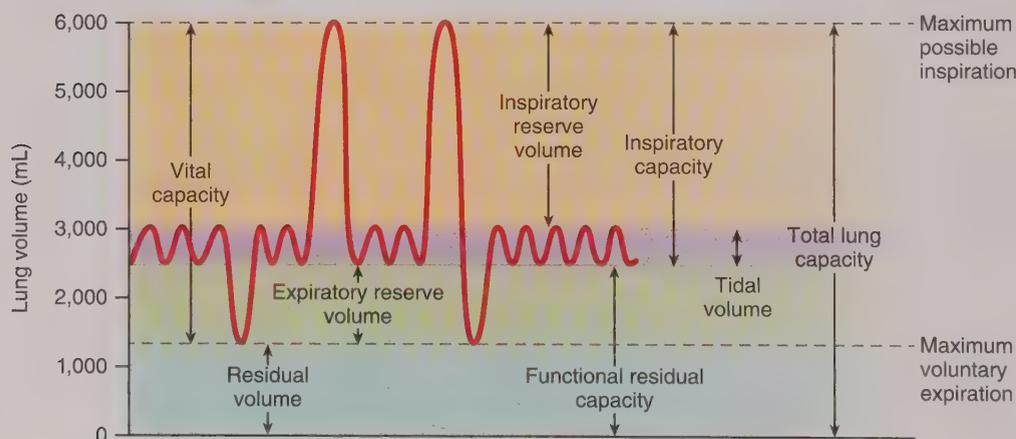

### **Nursing Implications**

Prior to beginning the procedure, the nurse should ensure that the appropriate consents have been signed and that a time-out procedure has been completed. The time-out should confirm the patient's identity and the procedure being performed. Flexible bronchoscopy can be performed at the bedside with the patient receiving moderate sedation. Rigid bronchoscopy typically requires general anesthesia and is performed in the operating room (OR).

**Table 23.6 Summary of Normal Pulmonary Function Tests**

Measurement	Typical Value	Definition
<b>Respiratory volumes</b>		
<b>Tidal volume (TV)</b>	500 mL	Amount of air inhaled and exhaled in one cycle during quiet breathing
<b>Inspiratory reserve volume (IRV)</b>	3,000 mL	Amount of air in excess of TV that can be inhaled with maximum effort
<b>Expiratory reserve volume (ERV)</b>	1,200 mL	Amount of air in excess of TV that can be exhaled with maximum effort
<b>Residual volume (RV)</b>	1,300 mL	Amount of air remaining in the lungs after maximum expiration; the amount that can never voluntarily be exhaled
<b>Respiratory capacities</b>		
<b>Vital capacity (VC)</b>	4,700 mL	The amount of air that can be inhaled and then exhaled with maximum effort; the deepest breath possible ( $VC = ERV + TV + IRV$ )
<b>Inspiratory capacity (IC)</b>	3,500 mL	Maximum amount of air that can be inhaled after a normal tidal expiration ( $IC = TV + IRV$ )
<b>Functional residual capacity (FRC)</b>	2,500 mL	Amount of air remaining in the lungs after a normal tidal expiration ( $FRC = RV + ERV$ )
<b>Total lung capacity (TLC)</b>	6,000 mL	Maximum amount of air the lungs can contain ( $TLC = RV + VC$ )
<b>Forced vital capacity (FVC)</b>	5,000 mL	Amount of air an individual can forcefully exhale after maximum inspiration
<b>Forced expiratory volume (FEV1) (over 1 second or over 1 minute)</b>	Depends upon the FVC	Amount of air an individual can forcefully exhale within a set time frame (1 second or 1 minute)
<b>Forced expiratory flow (FEF)</b>	Depends upon the FVC	Expiratory flow during different portions of the FVC. The flow readings are obtained during the beginning, middle, and last portion of the FVC.

Adapted from Saladin, K. S. (2018). *Anatomy & physiology* (8th ed.). New York, NY: McGraw-Hill

**FIGURE 23.16** Respiratory volumes and capacities.

Moderate sedation involves giving the patient an IV pain medication and sedative. Depending on state and hospital protocols, this sedation may be administered by a nurse who has received specialized training in moderate sedation or an advanced practice nurse (i.e., a certified registered nurse anesthetist [CRNA]). Patients who receive moderate sedation are typically able to respond to verbal stimuli or gentle touch.

For flexible and rigid bronchoscopies, patients will need IV access and continuous cardiac monitoring, pulse oximetry, and blood pressure monitoring. Because patients are receiving moderate sedation or general anesthesia for the procedure, prior to starting the procedure, the nurse or OR staff needs to ensure that all of the emergency equipment is available at the bedside, including oxygen and suction. Nurses who are monitoring patients receiving moderate

**Table 23.7 Disease Processes and Pulmonary Function Test Results**

Pulmonary Function Test Result	Possible Disease Process
Increase in total lung capacity	Chronic obstructive pulmonary disease (COPD)
Decreases in total lung capacity	Sarcoidosis or pulmonary fibrosis
Decreases in forced vital capacity	COPD, sarcoidosis, pulmonary fibrosis, or neuromuscular diseases such as myasthenia gravis
Decreases in forced expiratory volume	COPD or may be caused by age-related changes
Decreases in forced expiratory flow	Disease processes related to obstructions such as asthma or COPD

sedation need to constantly evaluate the patient's condition and vital signs. If a patient receiving moderate sedation experiences respiratory depression, bradycardia, or hypotension, immediate action is needed on the part of the nurse. At the conclusion of the test, the patient should be monitored (vital signs, lung sounds, and mental status) every 15 minutes until his or her level of consciousness returns to baseline. During the recovery process, the nurse should assess for complications of the procedure, such as bleeding or hypoxia. The patient should remain on NPO status until the patient is alert and the gag reflex is intact.

## Thoracentesis

### Description and Rationale

A thoracentesis can be used as a diagnostic test or treatment depending on the disease process. During a thoracentesis, a needle is inserted into the pleural space to remove excess fluid/air.

### Significance of Abnormal Values

If fluid is aspirated from the pleural space, it can be analyzed to determine if microorganisms or abnormal cells are present. If air is aspirated from the pleural space, this is consistent with a pneumothorax diagnosis. Thoracentesis can be used as a treatment option to remove fluid and/or air from the pleural space.

### Patient Preparation

As with a bronchoscopy, the patient needs to sign a consent form and be informed of the benefits and risks of the procedure. This procedure is normally completed under local anesthesia, so the patient is fully awake during the procedure. Because patients are awake, they need to be instructed not to move but to remain as still as possible. In order to assist the provider with the procedure, the patient is placed

in a sitting position. A bedside table is placed in front of the patient, and the patient leans against the table during the procedure. The patient should be informed that it is normal to feel the need to cough during the procedure and should be advised to try to deep breathe to avoid coughing.

### Nursing Implications

Prior to starting the procedure, the nurse should ensure that the patient has signed the appropriate consent forms and that a time-out procedure has been completed. The nurse should assist the patient into a seated position on the side of the bed with a bedside table in front of the patient. The patient should then be instructed to lean on the table during the procedure. The nurse should assess for potential complications that may arise during the procedure by monitoring vital signs and pulse oximetry. Any changes in the patient's vital signs may indicate complications and the need for the procedure to be discontinued. The output from the site of the thoracentesis should be monitored because excess drainage (more than 500 mL) may cause hypotension. Most patients who report shortness of breath prior to the procedure report immediate relief of symptoms once the fluid or air is removed from the pleural space.

At the conclusion of the procedure, the nurse needs to reevaluate the patient's vital signs and lung sounds to assess for possible complications such as pneumothorax. A chest x-ray should also be obtained because of the high risk of pneumothorax. The patient should be encouraged to cough and deep breathe following the procedure to decrease the risk of atelectasis and promote good lung expansion.

Patients may be discharged home following a thoracentesis with education as to signs and symptoms of complications. Patients should be told to immediately report any of the following symptoms to their provider:

- Elevated heart rate/heart palpitations
- Dyspnea/shortness of breath (SOB)
- Chest pain
- Hemoptysis (bloody secretions)

The patient should also receive education regarding wound care following the thoracentesis. Following the procedure, a dry sterile dressing is typically applied to the site. The area should be assessed for drainage and bleeding immediately following the procedure and prior to discharge if the patient is having the procedure completed as an outpatient. A minimal amount of blood noted on the dressing is normal.

## Lung Biopsy

### Description and Rationale

A lung biopsy allows for a small piece of lung tissue to be removed and analyzed under a microscope. Lung biopsies can be performed percutaneously or through an open procedure. The type of biopsy performed is based on the location and size of the tissue requiring biopsy. A biopsy is typically ordered to confirm lung cancer, sarcoidosis, or pulmonary fibrosis.

### Significance of Abnormal Values

Abnormal values may indicate an infectious process or malignancy.

### Patient Preparation

Patients who are receiving a percutaneous lung biopsy will need the same preparation pre-procedure as patients receiving a bronchoscopy. Patients who are receiving an open biopsy will need to be NPO for at least 8 hours prior to the procedure because they will be receiving general anesthesia. Prior to the procedure, the patient will need to be educated about the postoperative period (i.e., open biopsies require the use of a chest tube in the postoperative period). Depending on the type of open biopsy performed and the patient's respiratory function, the patient may require intubation and mechanical ventilation in the postoperative period.

### Nursing Implications

For percutaneous and open lung biopsies, there must be consent from the patient, and a time-out should be performed. During percutaneous biopsies, the nurse will assist the patient into the position that is utilized for a thoracentesis. Patients will receive a local anesthetic, injected at the site of the biopsy. During the procedure, the nurse will monitor the patient's vital signs, including pulse oximetry, for any complications that may arise. The nurse needs to remind the patient not to move or cough during the procedure.

Patients who are having an open biopsy will receive general anesthesia and will be monitored by an anesthesiologist or CRNA during the procedure. During an open biopsy, a thoracotomy will be performed, which will require a chest tube to allow for reexpansion of the lungs. The nurse will

need to monitor the patient during the postoperative period to assess for complications arising from the surgery and anesthesia.

### Connection Check 23.5

Which of the following is included in an arterial blood gas analysis?

- A. End-tidal CO<sub>2</sub>
- B. Hemoglobin
- C. PaCO<sub>2</sub>
- D. Sodium

### AGE-RELATED CHANGES OF THE RESPIRATORY SYSTEM

There are anatomical, physiological, and immunological changes that occur in the respiratory system as age increases. Table 23.8 details each of these changes.

### Connection Check 23.6

Which of the following is a finding attributable to age-related changes?

- A. Kyphosis
- B. AP-to-lateral diameter of 1:1
- C. PaCO<sub>2</sub> of 47 on an arterial blood gas
- D. PaCO<sub>2</sub> of 60 on an arterial blood gas

**Table 23.8** Age-Related Changes of the Respiratory System

	Changes to Respiratory System	Impact
<b>Structural changes</b>	<ol style="list-style-type: none"> <li>1. Stiffening of the thoracic cage</li> <li>2. Decrease in height of thoracic vertebrae from osteoporosis</li> <li>3. Kyphosis</li> <li>4. Decrease in chest-wall compliance</li> </ol>	Kyphosis and osteoporosis of the thoracic vertebrae cause a decrease in chest-wall compliance. The decrease in chest-wall compliance increases the residual volume, which decreases the function of the diaphragm. Therefore, elderly patients have increased residual volumes and respiratory effort during inspiration.
<b>Changes related to muscle function</b>	<ol style="list-style-type: none"> <li>1. Decrease in strength of diaphragm</li> <li>2. Decrease in strength of intercostals</li> </ol>	The decrease in function/strength of the intercostals and diaphragm increases inspiratory effort to maintain adequate ventilation.
<b>Tissue changes</b>	<ol style="list-style-type: none"> <li>1. Decrease in elasticity of tissue</li> </ol>	The decrease in the elasticity of lung tissue increases the residual volume while decreasing vital capacity.
<b>Reactivity of airway</b>	<ol style="list-style-type: none"> <li>1. Increase in potential for bronchoconstriction</li> </ol>	The airways of older adults are more reactive than those of younger adults. Older adults have a delayed response to bronchodilators, increasing the possibility of hypoxia and hypercapnia from bronchoconstriction.

**Table 23.8** Age-Related Changes of the Respiratory System—cont'd

	Changes to Respiratory System	Impact
<b>Gas exchange</b>	<ol style="list-style-type: none"> <li>1. Depressed cough reflex and ventilatory response to hypoxia and hypercapnia</li> <li>2. Delays in gas exchange across the alveolar membrane</li> </ol>	Increased potential for episodes of hypercapnia and hypoxia
<b>Immunological changes</b>	<ol style="list-style-type: none"> <li>1. Increase in the neutrophils in respiratory tissue</li> <li>2. Decrease in the macrophages in respiratory tissue</li> </ol>	The increase in neutrophils and decrease in macrophages create chronic inflammation of the lung tissue, which hinders gas exchange.

## Making Connections

### CASE STUDY: WRAP-UP

In addition to Mr. Thomas's complaint of shortness of breath, he reports chest pain that increases with coughing and thick yellow/green sputum for several days. His assessment is as follows:

Inspection upper respiratory system: Nasal and mouth mucosa are pink; no bleeding, masses, or deformities are noted in the upper respiratory system.

Inspection lower respiratory system: Patient has a respiratory rate of 20, with even and unlabored respirations. During the history, the patient is speaking freely and does not report any shortness of breath while talking. The patient has skin that is appropriate for his ethnic background, with no skin integrity issues noted during inspection.

Palpation: No masses, deformities, or crepitus are noted. Trachea is midline and nontender. The patient has equal lung expansion anterior and posterior; the patient reports pain that increases with inspiration.

Percussion: Dullness over right lower lobe, otherwise hyperresonance

Auscultation: Fine crackles in right lower lobe with inspiration and expiratory wheezes and diminished breath sounds noted throughout.

Vital signs:

Temperature: 100°F (38°C)

Respiratory rate: 22

Pulse oximetry on room air: 91% to 93%

Heart rate: 90 bpm

Blood pressure: 130/80 mm Hg

The chest x-ray notes pneumonia on the right lower lobe of the lung. On the basis of the diagnostic studies and assessment

findings, the provider diagnoses Mr. Thomas with pneumonia and exacerbation of his COPD. Oral antibiotics are prescribed, and Mr. Thomas is advised to stay home from work until the symptoms subside.

### Case Study Questions

1. Which of the following nursing diagnoses is the priority for Mr. Thomas on the basis of his diagnosis and symptoms?
  - A. Impaired gas exchange
  - B. Deficient knowledge
  - C. Risk for infection
  - D. Fluid volume deficit
2. Which of the following instructions should the nurse include in Mr. Thomas's teaching plan about the management of his pneumonia? (*Select all that apply.*)
  - A. Begin a robust exercise program.
  - B. Stop taking the antibiotics once his cough resolves.
  - C. Smoking will exacerbate symptoms and should be avoided during recovery.
  - D. To cough and deep breathe at least 10 times per hour to assist with airway clearance.
  - E. Stay in bed to rest as much as possible.
3. Which statement by the patient with pneumonia indicates that teaching has been effective?
  - A. "I will return to my provider's office if my symptoms are not improved 5 days after starting the antibiotics."
  - B. "I can continue to smoke following my illness, and it will not have any impact on my respiratory status."
  - C. "I will stop taking my blood pressure medication because it will increase my risk for developing pneumonia."
  - D. "A fever is expected until I am finished with my course of antibiotics."

4. Which of the following indicates a worsening of Mr. Thomas's respiratory condition?
  - A. Mr. Thomas is having difficulty speaking during the assessment.
  - B. Mr. Thomas has wheezes bilaterally.
  - C. Mr. Thomas's blood pressure has increased to 140/85 mm Hg.
  - D. Mr. Thomas's pulse oximetry is 93% on room air.
5. On the basis of Mr. Thomas's past medical history, which of the following assessment findings will the nurse expect as a result?
  - A. Clubbing of fingernails
  - B. Wheezes upon auscultation
  - C. Retractions on inspiration
  - D. Poor skin turgor

## CHAPTER SUMMARY

The respiratory system is a complex system that is divided into the upper and lower airways. Air enters the respiratory system through the nose or mouth and travels to the lungs, where respiration occurs at the alveoli level. The major functions of the respiratory system are ventilation and respiration. Ventilation occurs as air moves into the respiratory system through the process of inspiration. During ventilation, the structures of the respiratory system filter and humidify the air entering the system. The process of respiration occurs as oxygen and carbon dioxide are exchanged. Respiration, or air exchange, takes place in the respiratory bronchioles, which contain alveoli. Other functions of the respiratory system include acid-base regulation, temperature regulation, and fluid balance.

Because of the complexity of the respiratory system, a thorough assessment must be completed, including inspection, auscultation, percussion, and palpation, to identify dysfunction. If dysfunction of the system is noted, diagnostic tests can be ordered to determine the source of the dysfunction and assist in diagnosis. A finding of muscle retractions with inhalation is an abnormal finding indicating respiratory distress. Normal findings include symmetrical chest expansion, resonance with percussion, and pink mucosa.

Arterial blood gases and pulse oximetry are two tests to assess the adequacy of ventilation and respiration. Pulse oximetry is a less invasive means to determine oxygenation, but ensuring accuracy is essential. Arterial blood gases monitor PaCO<sub>2</sub>, HCO<sub>3</sub><sup>-</sup>, pH, and PaO<sub>2</sub>. Other diagnostic tests include pulmonary function tests, chest radiography, bronchoscopy, biopsy, and thoracentesis.

# Chapter 24

## Coordinating Care for Patients With Infectious Respiratory Disorders

*Stephanie Walter Coleman*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of infectious airway disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Influenza
  - b. Pneumonia
  - c. Tuberculosis
3. Describing the diagnostic results used to confirm the diagnosis of infectious airway disorders
4. Discussing the medical management of:
  - a. Influenza
  - b. Pneumonia
  - c. Tuberculosis
5. Developing a comprehensive plan of nursing care for patients with infectious airway disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with infectious airway disorders

### CONCEPTS

- Assessment
- Infection
- Medication
- Nursing Roles
- Oxygenation
- pH Regulation

### ESSENTIAL TERMS

Airborne  
Airborne precautions  
Alveolar  
Aspiration  
Bactericidal  
Colonization  
Consolidation  
Directly observed therapy (DOT)  
Droplet  
Droplet precautions  
Drug-resistant TB infection (MDR TB)  
Fomites  
Isolation precautions  
Latent tuberculosis infection (LTBI)  
Lobar  
Mantoux test  
Mucociliary escalator  
Parenchyma  
Primary progressive TB infection (PPTBI)  
Primary tuberculosis infection (PTBI)  
Rapid influenza diagnostic tests (RIDTs)  
Tubercule  
Vaccination  
Virulent

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. Harold Markham is a 70-year-old man who presents to the emergency department with fatigue, weight loss, and night sweats. He complains of a cough that produces rusty-colored or blood-streaked sputum. His vital signs are:

Blood pressure (BP) = 145/85 mm Hg

Heart rate (HR) = 95 bpm

Respiratory rate (RR) = 22

Pulse oximetry (SpO<sub>2</sub>) = 92%

Temperature (T) = 100.3°F (38°C)

Mr. Markham works as a volunteer in the food service department of an HIV community support center. His past history consists of coronary heart disease with two cardiac stents (placed last year), mild emphysema, long-term type 2 diabetes, and arthritis. His current home medications are aspirin, 81 mg daily; ipratropium (Atrovent), 2 puffs three times daily; celecoxib, 100 mg twice daily; metformin, 500 mg twice daily; and an over-the-counter daily multivitamin...

## INTRODUCTION

All body functions require a constant supply of oxygen to support their many metabolic activities. As a consequence of supplying continual oxygen, the respiratory tract maintains a persistent interface with the external physical environment, resulting in a high degree of direct exposure to microorganisms. It is for this reason that the respiratory tract is a common site of infection by pathogens. Fortunately, there is a series of complex, comprehensive, and efficient protective and defense mechanisms against harmful pathogens for both the upper and lower respiratory tracts.

### The Upper Respiratory Tract

A wide variety of pathogens can produce infection within the respiratory tract, including bacteria, viruses, and fungi. As environmental air is inhaled, the first line of defense lies within the upper respiratory tract, which consists of the nasal cavities, the pharynx, and the larynx.

The nares and nasal cavities are equipped with coarse hairs (vibrissae) and a mucous layer that filter out and trap macroparticulates (large particles). In addition, the nasal cavities are lined with epithelial tissues and blood vessels that filter and warm the inspired air. The surface epithelium secretes antimicrobial peptides that exert a **bactericidal** effect on a variety of pathogens. The endothelial lining of the nasal cavities contains hairlike projections, called cilia, that,

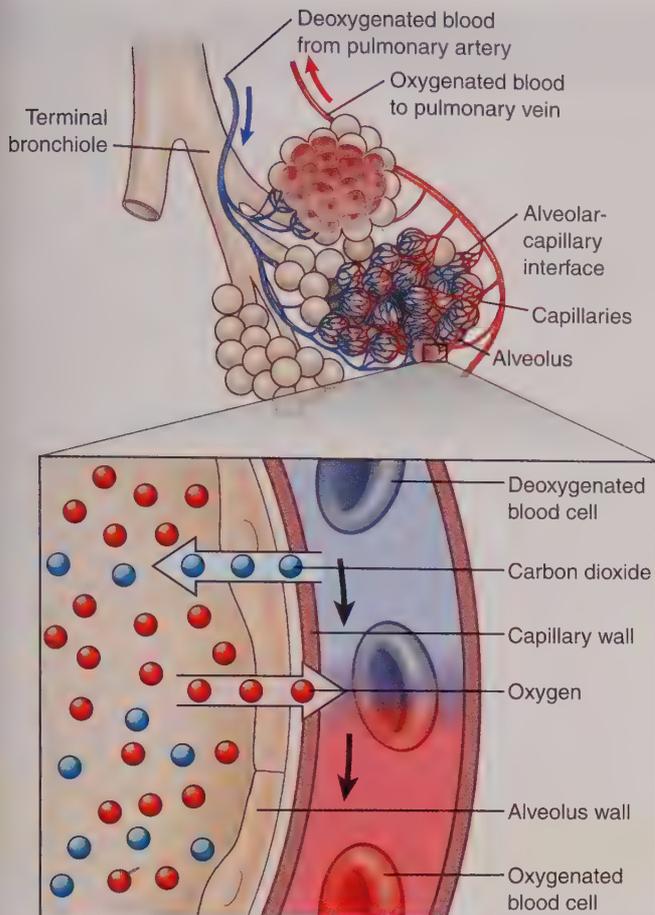

through their wavelike motion, transport any particles trapped by the mucous lining back into the nasopharynx and oropharynx. This mechanism is called the **mucociliary escalator**. Here, the particulate matter is expelled from the respiratory tract by the protective sneezing and coughing reflexes. After inhaled air moves through the nasal cavities, the anatomy of the upper airway changes direction, causing any remaining large particles to come in contact with the back of the throat. The tonsils and adenoids (lymphoid organs) play an integral role in the development of an immune response to pathogens remaining in contact with the mucoid surfaces of the throat through trapping and filtering. Next, the larynx (voice box), which houses the epiglottis, provides mechanical protection of the airways. During breathing, the epiglottis remains open to allow air to pass into the trachea. While food and fluids are swallowed, the epiglottis closes, directing solid material into the esophagus and preventing **aspiration**, or movement of gastric contents into the airways.

Additional protective mechanisms of the upper respiratory tract are provided by the **colonization** (a collection of a number of bacteria small enough not to cause infection) of resident bacteria and some viruses. Examples of resident bacteria and viruses include but are not limited to forms of *Staphylococcus*, *Streptococcus*, spirochetes, mycobacteria, *Pseudomonas*, *Proteus*, and *Enterococcus*. This “normal flora” functions to maintain a healthy respiratory status by competing with pathogens for attachment sites in the respiratory mucous lining and producing bactericidal substances that destroy harmful microorganisms.

### The Lower Respiratory Tract

The trachea marks the beginning of the lower respiratory tract, along with the bronchi, bronchioles, and alveoli. A layer of ciliated cells and the mucous-secreting cells within the trachea, bronchi, and bronchioles protect the lower respiratory tract via the mucociliary escalator from smaller-size particles that have avoided the upper airway defenses. Any pathogens that reach this area are trapped in an additional ciliated mucous layer and are driven upward via ciliary motion to the larynx and oropharynx, where they are swallowed and eventually destroyed by digestive enzymes in the stomach.

The lower respiratory tract houses no resident flora and is considered a “sterile site.” This is in part due to the efficiency of the upper respiratory tract’s ciliated epithelial lining in eliminating the majority of inhaled pathogens. Should pathogens gain access to the lowest portion of the respiratory tract (the alveoli), **alveolar** macrophages are the most important means of eliminating microorganisms from this area by phagocytosis. It is of the utmost importance that the alveoli remain free of pathogens because it is here that the vital exchange of gases occurs (Fig. 24.1). It is only when the respiratory epithelium becomes damaged or the sheer numbers of inhaled pathogens exceed the ability of these protective mechanisms to function that a respiratory infection occurs.

**FIGURE 24.1** Gas exchange at the alveolar level: gases moving from areas of higher to lower concentration. Oxygen moves into the blood; carbon dioxide moves out of the blood.

## Establishment of a Respiratory Tract Infection

In order for a respiratory infection to be fully established in the lower respiratory tract, the following barriers must be avoided and conditions met:

1. Avoidance of trapping in the mucociliary layer of the upper respiratory tract
2. Avoidance of the phagocytic action of the alveolar macrophages in the lower respiratory tract
3. Infectious organisms must be **airborne** (particles less than 5  $\mu\text{m}$  that remain suspended in the air for a prolonged period of time) and have the ability to remain **virulent** (toxic) while in the air.
4. There must be sufficient numbers of infectious organisms inhaled and deposited on susceptible tissues within both the upper and lower respiratory tracts, preventing innate protective mechanisms from functioning effectively.

## The Inflammatory Response of the Respiratory Tract

Once pathogens have been established in the respiratory tract, an inflammatory response is initiated. Direct stimulation by infecting organisms leads to the secretion of

pro-inflammatory cytokines (interleukin [IL] and tumor necrosis factor [TNF]) by airway epithelial cells. Neutrophils (a type of white blood cell [WBC]) are recruited to the infected alveoli along with other immune cells and serum components (see Chapter 18). Capillary permeability increases, and the alveoli fill with fluid and plasma proteins. This accumulation of exudate (a mass of cells and fluid) provides the perfect medium for the proliferation of the infecting organism(s) and assists with movement to other nearby alveoli. The fluid- and exudate-filled alveoli are prevented from effective gas exchange at the alveolar-capillary level. This produces varying degrees of hypoxia depending on the severity of the infection.

## INFLUENZA

### Epidemiology

Influenza is a highly contagious infection that is rapidly spread from one individual to another. Outbreaks of influenza are tracked, recorded annually, and reported by the Centers for Disease Control and Prevention (CDC). The extent and severity vary widely among geographical areas throughout the United States. Localized outbreaks that affect more than the expected population (e.g., when the disease is expected to affect 15% of the population, but 40% become infected) are called *epidemics*. They occur at varying intervals, usually every 1 to 3 years. Epidemics typically begin abruptly, peak at 2 to 3 weeks, last approximately 2 to 3 months, and then rapidly subside. Global outbreaks (outbreaks that spread across a large geographical area) or outbreaks that are limited to a smaller geographical area but affect more people than expected (again using the example of an expected outbreak of 15%, but 70% of the population is affected) are referred to as *pandemics*. They also occur at variable intervals but less frequently than local outbreaks. The last influenza pandemic was the H1N1 pandemic in 2009, where estimates of the number of deaths ranged from 151,700 to 575,400. Morbidity and mortality rates were high, predominantly among those with underlying comorbid medical conditions or those of very young or advanced age. Other predominant risk factors for influenza are outlined in Table 24.1.

The CDC reported the highest influenza burden in the 2017–2018 season since the 2009 pandemic. Estimates for reported illnesses were 48 million, with 22 million doctors' visits, 959,000 hospitalizations, and 79,400 deaths.

### Pathophysiology

Human influenza viruses are divided into three types, designated as A, B, and C. Influenza A viruses are divided into subtypes based on differences in two viral proteins—hemagglutinin (H) and neuraminidase (N). Influenza B is not broken down into subtypes but can be categorized by different strains. Influenza types A and B are responsible for epidemics of respiratory illness that occur mostly during the winter months and are often associated with increased

**Table 24.1 Risk Factors for Influenza Infection**

Risk Factor	Description
1. Age	Young children and older adults (younger than 2 years and older than 65 years) as a result of immature or less active immune systems
2. Occupation	Healthcare workers, family caregivers, daycare providers, and early childhood educators are more likely to be in frequent contact with those who are infected with the influenza virus.
3. Environmental	People living in dormitories, military quarters, and long-term care facilities who remain in close proximity for lengthy periods of time
4. Immune system compromise	Those with malignancies treated with chemotherapy, transplant recipients receiving anti-rejection medications, individuals with HIV/AIDS with CD4+ counts less than 200 cells/L
5. Chronic illness	People with diabetes, renal failure, asthma, and cardiac and respiratory diseases are at higher risk for developing serious complications.
6. Pregnancy	Females who are considering pregnancy, are pregnant, or have recently given birth are at greater risk for developing severe viral pneumonia and have a four-fold overall mortality rate, even if they are otherwise healthy.

hospitalizations and deaths. The most extensive and severe outbreaks are from influenza A because of the tendency of the H and N antigens to mutate. Seasonal mutations of the viruses cause the emergence of a new and very different influenza virus and can contribute to a new pandemic. These mutations allow the viruses to escape the immune system surveillance of its host, making individuals susceptible to mutated influenza infections throughout their lives. Several pathogens that have been newly identified are hantavirus, metapneumoviruses, and coronavirus (SARS). Efforts to control the impact of influenza are focused on types A and B. Influenza C typically causes either no symptoms at all or a very mild respiratory illness. It is not associated with the occurrence of epidemics and does not have the serious public health concerns associated with influenza A and B.

The primary event that initiates an influenza infection is the aerosolization of small **droplets** (particles less than 5  $\mu\text{m}$  that settle within 3–6 feet from point of release) from an infected individual's sneezing or coughing or by direct contact with fomites. **Fomites** are inanimate objects that can carry organisms and facilitate their transfer from one person to another, such as stethoscopes, scissors, or pens. The infectious agents are inhaled and become deposited on the epithelial cells of the upper respiratory tract. Over a period of approximately 4 to 6 hours, these infected cells reproduce and spread the virus to other respiratory cells, extending the infection throughout the respiratory tract. The incubation period (from the time of initial droplet inhalation to symptom development) lasts approximately 18 to 72 hours. The severity of the symptoms and subsequent illness are dependent on the amount of viruses shed during the replication phase and the number of respiratory cells affected. Virus shedding usually ends 2 to 5 days after symptoms first appear; therefore, it is important to remember that individuals are infectious for up to 7 to 10 days.

## Clinical Manifestations

Clinical manifestations of the flu are more severe than those of a cold and have a rapid onset. They include fever, headache, sore throat, severe nasal congestion, cough, myalgia or muscle aches and pains, malaise (the general feeling of being unwell), and fatigue.

## Management

### Medical Management

#### Diagnosis

The diagnostic gold standard for identifying an influenza infection is a sampling of respiratory secretions for viral culture. The most significant drawback to this method is that viral cultures can take up to 10 days to provide confirmation. In emergency departments and outpatient clinics, the most commonly utilized tests for influenza are called **rapid influenza diagnostic tests (RIDTs)**. The identification of an influenza virus infection can be made in less than 30 minutes via nasopharyngeal/throat swab or nasal washings/aspirate. The sensitivity and specificity of RIDTs can be variable depending on the manufacturer's test used and the type of influenza virus circulating during a specific outbreak. Therefore, a negative RIDT does not necessarily mean that there is no influenza infection (a false-negative test). When utilizing an RIDT, clinicians should not make a diagnosis solely on the basis of the test result but should also consider the patient's symptoms and history and rely on their clinical judgment. Accepted influenza testing methods for types A and B are outlined in Table 24.2.

Circulating antibodies can be detected in the blood of individuals with an influenza infection within 2 weeks after initial infection. Specific laboratory tests conducted are hemagglutination inhibition, complement-fixation, and enzyme-linked immunosorbent assay.

**Table 24.2** Approved Influenza Testing Methods for Types A and B

Method	Acceptable Specimens	Test Time
<b>Viral cell culture (conventional)</b>	Nasopharyngeal swab/bronchial wash, throat swab, nasal or endotracheal aspirate, sputum	3–10 days
<b>Rapid cell culture</b>	As above	1–3 days
<b>Immunofluorescence, direct or indirect antibody staining</b>	As above	1–4 hours
<b>RT-PCR</b>	As above	Varied; generally 1–6 hours
<b>Rapid influenza diagnostic tests</b>	Nasopharyngeal swab, throat swab, nasal wash, nasal aspirate	Less than 30 minutes

RT-PCR, Reverse transcription polymerase chain reaction.

## Treatment

Treatment for influenza illness is directed primarily toward prevention by annual **vaccination**. Inoculation by inactivated influenza viruses that were identified as causing outbreaks the preceding year can provide up to 80% protection from the projected upcoming year's virus. Side effects from vaccinations occur infrequently and consist of low-grade fever and soreness at the injection site. Individuals who have an allergy to eggs should not receive this form of the vaccine because it contains an inactive ingredient of an egg protein. Alternative forms of vaccine (without this protein) are available. The most appropriate time of year for vaccination is in the early fall before the “flu season” begins.

## Medications

Medications for the treatment of mild influenza illness are directed toward the relief of symptoms. Antipyretics/analgesics for fever and aches, adequate fluid intake to avoid dehydration, and rest are typically prescribed. For more serious forms of influenza or widespread local outbreaks, several antiviral medications are available for prophylaxis or treatment. The decision to treat flu symptoms utilizing antiviral medications is made on the basis of the severity of the presenting symptoms, such as an illness requiring hospitalization or a severe, complicated illness; the presence of any significant underlying comorbid risk factors; age greater than 65; and pregnancy or recent postpartum. The administration of antiviral medications does not “cure” the flu; however, further viral replication within the respiratory tract is impaired. This reduces the severity and duration of symptoms and plays a key role in preventing the risk of flu-related complications. The best results are achieved when antiviral medications are initiated within 24 to 48 hours of symptom onset. Antiviral medications are described in Table 24.3. Antibiotic preparations should be reserved for documented bacterial infections.

## Complications

Primary influenza viral pneumonia is the least common but severest complication of influenza infection and occurs

**Table 24.3** Antiviral Medications for the Treatment of Influenza

Antiviral Agent Generic (brand name)	Route	Treatment
<b>Zanamivir (Relenza)</b>	Inhaled	Influenza A and B
<b>Oseltamivir (Tamiflu)</b>	Oral	Influenza A and B
<b>Peramivir (Rapivab)</b>	IV	Influenza A and B
<b>Baloxavir (Xofluza)</b>	Oral	Influenza A and B
<b>Rimantadine (Flumadine)</b>	Oral	Influenza A

more frequently in individuals over the age of 65 years with or without chronic underlying illness. This complication is marked by progressive shortness of breath, persistent fever, and cardiovascular compromise. Dyspnea with negligible sputum production that may be visibly blood-streaked is also associated with the onset of a secondary bacterial pneumonia. Frequent bacterial organisms linked to secondary pneumonia are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*. These organisms are resident “normal flora” within the nasopharynx that become pathologic when the respiratory defenses are altered. Secondary bacterial pneumonia classically presents as improvement in viral symptoms followed by an acute recurrence of symptoms and purulent nasal and tracheal secretions. Sinus and middle ear secondary bacterial infections may also accompany an influenza viral illness.

## Nursing Management

### Assessment and Analysis

The clinical manifestations observed in the patient with influenza—cough, headache, nasal congestion, sore throat, and fever—are typically the result of the inflammatory response once the virus has invaded the respiratory epithelium.

## Nursing Diagnoses

- **Ineffective breathing pattern** related to infection of the lung
- **Decreased activity tolerance** related to hypoxia
- **Alteration in gas exchange—decreased** related to impaired alveolar-capillary interface
- **Fluid volume deficit** related to insensible losses from fever and tachypnea

## Nursing Interventions

### ■ Assessments

- **Vital signs**

*Tachypnea: The body's first compensatory mechanism to a decreased oxygen delivery is increased respiratory rate and depth.*

*Tachycardia: The body's second compensatory mechanism for a continued impairment of oxygen delivery is to raise the heart rate.*

*Decreased oxygen saturation: Impaired gas exchange at the alveolar level results in hypoxia. Tachypnea and tachycardia decrease cardiac output, reducing perfusion and peripheral oxygen saturation.*

*Fever occurs as a part of the inflammatory response.*

- **Neurological function**

*Agitation, restlessness, anxiety, lethargy, and fatigue are the result of decreased tissue perfusion from altered alveolar gas exchange.*

- **Breath sounds**

*Adventitious breath sounds such as rhonchi, crackles, and rales may be audible on lung assessment from fluid and exudates filling the alveoli. Audible wheezing is a result of airway reactivity due to inflammation and/or bronchospasm.*

- **General appearance**

*Sudden onset of fever, chills, muscle aches, and fatigue in a generally ill-appearing patient*

- **Cough, nasal congestion, sneezing, rhinorrhea**

*Primary viral pneumonia from influenza can cause coughing that lasts up to 2 weeks. Secretions that are white in color are consistent with viral infection. Purulent nasal discharge/sputum indicates a secondary bacterial infection.*

- **Peripheral pulses and skin temperature and color**

*Diminished tissue perfusion causes blood to be shunted away from peripheral areas to the main core body organs. Peripheral pulses diminish, and skin becomes moist and pale.*

*Peripheral cyanosis (bluish color to the nailbeds) is a late sign of tissue hypoxia.*

- **Laboratory values**

*Arterial blood gases (ABGs): Primary respiratory infections may initially cause a respiratory alkalosis (increased pH, decreased carbon dioxide [CO<sub>2</sub>]) in response to tachypnea. As the condition progresses, a respiratory acidosis (decreased pH, increased carbon dioxide [CO<sub>2</sub>]) will develop.*

*Positive RIDTs: These tests are sensitive, so a positive test is indicative of the presence of flu, but a negative test needs to be evaluated taking into account the patient's clinical presentation—a potential false negative.*

### ■ Actions

- **Initiate appropriate isolation precautions** (Table 24.4). *Place patient on droplet precautions to avoid viral transmission. Personal protective equipment required includes a mask, gown, gloves, and eye protection if there is a risk of splashing of bodily fluids. The patient should wear a mask when outside the room. Visitors should wear a mask while in the room. A private room is desirable unless patients with similar infections are cohorted.*

- **Administer humidified supplemental oxygen**

*Improving oxygen delivery, reversing hypoxia, and maintaining moist respiratory mucosa are essential to avoid complications.*

- **Position patient in semi- to high Fowler's** (head of bed raised to 30 degrees)

*Sitting up or elevating the head can provide for the relief of nasal drainage, promoting optimal lung expansion, preventing atelectasis, and preventing aspiration that can lead to secondary bacterial pneumonia.*

- **Medication administration**

- **Administer antipyretics as ordered/indicated.**

*Fever reduction can help reduce hyperdynamic effects on the respiratory and cardiovascular systems and increase patient comfort.*

- **Administer antiviral medications if ordered/indicated.**

*Early administration of antiviral medications (within 24–48 hours of symptom onset) offers the most favorable outcome for shortening the severity and duration of symptoms and decreasing the incidence of respiratory complications in high-risk patient populations.*

- **Administer analgesics as ordered/indicated.**

*Pain relief can increase comfort and allow for mobilization and effective coughing/expectoration of respiratory secretions.*

- **Provide adequate fluid intake.**

*Replacing insensible losses from fever and tachypnea allows for optimal cardiovascular performance and liquefaction of respiratory secretions.*

- **Provide adequate nutritional intake.**

*Adequate caloric intake is essential for cell recovery. Frequent small meals high in protein are recommended.*

- **Obtain cultures** (nasal swabs, throat swabs, sputum, blood, and urine) before the administration of antiviral medications.

*To assess for the presence of bacterial infection before presence is masked by medication administration*

### ■ Teaching

- **Practice good hand hygiene.**

*Hand washing is essential to prevent the spread of the virus to others.*

- **Disinfect frequently used objects and surfaces.**

*Household cleaning products or soap and warm water are sufficient. Hospital-approved cleaners are to be used to disinfect horizontal surfaces during inpatient care.*

- **Limit contact with others for up to 10 days** after the first symptoms appear or for at least 24 hours after fever has gone.

*Viral shedding continues from 10 days up to several weeks.*

**Table 24.4** CDC Isolation Precautions

Transmission-Based Precautions	Recommendation
<b>General Principles</b>	In addition to standard precautions, use transmission-based precautions for patients with documented or suspected infection or colonization with highly transmissible or epidemiologically important pathogens for which additional precautions are needed to prevent transmission.
<b>Contact Precautions</b>	<p>In acute care hospitals, place patients who require contact precautions in a single-patient room when available.</p> <p>When single-patient rooms are in short supply:</p> <ul style="list-style-type: none"> <li>● Prioritize patients with conditions that may facilitate transmission (e.g., uncontained drainage, stool incontinence) for single-patient room placement.</li> <li>● Place together in the same room (cohort) patients who are infected or colonized with the same pathogen and are suitable roommates.</li> </ul>
<b>Use of personal protective equipment (PPE)</b>	<p>Gloves, Gowns</p> <p>Discontinue contact precautions after signs and symptoms of the infection have resolved or according to pathogen-specific recommendations.</p>
<b>Droplet Precautions</b>	Use droplet precautions as recommended for patients known or suspected to be infected with pathogens transmitted by respiratory droplets (i.e., large-particle droplets >5 $\mu$ in size) that are generated by a patient who is coughing, sneezing, or talking.
<b>Patient placement</b>	<p>In <i>acute care hospitals</i>, place patients who require droplet precautions in a single-patient room when available. When single-patient rooms are in short supply:</p> <p>Prioritize patients who have excessive cough and sputum production for single-patient room placement.</p> <p>Place together in the same room (cohort) patients who are infected with the same pathogen and are suitable roommates.</p>
<b>Use of PPE</b>	<p>Don a mask upon entry into the patient room or cubicle</p> <p>If transport is necessary, instruct patient to wear a mask. No mask is required for persons transporting patients on droplet precautions.</p> <p>Discontinue droplet precautions after signs and symptoms have resolved or according to pathogen-specific recommendations.</p>
<b>Airborne Precautions</b>	Use airborne precautions as recommended for patients known or suspected to be infected with infectious agents transmitted from person to person by the airborne route.
<b>Patient placement</b>	In <i>acute care hospitals</i> and <i>long-term care settings</i> , place patients who require airborne precautions in an airborne infection isolation room (AIIR) that has direct exhaust of air to the outside or where the air is directed through high-efficiency particulate air (HEPA) filters.
<b>Use of PPE</b>	<p>Wear a fit-tested N95 or higher-level respirator for respiratory protection.</p> <p>If transport or movement outside an AIIR is necessary, instruct patients to wear a surgical mask.</p> <p>Discontinue airborne precautions according to pathogen-specific recommendations.</p>

From Centers for Disease Control and Prevention. (2007). *Isolation precautions*. Retrieved from <https://www.cdc.gov/infectioncontrol/guidelines/isolation/index.html#5>

- Report worsening shortness of breath; change in amount, color, and viscosity of pulmonary secretions; and recurrent fever.

*Viral infections can be mild at first, rapidly progressing to primary viral pneumonia or secondary bacterial pneumonia.*

- Maintain adequate fluid intake.

*Insensible losses from tachypnea and fever can lead to dehydration and thickening of pulmonary secretions with difficult expectoration.*

- Perform medication teaching for expected/desired effects, potential side effects, and expected duration of treatment.

*Take antiviral medications if they are prescribed for you. Make sure to take all of the medication—even if you begin to feel better. Explain that the addition of antibiotics may become necessary for the occurrence of a secondary bacterial infection.*

*Antiviral medications do not “cure” the flu; they just shorten the duration and severity of symptoms and may prevent serious complications. The antiviral choice should be based on local community patterns and susceptibility.*

- Be sure to get a flu vaccination every year.

*Vaccination is the best method of preventing the flu. As part of the national hospital performance measures, the Centers for Medicare and Medicaid Services (CMS) and The Joint Commission require all inpatients to be screened for the influenza vaccine and offered the vaccine prior to discharge if appropriate.*

### Evaluating Care Outcomes

Influenza may be avoided with flu vaccination. Mild cases of influenza usually resolve without complications. Indicators of resolving viral influenza infection are vital signs within the patient’s normal limits, absence of fever for 24 hours after completion of antiviral medications (if prescribed), even and unlabored respirations, oxygen saturation above 92% or return to patient’s baseline without oxygen administration, absence of nasal drainage, no sputum production, and a clear chest x-ray.

### Connection Check 24.1

The nurse understands adequate teaching has been done by which of the following statements?

- “I got a flu shot last year; I’m covered for a while.”
- “I don’t need a flu shot; I never get sick.”
- “I guess it’s important to get a flu shot every year.”
- “I don’t get a flu shot, but I make sure my kids get one.”

## PNEUMONIA

### Epidemiology

Infectious pneumonia can occur at any time and in individuals of any age. According to the CDC, in the United States, there are approximately 3 to 4 million cases reported annually. One-third of these cases occur in persons over 65 years of

age. The National Center for Health Statistics reports that older individuals (over 65 years) are at higher risk of death from respiratory infections. Nearly 90% of deaths are in this age group, but pneumonia is also responsible for 16% of deaths in children under age 5. Overall, approximately 60,000 deaths are attributable to pneumonia each year. Pneumonia remains among the most frequent conditions for which the death rate has not significantly declined over the past decade.

Key risk factors for the development of pneumonia among the adult population include but are not limited to advanced age; long-term care residence; smoking; chronic respiratory disease (asthma, emphysema); immune system dysfunction (malignancy, transplantation, HIV/AIDS); altered mental status; prolonged immobility; aspiration of stomach contents or foreign material; prolonged nothing-by-mouth (NPO) status; diminished cough, gag, and/or swallow reflexes; exposure to air pollutants, gases, or noxious inhalants; and hospitalization for longer than 48 hours.

Pneumonia can be classified into several types: community-acquired pneumonia (CAP), methicillin-resistant *Staphylococcus aureus* (MRSA) community-acquired pneumonia (MRSA CAP), hospital-acquired pneumonia (HAP), and healthcare-associated pneumonia (HCAP). Table 24.5 describes the classifications and common causative organisms.

Community-acquired pneumonia occurs in individuals who have not been recently hospitalized or are living outside of a healthcare/long-term care facility. *Streptococcus pneumoniae* is the most common causative organism. Few clinical studies have been able to confirm MRSA as a frequent cause of CAP; however, the data to date may indicate that incidence is escalating. Methicillin-resistant CAP results from colonization of MRSA within the upper respiratory tract. This can produce mild, virtually asymptomatic illness that is customarily treated on an outpatient basis with oral antibiotics. Healthy individuals with no existing risk

**Table 24.5 Pneumonia Classifications and Common Causative Organisms**

Community Acquired	Hospital Acquired	Healthcare Associated
<i>Streptococcus pneumoniae</i>	<i>Pseudomonas aeruginosa</i>	<i>Staphylococcus aureus</i>
<i>Mycoplasma pneumoniae</i>	<i>S. aureus</i>	Methicillin-resistant <i>S. aureus</i>
<i>Haemophilus influenzae</i>	<i>Klebsiella pneumoniae</i>	
<i>Legionella</i>	<i>Escherichia coli</i>	<i>P. aeruginosa</i>
Methicillin-resistant <i>S. aureus</i>	<i>Enterobacter</i> sp.	<i>H. influenzae</i>
<i>Chlamydia pneumoniae</i>		

factors for MRSA colonization are most frequently diagnosed with MRSA CAP after experiencing a viral illness.

Hospital-acquired pneumonia develops in patients after 48 hours of hospital admission. The diagnosis of health-care-associated pneumonia is made 48 to 72 hours after admission and is accompanied by the following risk factors:

- Recent antibiotic therapy
- Receiving immunosuppressive therapy
- Diagnosed with a chronic disease
- Treated within healthcare facilities, such as dialysis clinics, adult daycare centers, and rehabilitation facilities, where they are in frequent, close contact with healthcare personnel and other patients who may be colonized with various infection-causing organisms

Pneumonia caused by atypical organisms is often associated with mild respiratory illness. The inability to identify them by culture or Gram staining is what makes them atypical. Examples of atypical organisms are *Mycoplasma*, *Chlamydia* (from handling birds), *Legionella* (present in intricate water delivery systems), and *Bordetella pertussis* (responsible for whooping cough).

### Connection Check 24.2

The correct statement about the prevalence of pneumonia is which of the following?

- Pneumonia is no longer a major health problem.
- The prevalence of pneumonia is increasing dramatically.
- The prevalence and mortality are highest in persons older than 65 years.
- The frequency has not declined, but mortality has declined.

### Pathophysiology

Pneumonia is an inflammation of the lung **parenchyma** (functional lung tissue) resulting from a bacterial, viral, or fungal infection. Organisms enter the respiratory tract through inhalation of infected droplets or aspiration from the oropharynx. They evade the protective mechanisms of the respiratory tract and initiate the inflammatory process. The respiratory protective mechanisms become either ineffective or overwhelmed. An inflammatory cascade of events is initiated in response to the offending pathogen. Inflammatory mediators stimulate the production and release of neutrophils and macrophages that travel to the site of infection. Organisms continue to proliferate at the alveolar level. As the inflammatory response unfolds, protein-rich fluid and exudates fill the alveoli, impairing the exchange of oxygen and CO<sub>2</sub>. A ventilation-perfusion mismatch results from adequate blood flow to a nonfunctioning, fluid-filled alveolar unit.

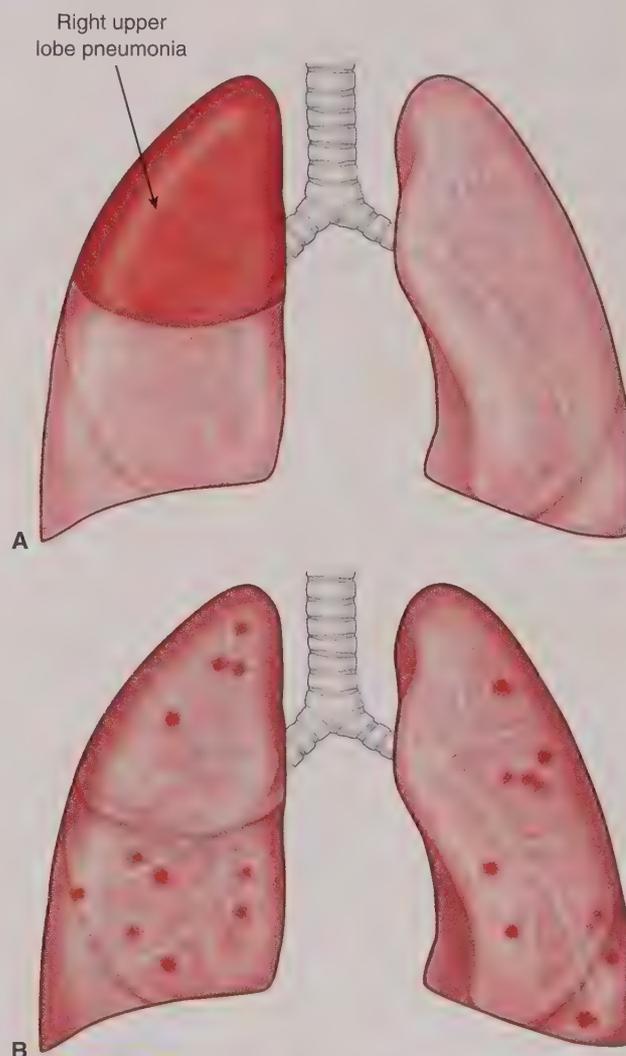

Organisms can localize to one or more lobes (**lobar** or **multilobar pneumonia**) or spread throughout the lung

parenchyma, resulting in the diffuse location of organisms (Figs. 24.2A and B). Bacteria causing pneumococcal pneumonia (*S. pneumoniae*) can gain access to the bloodstream, leading to septicemia and septic shock. Elderly individuals over the age of 65 years or those with chronic illness are at high risk for mortality from contracting this bacterial organism.

### Clinical Manifestations

The clinical manifestations produced by the inflammatory response can vary from mild to severe and include:

- Fever
- Tachypnea/dyspnea
- Tachycardia
- Chills
- Cough, productive or nonproductive
- Pleuritic chest pain
- Fatigue
- Myalgia/arthralgia

**FIGURE 24.2** Localizing or diffuse pneumonia. A, Right upper lobe lobar pneumonia. B, Diffuse pneumonia.

In more severe forms, additional manifestations can be:

- Purulent or blood-streaked sputum
- Hypotension
- Dysrhythmias

Awareness of the clinical manifestations and predictors of increased mortality is essential to help ensure the speedy identification and treatment of pneumonia. Validated clinical predictors of increased mortality and morbidity from severe infectious pneumonia include:

1. Altered mental status
2. Respiratory rate greater than 30 breaths per minute
3. Hypotension (systolic blood pressure less than 90 mm Hg)
4. Heart rate greater than 125 beats per minute
5. Body temperature less than 95°F (35°C) or greater than 104°F (40°C)
6. Arterial blood pH less than 7.35
7. Serum sodium level less than 130 mg/dL
8. Hematocrit less than 30%
9. PaO<sub>2</sub> less than 60 mm Hg on supplemental oxygen greater than or equal to 40%
10. Presence of pleural effusion on chest x-ray or computed tomography (CT) scan

## Management

### Medical Management

#### Diagnosis

Diagnosis is based on laboratory and imaging studies. Laboratory findings consistent with the diagnosis of pneumonia include:

- Elevated WBC count (leukocytosis) with elevated bands (immature neutrophils) on differential indicating acute inflammation
- Elevated C-reactive protein level, an accurate, sensitive, and historically used test to detect the presence of inflammation and infection. Values can range from 30 to 300 mg/dL in cases of bacterial and viral pneumonia.
- Arterial blood gases may initially reflect a primary respiratory alkalosis (decreased CO<sub>2</sub>, increased pH) due to tachypnea. As the condition progresses, a primary respiratory acidosis with hypoxemia (elevated CO<sub>2</sub>, decreased PaO<sub>2</sub>, and decreased pH) will occur.
- Sputum cultures will reveal a preliminary category of the offending organism by Gram stain and confirm the specific organism after 24 to 48 hours of incubation in the laboratory. Expecterated sputum specimens yield little information because of contamination with normal oral bacteria. Specimens obtained by deep tracheal suctioning or bronchoscopy offer the best yield for confirming a diagnosis and directing the choice of antimicrobial management.

Imaging studies reveal:

- Chest x-rays may or may not show infiltrates and can be up to 72 hours behind in their ability to reveal an infectious process.
- Computed tomography scans of the chest may better demonstrate **consolidation** (solidification of lung tissue) and the presence of pleural effusions.

As noted previously with clinical manifestations, prompt diagnosis is essential in providing timely and effective treatment.

### Treatment

The treatment of pneumonia is dependent on the type of pneumonia, an early diagnosis, and the overall health of the patient. Uncomplicated pneumonias can be effectively treated in the outpatient setting. More severe cases require hospitalization and supportive care. Because pneumonia may result in hypoxia, administration of oxygen to reverse or prevent hypoxia is an essential first step. In the case of patients with chronic lung pathology, high concentrations of oxygen can depress the drive to breathe. Those patients require careful monitoring while receiving oxygen. Ensuring adequate hydration is also an important intervention to support the patient's cardiovascular status and assist in thinning respiratory secretions for easy expectoration.

### Medications

Bronchodilator therapy with albuterol (short-acting selective beta-2 adrenoceptor agonist) or Combivent (slow-onset anticholinergic agent) delivered either by aerosol nebulization or by metered-dose inhaler will open swollen and narrowed airways and promote ease of breathing.

Antibiotic therapy, the definitive treatment, is based on the offending organism, and initially, broad-spectrum antibiotics are initiated promptly. For HAP, antibiotic treatment is empiric—treatment based on clinical experience before the exact offending organism is identified. Because *Pseudomonas aeruginosa* is the major pathogen associated with HAP, initial treatment is focused on that organism. Specific antibiotic recommendations for the treatment of CAP, HCAP, and HAP are outlined in Table 24.6.

### Complications

Severe MRSA CAP can lead to a necrotizing bacterial pneumonia requiring hospitalization. In aspiration pneumonia, the acidity of stomach contents is caustic to the delicate lung tissue. A necrotizing pneumonia may develop, resulting in fibrosis and scarring of the lung tissue. Pulmonary fibrosis and pulmonary hypertension from severe pulmonary infections can impair lung function after the respiratory infection resolves. Most antibiotics do not cross the blood–brain barrier, making the central nervous system a potential site of bacterial spread via the bloodstream. Acute meningitis can occur as a complication of a pneumococcal pneumonia.

**Table 24.6 Recommended Antimicrobial Treatment for Community-Acquired Pneumonia**

Patient Assessment	Recommended Antimicrobials
<b>Outpatients</b>	
● Previously healthy	
● No antibiotics within the past 3 months	Macrolides or doxycycline
● Comorbidities	Respiratory fluoroquinolones OR
● Have received antibiotics within the past 3 months	β-Lactam antibiotics and a macrolide
<b>Inpatients (all)</b>	
	Respiratory fluoroquinolones OR
	β-Lactam and a macrolide
	If CAMRSA: add vancomycin or linezolid

An empyema, a collection of purulent material in the pleural space, another possible complication, should be drained by the insertion of a chest tube. Pleurodesis, the injection of a sclerosing or scarring agent into the pleural space, causing the visceral and parietal pleura to “stick together,” may be performed after the empyema has been resolved to prevent recurrence.

Other significant complications that can develop as a result of pneumonia include bacteremia (bacteria in the bloodstream); atelectasis, a complete or partial collapse of the lung more typically seen in the postoperative or immobile patient; septic shock; and acute respiratory failure with multiple organ failure. Evidence of organ impairment/failure due to decreased tissue perfusion includes:

- Agitation/confusion: It is important to stress that this may be the only presenting sign/symptom in those over 65 years of age.
- Peripheral cyanosis
- Central cyanosis
- Decreased urinary output/elevated creatinine level
- Hypoactive bowel sounds
- Increased liver function laboratory values (aspartate aminotransferase/alanine aminotransferase)

### Nursing Management

#### Assessment and Analysis

The clinical manifestations in the patient with pneumonia result from the initiation of the inflammatory response and the buildup of fluid and exudate in the alveoli. They include fever; the deterioration of oxygenation, resulting in tachypnea and tachycardia; and the resultant decreases in cardiac output. This decrease in oxygen delivery results in shunting blood away from the periphery, producing weak and

thready pulses. Exudate and excess secretions in the lungs and alveoli result in adventitious breath sounds such as wheezing, rhonchi, and rales.

#### Nursing Diagnoses

- Ineffective peripheral tissue perfusion related to decreased gas exchange
- Ineffective breathing pattern
- Impaired gas exchange
- Risk for acute confusion

#### Nursing Interventions

##### ■ Assessments

- Vital signs

*Tachypnea: The body's first compensatory mechanism to a decreased oxygen delivery is increased respiratory rate and depth.*

*Tachycardia: The body's second compensatory mechanism for a continued impairment of oxygen delivery is to raise the heart rate.*

*Decreased oxygen saturation: Impaired gas exchange at the alveolar level results in hypoxia. Tachypnea and tachycardia decrease cardiac output, reducing perfusion and peripheral oxygen saturation.*

*Fever occurs as a part of the inflammatory response.*

- Neurological function

*Agitation, restlessness, anxiety, lethargy, and fatigue are the result of decreased tissue perfusion from altered alveolar gas exchange.*

*Diminished cough, gag, and swallow reflexes resulting from altered levels of consciousness can contribute to aspiration risk.*

- Breath sounds

*Adventitious breath sounds such as wheezing, rhonchi, crackles, and rales may be audible on lung assessment as a result of bronchospasm and/or fluid and exudates filling the alveoli.*

- Peripheral pulses and skin temperature and color

*Diminished tissue perfusion causes blood to be shunted away from peripheral areas to the main core body organs. Peripheral pulses diminish, and skin becomes moist and pale. Peripheral cyanosis (bluish color to the nailbeds) is a late sign of tissue hypoxia.*

- Respiratory secretions

*Purulent and/or bloody secretions may result from a buildup of exudate in the alveoli.*

- Laboratory testing

- Sputum microbiology

*Culture and sensitivity reports indicate the offending organism and list the antibiotics to which the organism is sensitive.*

- Arterial blood gases

*Bacterial respiratory infections may initially cause primary respiratory alkalosis (increased pH, decreased CO<sub>2</sub>) due to increased respiratory rate. As the condition progresses, a primary respiratory acidosis will occur (decreased pH, increased CO<sub>2</sub>).*

- Intake and Output

*Insensible losses from fever and tachypnea along with decreased intake from malaise and increased work of breathing can lead to more serious tachycardia and dehydration.*

### ■ Actions

- Administer humidified oxygen as ordered.  
*Oxygen administration helps maintain adequate oxygen levels. Humidification of respiratory tract mucous membranes helps liquefy secretions to facilitate expectoration. Careful administration should be given to the patient with chronic lung pathology in whom the drive to breathe comes from decreased oxygen levels.*
- Administer antibiotics as ordered.  
*Prompt administration of antibiotics to defeat the offending organism is the definitive treatment of choice.*
- Pulmonary hygiene:
  - Incentive spirometry
  - Coughing and deep breathing
  - Postural drainage
  - Vibration/percussion
  - Early mobility  
*Pulmonary hygiene is done in an effort to mobilize respiratory secretions and allow expectoration. This reduces the incidence of atelectasis and worsening pneumonia in hospitalized patients.*
- Patient positioning  
*Elevating the head of the bed to 30 degrees prevents aspiration of colonized nasopharyngeal secretions and gastric contents and facilitates lung expansion. Side-to-side turning assists with alveolar recruitment strategies to ensure maximum ventilation-perfusion. For infiltrates of only one lung, when turning, preferentially position patient with the good lung down to maximize perfusion to the functional alveolar units.*
- Monitor intake and output.  
*Optimal fluid balance assists with thinning respiratory secretions for ease of expectoration and maintains adequate tissue perfusion/oxygenation.*
- Ensure adequate nutritional support.  
*Adequate caloric intake is necessary for cellular recovery. Small, frequent meals that are high in protein and vitamins are recommended. Assess cough, gag, and swallow reflexes prior to offering food and drink. If reflexes are impaired, maintaining NPO status or initiating enteral feedings via feeding tube may be required until a formal swallow evaluation can be obtained and the degree of aspiration risk can be determined.*
- Activity grouping  
*Approach activities of care with intervals of rest. Fatigue and decreased tissue oxygen delivery limit activity tolerance.*

### ■ Teaching

- Hand hygiene and respiratory etiquette  
*Frequent and effective hand washing is the most effective method for minimizing the spread of infectious organisms. Proper use and disposal of tissues for sneezing and coughing are also important.*
- Encourage adequate rest.  
*Introduce strategies to combat fatigue and conserve energy.*

- Take antibiotics as prescribed; stress the importance of finishing all medication even if patients begin to feel better.  
*Antibiotics offer a “cure” for bacterial infections. Incomplete treatment can lead to a recurrence of symptoms and the emergence of drug-resistant organisms.*
- Encourage proper nutrition and fluid intake.  
*Adequate nutrition is essential for healing and recovery from respiratory infections. Sufficient fluid intake can thin secretions for easy expectoration.*
- Understanding of signs and symptoms indicating worsening respiratory status; how and where to seek medical attention  
*Patients and families should be able to verbalize a clear understanding of which signs and symptoms indicate the need to seek medical attention.*
- Encourage “at-risk” patients to get a pneumonia vaccine annually.  
*Vaccination affords the best protection against future illness from pneumonia. As part of the national hospital performance measures, the CMS and The Joint Commission require all inpatients to be screened for the pneumonia vaccine and offered the vaccine prior to discharge if appropriate.*

### Evaluating Care Outcomes

Patients with mild cases of bacterial pneumonia are successfully managed as outpatients on oral antibiotic regimens. Most patients with pneumonia requiring hospitalization fully recover from their illness and are discharged without complications. A well-managed patient recovering from bacterial pneumonia will demonstrate stable vital signs, absence of fever for 24 hours after completion of antibiotic therapy, unlabored breathing, oxygen saturation above 92% (or return to patient’s baseline) without the use of oxygen therapy, absence of cough/sputum production, and clear chest x-ray with increased energy levels and activity tolerance.

### CASE STUDY: EPISODE 2

Mr. Markham’s chest x-ray shows suspicious cavitating lesions. He is admitted to the medical unit with suspicion of TB. He is immediately put in isolation on airborne precautions. His temperature, heart rate, and respiratory rate remain elevated at 38°C (100.5°F), 100 bpm, and 24, respectively. His oxygen saturation decreases to 90%. He is started on oxygen via a face mask. An IV line is inserted, and IV fluids are started. Sputum and blood cultures are sent to the laboratory...

## TUBERCULOSIS

### Epidemiology

Tuberculosis (TB) is a significant and potentially life-threatening respiratory infection caused by the organism

*Mycobacterium tuberculosis*, an aerobic acid-fast bacillus (AFB). Tuberculosis infects one-third of the world's population. The CDC monitors the prevalence of TB in the United States and reported 9,093 new cases of TB (2.8/100,000 persons) in the United States in 2017, which represents a 1.8% decline from 2016, the smallest decline in 10 years. The majority of these new cases occurring in the United States were caused by reactivated latent tuberculosis infection (LTBI). Populations living outside of the United States, low socioeconomic groups that have obstacles in accessing healthcare, and racial and ethnic minorities have the highest incidence. Tuberculosis disproportionately affects blacks, Hispanics, and Asians. Tuberculosis is also a persistent problem in the homeless and incarcerated populations. Persons infected with HIV or who have AIDS are at exceptional risk of contracting TB or reactivating latent TB. This population poses a particular concern because of the extent of immunosuppression and the risk of contracting and spreading new strains of drug-resistant TB (MDR TB). An estimated 11 million people with HIV (one-third of the HIV population) are infected with *M. tuberculosis*. Tuberculosis is the leading killer of people with HIV infection.

## Pathophysiology and Clinical Manifestations

*Mycobacterium tuberculosis* is typically transmitted by aerosolized droplets inhaled from the coughing or sneezing of an infected individual. Droplets of *M. tuberculosis* are tiny and can remain suspended in the air for several hours. Focused studies documenting transmission of active **tubercule** bacilli have shown that in close-contact situations, those whose sputum is infected with AFB are most likely to transmit the infection. It is estimated that up to 3,000 infectious nucleated droplets can be released in one cough. After the small infected droplets are inhaled, most of the bacilli remain within the upper airway and rarely cause active disease. Bacilli that manage to evade the mucociliary escalator defense are deposited within the alveoli and are quickly engulfed by phagocytic pulmonary macrophages. Once they are ingested by the macrophages, there is a slow but continued multiplication of the *Mycobacterium*. Tuberculosis is classified as follows:

- Latent tuberculosis infection (LTBI)
- Primary tuberculosis infection (PTBI)
- Primary progressive TB infection (PPTBI)
- Drug-resistant *M. tuberculosis* (MDR TB)

### Latent Tuberculosis Infection

In those individuals with an intact immune system, a granuloma forms and limits further proliferation and spread of the *Mycobacterium*. Necrosis at the center of the granuloma leads to fibrosis and calcification. A calcified granuloma evident on chest x-ray is a classic sign of the type of TB termed **latent tuberculosis infection (LTBI)**. The inactive bacilli remain dormant within the

healed granuloma. Patients with LTBI have no symptoms, do not feel ill, and are not contagious. As long as the immune system remains intact, the bacilli remain in the healed tissue of the granuloma for the individual's lifetime and do not progress to TB infection. It is only when the immune system becomes compromised that the disease can become reactivated. The most common factors associated with reactivation are HIV infection, long-term diabetes, chronic renal disease, long-term steroid administration, sepsis, and malnutrition.

### Primary Tuberculosis Infection

Individuals with a weakened immune response are unable to control the multiplication of *Mycobacterium*. Granuloma formation is initiated but is unable to progress to calcification and results in a **primary tuberculosis infection (PTBI)**. Primary TB infection is often asymptomatic and is confirmed only by positive sputum cultures and a positive skin test. This person is not infectious.

### Symptomatic TB Infection

Symptomatic TB infection, referred to as **primary progressive TB infection (PPTBI)**, develops in a very small percentage of individuals who have been exposed to the bacterium. Initial symptoms are relatively nonspecific and consist of fatigue, weight loss, and night sweats. A cough develops eventually and produces a rusty-colored or blood-streaked sputum. As the disease progresses, dyspnea, orthopnea, and rales become evident.

### Drug-Resistant Mycobacterium Tuberculosis

**Drug-resistant *M. tuberculosis* (MDR TB)** can be mono-drug or poly-drug resistant. This means that one or more of the first-line medications used for the treatment of TB are not effective. Drug-resistant TB can be caused by primary or secondary means. Primary resistance is caused by person-to-person transmission of the resistant organism. Secondary (acquired) resistant TB develops during treatment and results from an ineffective treatment regimen or an incomplete treatment regimen.

## Management

### Medical Management

#### Diagnosis

The diagnosis of TB infection is made by laboratory testing, a skin test, and chest x-ray. Laboratory testing consists of a sputum test for culture and acid-fast staining. Suspicious cavitating lesions (resulting from pathologic processes leading to necrosis and formation of a "gas-filled" space within the lung tissue) are seen on chest x-rays. The skin test is a positive purified protein derivative (PPD) screen skin test, also called a **Mantoux test**. The Mantoux tuberculin skin test is the standard method for determining if an individual is infected with the TB-causing organism. The test is administered by injecting 0.1 mL of PPD intradermally into the tissue of the forearm. Within 48 to 72 hours after

injection, the administration site should be observed for any reaction (Table 24.7).

Individuals who have received a bacille Calmette–Guérin (BCG) immunization may show a false-positive PPD when not infected with the TB bacteria. Further testing in these individuals is required, such as a chest x-ray and/or blood testing using an interferon gamma release assay (IGRA). There are currently two IRGAs approved for use by the U.S. Food and Drug Administration (FDA): QuantiFERON®-TB Gold In-Tube (QTF-GIT) and T-SPOT® TB test (T-SPOT). These blood tests can determine if an individual has been infected with TB bacteria. A negative result indicates unlikely TB infection. A positive test confirms TB infection, and further work-up is necessary to establish whether the infection is latent TB or TB disease.

### Treatment

According to the American Thoracic Society, the CDC, and the Infectious Diseases Society of America, the goals of treatment for TB infection are (1) to cure the patient and (2) to minimize the transmission of *M. tuberculosis* to other persons. A basic four-drug combination is recommended for the treatment of TB and should continue for 9 to 12 months (Table 24.8). The basic recommended treatment for TB is broadly applicable, but modifications may be necessary in special circumstances, such as HIV+, pregnancy, drug resistance, and children.

**Safety Alert** Immediate isolation of the patient with suspected or confirmed TB infection in a private room with negative airflow capabilities is a priority. Negative airflow occurs when air moves into the contaminated area or into the patient's room from bordering areas. The institution of **airborne precautions**, the use of an N95 mask respirator for healthcare personnel entering the patient's room (requires fit-testing), and a snug-fitting surgical mask for visitors are essential interventions. The patient's movement and transportation to other departments should be limited to essential needs only. Patients who must leave the negative-pressure room should also wear a surgical mask.

### Complications

Extensive respiratory tissue destruction by *M. tuberculosis* can lead to respiratory failure, bronchopleural fistula formation (an abnormal pathway or sinus tract that develops between the bronchus and pleural space), and pleural effusions (collections of fluid in the pleural space). Untreated active TB can spread to parts of the body outside the respiratory system via the bloodstream and lymph circulation. Extrapulmonary TB can present as meningitis, lymphadenopathy, bone disease, and liver and kidney failure.

### Connection Check 24.3

The nurse understands that the priority intervention with the patient with TB is which of the following?

- A. Antibiotic administration
- B. Initiation of isolation
- C. TB test
- D. Chest x-ray

### Nursing Management

#### Assessment and Analysis

Unexplained weight loss, night sweats, fever, and chills are seen as a result of the inflammatory response, specifically the body's attempt to interact with the *Mycobacterium*. The *Mycobacterium* itself may also release fever-causing signals. Rusty-colored sputum occurs as a result of the destruction of lung tissue during granuloma formation. Tissue fragility and microbleeds result. The collection of WBCs presents in an attempt to wall off the infection, resulting in the production of sputum. Pleuritic chest pain is a result of chronic coughing.

#### Nursing Diagnoses

- **Ineffective airway clearance**
- **Alteration in gas exchange** related to necrosis of lung tissue
- **Alteration in comfort:** pain related to pleurisy
- **Ineffective coping** related to isolation and long-term therapy

#### Nursing Interventions

##### ■ Assessments

- **Oxygen saturation**  
*Decreased oxygen saturation occurs with the destruction of lung tissue, lessening the available surface area for air exchange.*
- **Temperature**  
*Fever is a result of the inflammatory process.*
- **Sputum**  
*Blood-tinged or rusty-colored sputum is present as a result of the destruction of lung parenchyma tissue.*
- **Breath sounds**  
*Wheezing from irritated airways; rales and rhonchi from fluid/exudates*

##### ■ Actions

- **Humidified oxygen**  
*Humidified oxygen helps ensure adequate oxygen delivery to the tissues and maintains the integrity of the mucous membranes.*
- **Institute airborne isolation** (see Table 24.4).  
*Tuberculosis is an extremely contagious disease. Care must be taken to avoid transmission to other individuals, especially other hospitalized individuals with an increased risk for infection.*

**Table 24.7 Classification of Tuberculin Skin Test Reactions****5 mm or Greater**

An induration of 5 mm or greater is considered positive in:

- HIV-infected persons
- A person having recent contact with a person with TB
- Persons with fibrotic changes on chest radiography consistent with prior TB
- Persons who are immunosuppressed including those with organ transplants

**10 mm or Greater**

An induration of 10 mm or greater is considered positive in:

- Recent immigrants from high-prevalence countries
- IV drug abusers
- Residents and employees of high-risk settings
- Mycobacteriology laboratory personnel
- Persons with clinical conditions that place them at high risk
- Children younger than 4 years
- Infants, children, and adolescents exposed to adults in high-risk categories

**15 mm or Greater**

An induration of 15 mm or greater is considered positive in any person, including persons with no known risk factors for TB.

Adapted from Centers for Disease Control and Prevention. (2016). *Tuberculosis (TB) fact sheet*. Retrieved from <http://www.cdc.gov/tb/publications/factsheets/testing/skintesting.htm>  
TB, tuberculosis.

**Table 24.8 Recommended Tuberculosis Treatment Regimens**

Initial Daily Treatment	Isoniazid	Rifampin	Pyrazinamide	Ethambutol
<b>New infection/culture +</b>	Daily dose × 2 months, then 4 additional months	Daily dose × 2 months, then 4 additional months	Daily dose × 2 months	Daily dose × 2 months
<b>New infection/culture -</b>	Daily dose × 2 months, then 2 additional months	Daily dose × 2 months, then 2 additional months	Daily dose × 2 months	Daily dose × 2 months
<b>Isoniazid resistance</b>	—	Daily dose × 6 months	Daily dose × 6 months	Daily dose × 6 months

- Administer antibiotics as ordered.  
*Antibiotics are the definitive treatment for TB and are essential in controlling the spread of the disease.*
- Ensure adequate nutrition.  
*Adequate caloric intake to maintain optimum body weight is necessary for recovery. Often, patients report substantial weight loss during the time prior to diagnosis.*

**Teaching**

- Stress the importance of skin/blood testing for individuals living with or exposed to the infected person.  
*Skin/blood testing helps monitor the spread of TB and ensures prompt treatment if necessary. TB is a reportable disease and is tracked by local, state, and federal health authorities. Healthcare providers are obligated to notify local health departments of an identified TB infection so that an investigation of contacts can be initiated and any positive TB infections can be identified and treated.*

- Ensure that the patient and family understand the importance of completing all medications.  
*Treatment for those who have become infected is necessary to prevent the spread of the disease and prevent complications that can occur from nontreatment. Incomplete treatment or interruptions in treatment can cause the emergence of drug-resistant forms of the bacterium. Directly observed therapy (DOT) may be necessary to ensure adherence.*
- Assess the patient's support systems and community resources that will ensure successful adherence to the treatment plan after discharge.  
*Early involvement of family, the medical team, and case management will provide the best support for the patient to comply with the established long-term treatment plan.*

**Evaluating Care Outcomes**

The successful treatment of the patient with TB requires early detection and a comprehensive, interprofessional structure that addresses the clinical, psychosocial, environmental, and financial issues. Because of the long treatment

period, patients need to be encouraged to follow the prescribed plan of care after discharge into the community (see Transitional Care). Indicators of resolving TB infection are the ability of the patient to gain and maintain a stable body weight, improved skin turgor and muscle tone, absence of cough and sputum production, even and unlabored breathing, and the cessation of fevers and night sweats.

## Transitional Care

### Tuberculosis

Once the patient with tuberculosis (TB) has been stabilized and has started therapy, treatment can continue at home. National TB treatment guidelines strongly recommend using **directly observed therapy (DOT)** when treating persons with active TB disease. Directly observed therapy is in place when a trained healthcare worker, home healthcare nurse, aide, or designated and trained individual provides the prescribed TB medications and watches the patient swallow every dose. Family members are typically excluded from this role. A recent study indicates that the use of mobile applications for “video” DOT is showing promise. The patient remains on home isolation, receiving periodic sputum cultures to determine the effectiveness of treatment. The need for home isolation may last up to 6 weeks depending on the patient’s response to therapy.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Harold Markham is admitted to the medical unit with the diagnosis of TB. He remains in a private negative airflow room on strict isolation and airborne precautions. He is started on the four-drug combination therapy recommended for treatment of TB. He will stay on this drug therapy for 9 to 12 months. It is suspected that he was exposed to TB at the HIV clinic where he volunteers. Centers for Disease Control and Prevention personnel are alerted and sent to screen patients and staff at the clinic.

#### Case Study Questions

- Which statement is correct related to isolation and airborne precautions for Mr. Markham?
  - Mr. Markham should wear a mask at all times.
  - Staff entering the room should wear a surgical mask.
  - Visitors entering the room should wear an N95 mask respirator.
  - Staff entering the room should wear an N95 mask respirator.
- The nurse should question which order concerning Mr. Markham’s care?
  - Humidified oxygen via nasal cannula
  - NPO
  - Vital signs with oxygen saturation every 4 hours
  - Activity as tolerated
- Mr. Markham’s TB can be characterized as which type of infection?
  - An LTBI
  - A PTBI
  - A symptomatic, noncontagious TB infection
  - A symptomatic TB infection
- Which statement demonstrates adequate teaching has been done?
  - “Wow! I’m going to be on these drugs for a long time!”
  - “I can stop taking the drugs when I feel better.”
  - “My family doesn’t need to wear a mask when they come to visit.”
  - “I’m looking forward to going down to the cafeteria to get something to eat.”
- What symptoms indicate a resolving TB infection? (*Select all that apply.*)
  - Decreased sputum production
  - Productive cough
  - Stable body weight
  - Fevers only at night
  - Cessation of night sweats

## CHAPTER SUMMARY

The human respiratory system has its own innate protective mechanisms to prevent infectious respiratory illness. When these mechanisms become overwhelmed or are impaired, viral, bacterial, and fungal infections occur. The patients at greatest risk for infectious airway disorders are the very young and those over 65 years of age, most often as a result of underlying chronic illnesses of the respiratory, cardiovascular, endocrine, and immune systems.

Clinical manifestations of infectious airway disorders can cause mild to severe symptoms, can occur suddenly or over a period of days to weeks, and can be highly contagious.

Influenza presents with a sudden onset of symptoms that includes fever with respiratory symptoms. Clear respiratory secretions indicate an influenza viral infection. Treatment is symptom based but may include antivirals with severe symptoms. The administration of antiviral medications does not cure a viral infection but does reduce the severity and duration of symptoms so that individuals can return to their daily activities sooner.

Pneumonia remains among the most frequent conditions for which the death rate has not significantly declined over the past decade. It can be viral or bacterial. Clinical manifestations include fevers, tachypnea, tachycardia, decreased SpO<sub>2</sub>, fatigue, and a productive cough. Purulent respiratory secretions indicate a primary or secondary bacterial infection. Primary treatment options include bronchodilator therapy to open up inflamed airways and antibiotic therapy.

Tuberculosis is an extremely contagious disease that is most prevalent in at-risk populations. Night sweats with bloody or rusty sputum are common manifestations of TB infection. Treatment is long-term antibiotic therapy.

Vaccination with inactivated virus or bacterium is the best method for preventing the onset of respiratory illness due to influenza. Regular monitoring for TB is done through the Mantoux TB skin test. It is required in all healthcare workers. Blood testing using IRGAs for any positive skin test will confirm or rule out the presence of TB infection.

Any patient presenting with respiratory symptoms who is suspected of having a contagious respiratory illness should be placed in a private room or should be cohorted with patients with similar symptoms. Patients who present with unexplained weight loss, fever, and night sweats should be placed in an AFB negative airflow room immediately to prevent transmission within the healthcare facility.

# Chapter 25

## Coordinating Care for Patients With Upper Airway Disorders

Linda Cook

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of upper airway disorders
2. Explaining the pathophysiological processes of upper airway disorders
3. Correlating clinical manifestations to pathophysiological processes of
  - a. Rhinitis
  - b. Rhinosinusitis
  - c. Obstructive sleep apnea
  - d. Laryngitis
  - e. Laryngeal cancer
  - f. Laryngeal trauma
4. Describing the diagnostic results used to confirm the diagnoses of selected upper airway disorders
5. Discussing the medical management of:
  - a. Rhinitis
  - b. Rhinosinusitis
  - c. Obstructive sleep apnea
  - d. Laryngitis
  - e. Laryngeal cancer
  - f. Laryngeal trauma
6. Describing complications associated with selected upper airway disorders
7. Developing a comprehensive plan of nursing care for patients with upper airway disorders
8. Developing a teaching plan for patients with upper airway disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Infection
- Inflammation
- Medication
- Nursing Roles
- Nutrition
- Oxygenation
- Promoting Health

### ESSENTIAL TERMS

Acute bacterial rhinosinusitis (ABRS)  
Acute rhinosinusitis  
Antihistamines  
Apnea  
Bronchoscopy  
Continuous positive airway pressure (CPAP)  
Decongestants  
Dysphagia  
Dyspnea  
Electrolarynges  
Esophageal speech  
Fiberoptic laryngoscopy  
Hemoptysis  
Hypercapnia  
Hypoxemia  
Laryngeal cancer  
Laryngeal mirror  
Laryngeal trauma  
Laryngectomy  
Laryngitis  
Obstructive sleep apnea (OSA)  
Osteomeatal complex  
Polysomnography  
Rhinitis  
Rhinorrhea  
Rhinosinusitis  
Stridor  
Tracheostomy  
Tracheotomy  
Viral rhinosinusitis

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Henry Comstock is a 56-year-old male who reports a history of snoring and frequently waking during the night. He works as a business manager. He weighs 260 pounds and is 5 ft 10 in. tall. His wife insisted that he see his primary care provider (PCP) because he frequently falls asleep when he sits for short periods of time. He is constantly irritable as a result of his lack of sleep...

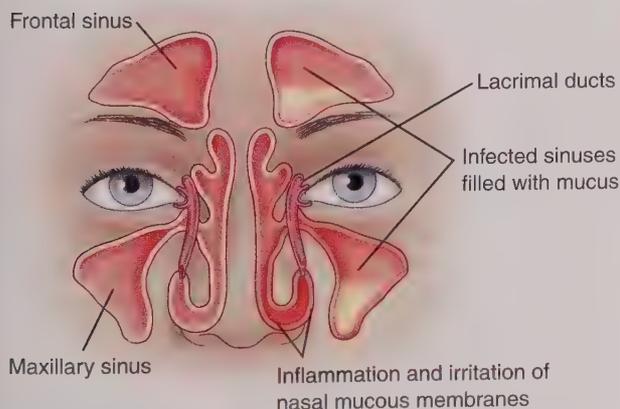

## RHINITIS

### Epidemiology

Rhinitis is the most common problem with the nose and sinuses, affecting 20% of the population. Although not life threatening, rhinitis can impact quality of life by causing headaches, fatigue, sleep disturbances, and cognitive impairment. Rhinitis can result in widespread morbidity with significant financial impact from medical treatment costs, lost workdays with resulting reduced work productivity, and lost school days. Thirty to 60 million American adults and children experience allergic rhinitis.

### Pathophysiology

Rhinitis is classified as allergic or nonallergic and acute or chronic. It is an inflammation and irritation of mucous membranes lining the nose (Fig. 25.1). It can also affect the eyes, throat, and ears. Allergic rhinitis is categorized as perennial (occurring throughout the year) or seasonal.

**FIGURE 25.1** Rhinitis: inflammation of the mucous membranes and sinuses filled with mucus.

It occurs in response to exposure to allergens found in the environment, medications, foods, or occupational irritants. Common environmental allergens include mold, dust mites, cockroach droppings, weeds, trees, and animal dander. Foods that may induce allergic rhinitis include peanuts, cow's milk, nuts, eggs, and wheat. Medications such as angiotensin-converting enzyme (ACE) inhibitors, phosphodiesterase-5–selective inhibitors such as Viagra, penicillin-based medications, and aspirin and other NSAIDs may also induce symptoms. In response to the offending allergens, the lining of the nasal mucosa becomes inflamed, congested, and edematous. Mechanical obstructions within the nose or sinuses, such as polyps, nasal septal deviation, and hypertrophy of the nasal turbinate or sinus tumors, may also result in the development of rhinitis.

Nonallergic rhinitis presents similarly to allergic rhinitis but does not involve the immune system. The most common example of nonallergic rhinitis is the common cold, which is caused by a variety of viruses and is usually self-limiting unless a bacterial infection occurs simultaneously. Acute rhinitis can last 1 to 3 weeks; chronic rhinitis may last up to 12 weeks.

### Clinical Manifestations

Symptoms of rhinitis include nasal itching, sneezing, nasal congestion, and **rhinorrhea** (runny nose, which is excessive nasal drainage). In chronic rhinitis, symptoms last 12 weeks or longer, with discolored nasal discharge and radiographical evidence of fluid levels within the sinuses.

### Management

#### Medical Management

#### Diagnosis/Treatment

Treatment and management of rhinitis are dependent on the cause. Diagnosis is based on history and symptoms. Obtaining a history of the onset of symptoms that focuses on the pattern, seasonal aspects, environmental exposures to allergens in the home or work, and precipitating factors serves as the basis of determining treatment. If rhinitis is the result of a viral cause, medication to relieve symptoms may be prescribed. In patients with allergic rhinitis, allergy testing may be indicated, followed by a desensitizing regimen. Referral to an ear, nose, and throat specialist for assessment of nasal polyps, nasal septal deviation, and hypertrophy of the nasal turbinate or sinus tumors may be indicated. Avoidance of exposure to known allergens at home, at work, or in the environment will assist in limiting symptoms.

Effective management of asthma and obstructive sleep apnea (OSA), which can coexist or be complicating respiratory conditions, is often dependent on adequate and appropriate management of rhinitis. Asthma and rhinitis can both be triggered in response to allergens. Nasal

inflammation as seen in rhinitis increases upper airway resistance, leading to OSA.

### Medications

Pharmacological management in allergic and nonallergic rhinitis is aimed at symptom relief. The use of oral **antihistamines**, nasal spray antihistamines and corticosteroids, and decongestant medications can assist in the relief of symptoms (Table 25.1). Prescription and over-the-counter (OTC) antihistamines are the most common treatment of rhinitis symptoms of sneezing, rhinorrhea, and pruritus. Sedation, performance impairment, and anticholinergic effects such as dry mouth and eyes, constipation, and increased heart rate are common side effects of first-generation antihistamines. Second-generation OTC antihistamines such as loratadine (Alavert, Claritin) have less or no tendency to cause sedation. Long-term use of non-sedating antihistamines in rare cases results in mild acute liver injury.

Intranasal corticosteroid is the most effective treatment of allergic rhinitis and related symptoms when used on a regular basis. As-needed use of these nasal sprays can also be effective in relieving symptoms. There is no systemic effect from the use of intranasal corticosteroid medication. Intranasal sprays that contain antihistamines are effective at symptom relief and can work within minutes, whereas an intranasal corticosteroid may take days or weeks to provide full symptom relief. Antihistamine nasal sprays can result in systemic effects. These sprays are sometimes used in combination. Saline nasal sprays can be effective in relieving symptoms such as nasal congestion and sinus pressure-related effects. They moisten dry nasal mucous membranes to remove or reduce nasal plugs. Saline nasal sprays have

**Table 25.1 Medications Used in the Treatment of Rhinitis**

Symptom	Medication
<b>Congestion, rhinorrhea</b>	First-generation antihistamines such as diphenhydramine (Benadryl Allergy)
	Second-generation antihistamines such as loratadine (Alavert, Claritin)
	Decongestants such as guaifenesin (Robitussin, Mucinex)
	Nasal sprays:
	Corticosteroids sprays such as fluticasone (Flonase)
	Antihistamine sprays such as azelastine (Astelin)
	Saline nasal sprays
	Decongestant such as oxymetazoline (Afrin)

no negative effects as can be seen with antihistamine or decongestants.

Decongestant medications can reduce nasal congestion and obstruction. Oral **decongestants** contain pseudoephedrine and phenylephrine, which reduce nasal congestion. Side effects of these medications include insomnia, irritability, and palpitations. The use of these medications should be avoided unless nasal antihistamines and a corticosteroid have been ineffective. They should also be avoided in patients with a history of cardiac disease, hypertension, glaucoma, cerebrovascular disease, and cardiac dysrhythmias because of the vasoconstriction caused by these medications. Decongestant nasal sprays such as oxymetazoline (Afrin) should only be used for a few days at a time because overuse may cause rebound congestion (severe congestion).

If infectious rhinitis is present, the administration of antibiotics is required, with the selection of the antibiotic based on patient history, allergies, and the severity of the infection.

### Nursing Management

#### Assessment and Analysis

Symptoms of rhinitis are due to irritation and inflammation of the mucous membranes of the nose, resulting in sneezing, excessive nasal congestion, and nasal drainage.

#### Nursing Diagnoses

- **Alteration in comfort** related to sinus inflammation
- **Knowledge deficit** related to medication regimen
- **Risk for infection** related to inadequate primary defenses

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Temperature elevation may indicate the presence of infection. Elevations in heart rate and blood pressure may be related to the medication used to treat symptoms.*
- Peak flow rate and spirometry (if acute asthma exacerbation also present)  
*Assessment of peak flow rate and spirometry may indicate the severity of exacerbation and response to therapy.*
- Nasal drainage  
*Nasal drainage should be thin and clear. Yellow or green indicates infection.*

##### ■ Actions

- Administer medications as prescribed: oral or nasal antihistamines, oral or nasal corticosteroids, decongestants, antibiotics.  
*Antihistamines, corticosteroids, and decongestants are used to control the symptoms of excessive drainage, inflammation, and nasal congestion. Antibiotics are used to treat infection.*

##### ■ Teaching

- Appropriate use of medications  
*Instruct patients to utilize medications as prescribed for best results. Avoid nasal decongestant use for greater*

than 2 to 3 days at a time due to the risk of rebound congestion. Instruct the patient to complete antibiotic therapy as prescribed to avoid superinfection or the creation of antibiotic medication resistance.

- Avoidance of known allergens or triggers  
Reduced exposure to triggers is the first-line treatment to avoid symptoms.
- Preventing the spread of infection  
Instruct patients about the importance of hand hygiene and covering the mouth when coughing or sneezing. Dispose of facial tissues containing nasal drainage.

### Evaluating Care Outcomes

Relief of symptoms is the expected outcome for the patient with rhinitis. A decrease in nasal drainage and congestion and the relief of headache can be achieved with the avoidance of allergens and the use of appropriate medications.

### Connection Check 25.1

The nurse is caring for a patient with seasonal allergy-related rhinitis. The nurse correlates which of the following symptoms with rhinitis?

- Productive cough
- Earache
- Rhinorrhea
- Headache

## RHINOSINUSITIS

### Epidemiology

**Rhinosinusitis** is the symptomatic inflammation of the nasal cavity and the paranasal cavity. Rhinosinusitis is the preferred term when referring to sinusitis because it is a more comprehensive term. According to the American Academy of Otolaryngology–Head and Neck Surgery Foundation, one in eight Americans is affected by rhinosinusitis, resulting in 30 million people diagnosed each year. Healthcare-related costs are estimated at \$11 billion annually. These costs are related to acute care and emergency department visits and surgical procedures on the paranasal sinuses.

Classification of rhinosinusitis is based on the duration of symptoms and includes acute, subacute, and chronic. Acute rhinosinusitis is defined as lasting less than 4 weeks; subacute is 4 to 12 weeks' duration. Chronic is more than 12 weeks and may include acute exacerbations of symptoms. **Acute rhinosinusitis** is further classified by etiology as either **acute bacterial rhinosinusitis (ABRS)** or **viral rhinosinusitis**. Viral upper respiratory infections that spread to the paranasal sinuses are the cause of most acute rhinosinusitis, which then can lead to bacterial infections. A deviated nasal septum, trauma to the nose, or tumors can interfere with nasal drainage and contribute to the development of acute rhinosinusitis. Annually in the United States, there are about 20 million cases of ABRS, with a

resulting healthcare cost of \$3 billion. Healthcare needs for the treatment of ABRS include primary care office visits, diagnostic testing, antibiotics, and additional prescription medications for symptom management. The socioeconomic impact of ABRS through indirect costs is also significant because of the loss of workdays and decreased productivity.

Acute rhinosinusitis can progress to chronic rhinosinusitis (CRS), which is one of the most common chronic diseases. Fourteen percent to 16% of the U.S. population is affected by CRS. Chronic rhinosinusitis is more common in females, and the presence of nasal polyps is seen in 19% to 36% of patients. Chronic rhinosinusitis results in significant healthcare costs because of repeated visits to PCPs and the use of prescription medications. Chronic rhinosinusitis also has an impact on quality of life due to symptoms and impaired physical functioning.

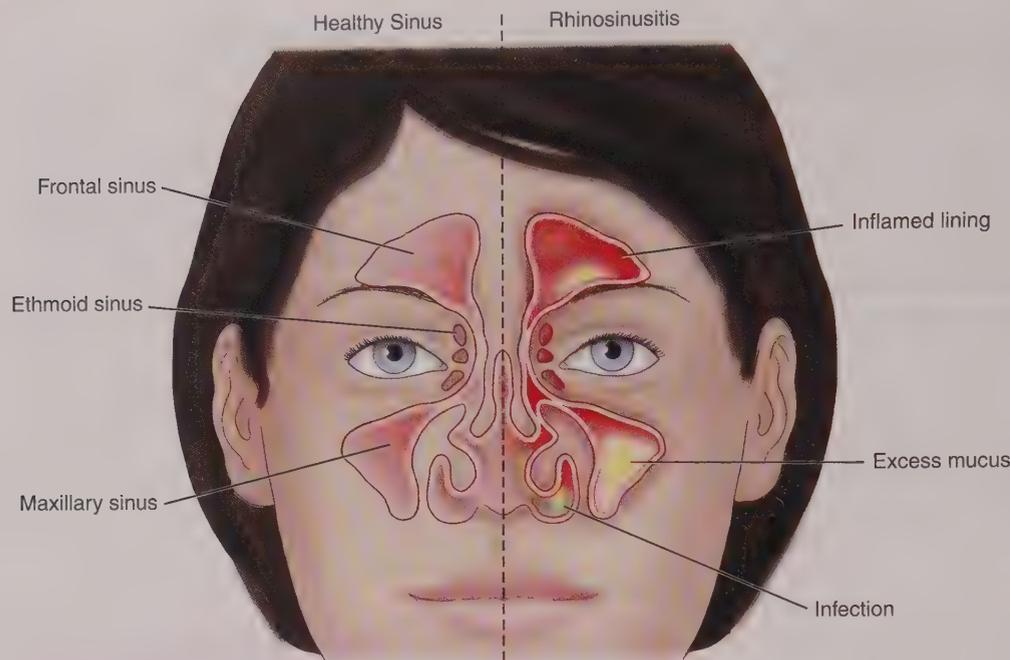

### Pathophysiology

Rhinosinusitis is infection and inflammation of the paranasal sinuses, the four paired air-filled spaces that surround the nasal cavity. They include the maxillary, frontal, sphenoid, and ethmoid sinuses. Inflammation of the nasal passages causes vasodilation, increased blood flow, and vascular permeability, reducing the size of the nasal passages. Nasal congestion occurs as a result of swelling of the nasal turbinates, bony structures along the nasal passages that aid in maintaining moisture and trapping airborne particles. This results in obstruction of nasal airflow (Fig. 25.2). Additional conditions that obstruct the flow of nasal secretions include a deviated nasal septum, trauma to the nose, and tumors. Lack of nasal airflow and increased drainage of nasal secretions provide the medium for bacterial growth. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are the most common bacterial species in the culture results of patients with acute rhinosinusitis. Additional bacteria that cause rhinosinusitis include *Staphylococcus aureus* and anaerobes.

### Clinical Manifestations

Acute rhinosinusitis is diagnosed by the presence of three symptoms: purulent nasal discharge; nasal obstruction; and facial pain, pressure, and fullness. Normal nasal secretions are clear. In acute rhinosinusitis, nasal secretions are colored or cloudy in nature. Nasal obstruction may be reported as congestion, stuffiness, or blockage of the nasal passages. Facial pain, pressure, and fullness may be located in the anterior face, in the periorbital areas, or as a diffuse or localized headache. The onset of these symptoms in relation to the development of upper respiratory symptoms indicates ABRS.

Additional symptoms may include fatigue, fever, maxillary dental pain, cough, and ear fullness or pressure. Nasal or purulent drainage may also be noted in the posterior pharynx. Indications of extra sinus involvement include signs of neck stiffness (due to the development of meningitis),

**FIGURE 25.2** Rhinosinusitis: inflamed sinuses filled with excess mucus.

orbital protrusion, cellulitis of the face or orbit, and abnormal eye movement.

## Management

### Medical Management

#### Diagnosis

Diagnosis is primarily based on a physical examination and starts with the completion of a history and physical examination focusing on the ears, nose, throat, teeth, sinuses, and chest. During the physical examination, the provider is looking for signs of inflammation, tenderness, firmness, or redness. Light palpation or percussion of the sinuses using the index finger is done to evaluate the presence of pain. A vital sign assessment also needs to be completed to identify temperature elevation. Diagnostic testing may include radiographical imaging of the sinuses, computed tomography (CT), and magnetic resonance imaging (MRI) if patients do not meet clinical diagnosis criteria. On radiographical studies, fluid; thickening of the mucous lining of the sinuses; and the presence of polyps, opacities, or foreign objects may be found, indicating rhinosinusitis.

#### Treatment

The focus of treatment in acute rhinosinusitis is based on the etiology. Treatment goals include pain relief, reduction of nasal mucosal inflammation, and treating infection if present. Normal saline irrigation has local effects that reduce symptoms in acute rhinosinusitis. In this procedure, the patient pours or sprays normal saline into one nostril; it flows through the nasal cavity and pours out the other nostril. Irrigation is beneficial in the removal of infectious

debris, bacteria, allergens, and inflammatory mediators. It also decreases edema of the nasal mucosa and the viscosity of nasal secretions.

Caution must be taken to prevent antibiotic use in nonbacterial illnesses such as viral rhinosinusitis to prevent the development of antibiotic resistance, but in bacterial infections, antibiotic therapy is required. A delay in initiating antibiotic therapy may be indicated if the patient presents with symptoms of nonsevere illness (temperature less than 101°F [38.3°C] or with mild pain). If after 7 days the patient fails to improve or worsens at any time, antibiotics are prescribed. Amoxicillin or amoxicillin-clavulanate is the first-line therapy for most patients with ABRs because of its efficacy, safety, narrow microbiological spectrum, and low cost. In patients with penicillin allergies, doxycycline or a respiratory fluoroquinolone such as moxifloxacin or Levofloxacin is used. In patients who fail to respond within 48 to 72 hours of treatment or who have persistent symptoms, second-line antibiotics may be required. Second-line antibiotics most commonly used include second- or third-generation cephalosporins (cefuroxime [Ceftin], cefpodoxime [Vantin]), macrolides (clarithromycin [Biaxin]), fluoroquinolones (ciprofloxacin [Cipro], levofloxacin [Levaquin], moxifloxacin [Avelox]), and clindamycin (Cleocin).

Antipyretics and analgesics are used as needed to control temperature elevation and pain. The use of intranasal corticosteroids is recommended in patients with a history of allergic rhinitis.

The use of decongestants can be helpful in reducing obstruction of the osteomeatal complex (the bony structures around the drainage openings of the sinuses), facilitating drainage of the sinuses. Patients with hypertension

should use caution when taking oral decongestants due to their action of vasoconstriction to reduce stuffiness, which can increase blood pressure. Medications typically used for symptomatic relief that should be used with caution include antihistamines that may cause drying of secretions, thus impairing mucus drainage, and topical decongestant sprays that, if used for more than 3 days, may result in rebound nasal congestion when discontinued. This is also referred to as rhinitis medicamentosa. Rhinitis medicamentosa results in nasal congestion without rhinorrhea or sneezing and is known as *rebound rhinitis* or *chemical rhinitis*. Treatment of rhinitis medicamentosa is the cessation of topical nasal decongestants.

### Complications

Acute rhinosinusitis, if left untreated or inadequately treated, can lead to several potentially serious although rare complications that include orbital cellulitis, orbital abscess, osteomyelitis, meningitis, sepsis, and subdural abscess. Orbital cellulitis and orbital abscess occur from the transfer of a sinus infection to the area surrounding the eye. In the setting of chronic sinus infection, bacteria can infect the facial bones, resulting in osteomyelitis. Meningitis and subdural abscess occur when bacteria pass through the meninges. Mucocoeles, collections of fluid, can develop within the sinuses, primarily the frontal or ethmoid sinuses, because of obstruction and can result in bony erosion.

### Nursing Management

#### Assessment and Analysis

Symptoms of rhinosinusitis are due to obstruction in the flow of nasal drainage from inflammation of the sinus lining. Symptoms include a combination of facial pressure, sense of fullness or pain or nasal obstruction, and the presence of purulent (yellow-green) nasal discharge.

#### Nursing Diagnoses

- **Risk for infection** related to obstruction and inflammation of the sinus lining
- **Acute pain** related to nasal congestion

#### Nursing Interventions

##### Assessments

- Vital signs  
*Temperature elevation may indicate the presence of infection. Increased blood pressure may be a side effect of the decongestants.*
- Physical examination of the mouth, nose, and face  
*Facial pressure, a sense of fullness or pain or nasal obstruction, and the presence of purulent (yellow-green) nasal discharge indicate impaired nasal drainage. Swelling, redness, and pain around the eyes may indicate an abscess or cellulitis.*
- Percussion of sinuses  
*Identifies presence of fluid within the sinus cavity, which results in pain*

##### Actions

- Administer medications as prescribed: normal saline irrigation, decongestants, and antibiotics.  
*Irrigation, decongestants, and antibiotics are used to control the symptoms of nasal congestion, excessive drainage, and inflammation. Antibiotics are used to treat bacterial infection.*

##### Teaching

- Symptoms to report to provider  
*Temperature, increase in pain, change in level of consciousness, redness, or edema around the face and eyes can indicate complications of rhinosinusitis.*
- Instruct patients on correct medication usage.  
*Instruct patients to read the content of the active ingredients and utilize medications as prescribed to prevent overdosing. Start taking decongestants at the onset of symptoms. Complete all antibiotics as prescribed. Limit use of decongestant nasal sprays to less than 4 days to avoid rebound congestion.*
- Teach proper use of normal saline nasal rinse.
  - Lean over the sink with head tilted to one side.
  - Insert the spout of the neti pot or other irrigating device into the upper nostril.
  - Slowly pour the normal saline into the upper nostril while continuing to breathe through the mouth.
  - Allow fluid to drain out the lower nostril.  
*Facilitates removal of debris and excess mucus*

##### Evaluating Care Outcomes

With treatment, patients experience a decrease in and resolution of symptoms, such as relief of nasal congestion and drainage, headache, and facial pressure or sense of fullness. The resolution of a bacterial infection is managed through antibiotics. It is important that the patient completes antibiotic therapy as prescribed and reports unresolved symptoms to avoid the serious complications of orbital cellulitis, osteomyelitis, or chronic sinus infection.

### Connection Check 25.2

Potential complications of rhinosinusitis include which of the following? (Select all that apply.)

- Orbital cellulitis
- Osteomyelitis
- Meningitis
- Pharyngitis
- Orbital abscess

## OBSTRUCTIVE SLEEP APNEA

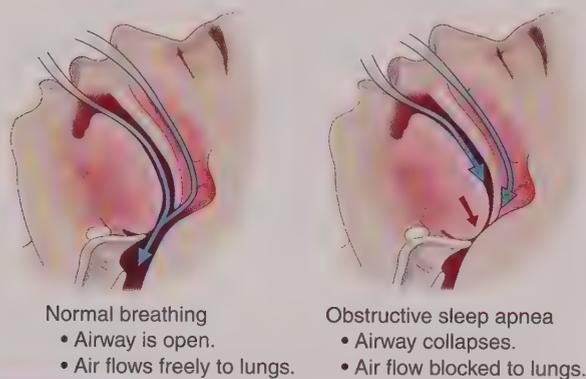

### Epidemiology

**Obstructive sleep apnea (OSA)** is a condition where the upper airway is obstructed during sleep, causing a narrowing of one or more sites of the upper airway, resulting in intermittent breathing patterns. It is estimated that 10% to

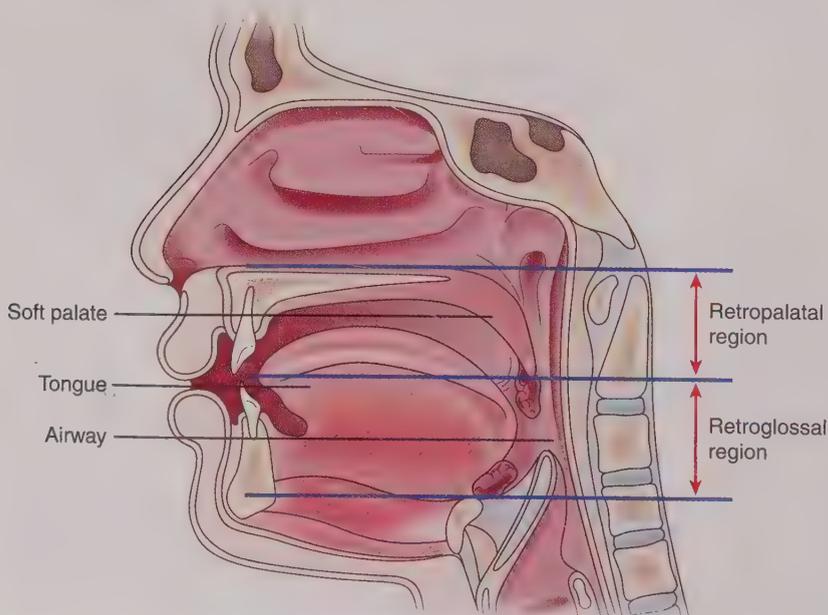

15% of females and 20% to 30% of males have OSA. Increased awareness and recognition, and thus testing, have resulted in an increased prevalence. A history of atrial fibrillation, nocturnal dysrhythmias, type 2 diabetes mellitus, heart failure, and pulmonary hypertension places patients at higher risk of OSA. Other risk factors for developing OSA include male gender, obesity, cigarette smoking, alcohol use, age between 40 and 65, craniofacial or upper airway soft tissue abnormalities, and menopause. Insulin resistance is seen in patients with OSA and is associated with increased severity. Increases in the prevalence of the risk factors have resulted in an increase in OSA.

### Pathophysiology

Obstructive sleep apnea occurs during sleep as the upper airways narrow or collapse, increasing resistance to airflow (Fig. 25.3). Narrowing can occur in the retropalatal region, retroglottal region, or nose (Fig. 25.4).

**FIGURE 25.3** Obstructive sleep apnea due to the collapse of the upper airways.

**FIGURE 25.4** Retropalatal region, retroglottal region of the upper airway.

With the onset of sleep, the body muscle tone relaxes, which includes the muscles of the upper airway. With OSA, the normal work of breathing is unable to overcome the increased resistance in the upper airway, causing airway collapse. Narrowing of the upper airways increases inspiratory pressure and intrathoracic pressure, resulting in decreased minute ventilation and gas exchange. Ultimately, there are periods of **apnea**. During apnea, there is no tidal volume or movement of air in or out; thus, no gas exchange occurs in the alveoli.

**Hypoxemia** (decreased concentration of oxygen in the blood), **hypercapnia** (increased concentration of carbon dioxide in the blood), acidosis, and increased sympathetic vasoconstrictive activity occur as a result of the decreased tidal volume and apnea.

### Clinical Manifestations

Obstructive sleep apnea is characterized by the following symptoms: loud snoring, snorting, witnessed apnea, gasping during sleep, recurrent waking during sleep, or choking. Spouses often report that patients have disruptive snoring and have witnessed periods of apnea. Fifteen or more obstructive sleep events per hour are sufficient to diagnose the presence of OSA. Because of these frequent sleep disruptions, patients complain of excessive daytime sleepiness, falling asleep during quiet times, short and repetitive attention lapses, and taking intentional naps. Daytime sleepiness has been linked to workplace and motor vehicle accidents and cognitive complaints of poor motor performance, executive performance, and visuospatial learning; storage and recall of visual information about the spatial relationship of objects, and constructional ability.

## Management

### Medical Management

#### Diagnosis

Diagnostic testing begins with a sleep history, which includes gathering information on sleep patterns, a history of snoring, and daytime sleepiness. **Polysomnography** (a sleep study) is performed to diagnose OSA and can be conducted in an overnight sleep laboratory or using home portable monitoring. Numerous biophysiological measurements are obtained during sleep, including an electrocardiogram, pulse oximetry, respiratory airflow, eye and skeletal muscle movement, and an electroencephalogram. A key value obtained during the sleep study is the apnea-hypopnea index value, the number of apneic events each hour. It can be used to characterize the severity of OSA.

#### Treatment

Treatment of OSA requires multiple interventions and the active participation of the patient. The use of **continuous positive airway pressure (CPAP)** is the treatment of choice (Fig. 25.5). Continuous positive airway pressure prevents collapse of the upper airway through the use of pressure delivered through the use of a nasal, oral, or oronasal mask during sleep (Fig. 25.6). A CPAP machine delivers a continuous stream of positive pressure, keeping the airway open and providing an unobstructed airway. Patients are taught about the operation, care, and maintenance of the CPAP machine. Follow-up care is conducted for problem solving and to evaluate the effectiveness of therapy.

Weight management and loss are encouraged as a first-line intervention in conjunction with the use of CPAP. Positioning during sleep in a nonsupine position by using pillows is an effective secondary intervention. The avoidance of alcohol and sedatives before bedtime is an additional intervention.

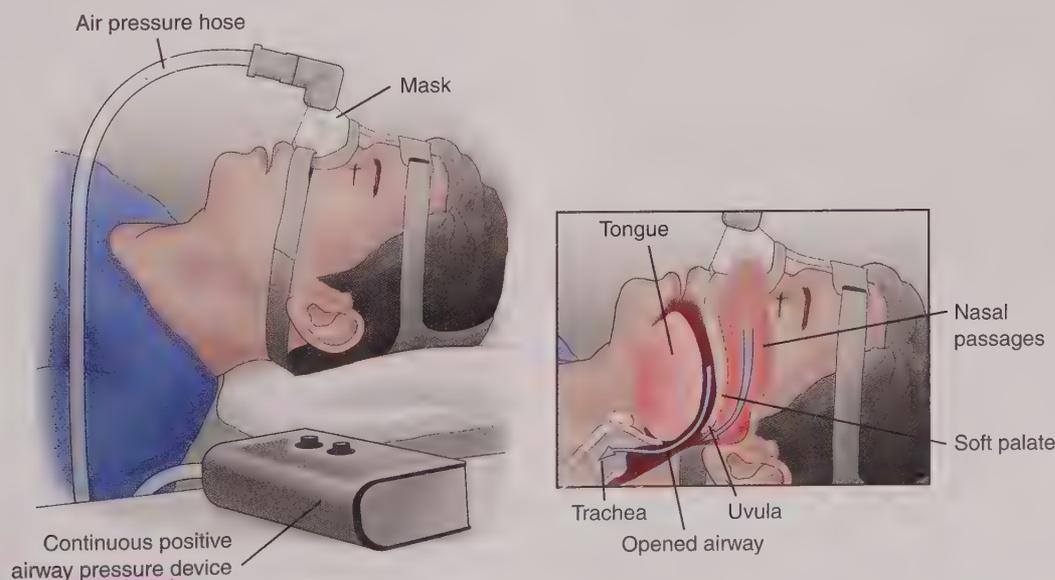

Oral appliances that are custom-made for the patient may be used to maintain airway patency. Oral appliances assist with mandibular repositioning to hold the mandible in a forward position to keep the airway open. Forward positioning of the tongue is accomplished with tongue-retaining devices.

#### Surgical Management

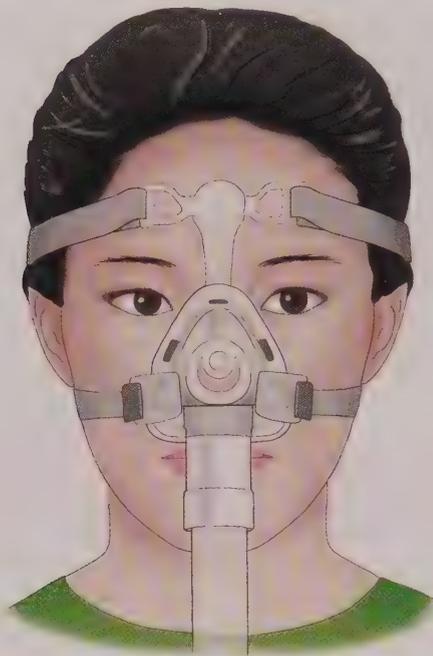

Surgical procedures for OSA are classified as primary or secondary interventions. Surgical procedures are considered primary interventions for patients with severe obstructing anatomy that surgery can correct. Surgery is considered a secondary intervention in patients who are intolerant of CPAP or oral appliances. **Surgical procedures that involve the airway include tonsillectomy and/or adenoidectomy, uvulopalatopharyngoplasty, septoplasty, nasal polypectomy, tongue reduction, and epiglottoplasty.** These procedures remove excess tissue in the airway that interferes with maintaining adequate airflow. Bariatric surgery to facilitate weight reduction is also a consideration.

#### Complications

Obstructive sleep apnea is recognized as a mediator of cardiovascular disease because of recurrent hypoxemia, the release of inflammatory mediators such as endothelins (proteins that constrict blood vessels), and insulin resistance. In response to hypoxia, inflammatory mediators are released, which leads to the adherence of white blood cells to the endothelium, causing endothelial damage and atherosclerosis. The release of endothelin, a potent vasoconstrictor, results in endothelial dysfunction and damage. Severe nocturnal hypoxemia can result in cardiac ischemia, myocardial infarction, erectile dysfunction, stroke, atrial fibrillation, heart failure, and sudden cardiac death.

**FIGURE 25.5** Continuous positive airway pressure (CPAP) machine with compressor and mask. The CPAP machine provides continuous positive airway pressure, keeping the upper airways patent.

**FIGURE 25.6** Continuous positive airway pressure mask.

### Connection Check 25.3

Monitoring of which of the following biophysiological parameters occurs during a sleep study? (Select all that apply.)

- A. Cardiac rhythm
- B. Electroencephalogram
- C. Eye movement
- D. Blood pressure
- E. Oxygen saturation

### CASE STUDY: EPISODE 2

Henry returns to his PCP 6 weeks after his initial visit regarding his sleep patterns. He has increased his activity by walking 2 miles at the local school track every other day and has modified his diet by reducing his carbohydrate intake. At this visit, he has lost 8 pounds. His wife states he still drifts off to sleep quickly when sitting and abruptly wakes up at night. His PCP recommends a sleep study to be done at the local sleep center...

### Nursing Management

#### Assessment and Analysis

The symptoms of OSA are due to the relaxation of soft tissue in the upper airway that results in occlusion of the airway. Because of the occlusion of the airway, the patient snores, and periods of apnea occur. During apnea, there is no oxygen exchange, resulting in hypoxia and hypercapnia.

As hypoxia and hypercapnia progress, the patient wakes and resumes breathing.

#### Nursing Diagnoses

- **Sleep deprivation** related to inability to breathe during sleep
- **Risk for decreased cardiac tissue perfusion** related to hypoxia during sleep
- **Ineffective sleeping pattern** related to cessation of breathing during sleep

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Hypertension and dysrhythmias are common findings in OSA due to the hypoxia and release of inflammatory mediators as a result of the apneic episodes.*
- Height and weight  
*Obesity is a risk factor for OSA.*
- Sleep, rest, and activity history  
*Disruptive sleep patterns, daytime fatigue, increased sleepiness, and the presence of snoring indicate OSA.*
- Assess for edema, bleeding, and respiratory distress postoperatively if a surgical option is pursued.  
*Surgical procedures put the patient at risk for bleeding. Additionally, procedures in that area may cause respiratory distress if swelling occurs.*

##### ■ Actions

- Administer medications as ordered.  
*Patients with OSA may have uncontrolled hypertension or cardiac dysrhythmias.*
- Diagnostic testing  
*Patient may undergo a sleep study, electrocardiogram, and echocardiogram.*

##### ■ Teaching

- Disease process  
*Instruct the patient and family members about OSA, risk factors, and management.*
- Instruct patient on medication use.  
*The patient may be started on antihypertensive medications to control blood pressure.*
- Instruction on CPAP  
*Depending on the results of the sleep study, the patient may be started on CPAP therapy. Provide instruction on the use and maintenance of equipment and the application of the mask.*
- Instruct patient on weight reduction and management  
*Obesity is a risk factor for OSA.*

#### Evaluating Care Outcomes

Weight loss and the use of CPAP at night may help with the control of OSA. Patients with well-managed OSA will verbalize improved sleep patterns, fewer night-time awakenings, less daytime sleepiness and fatigue, improved mental alertness, and less irritability. In OSA patients with hypertension, control of blood pressure values will be achieved.

## Connection Check 25.4

A nurse is providing patient education regarding OSA to a newly diagnosed patient. Patient understanding is indicated by which of the following statements?

- A. "I guess I should really lose weight."
- B. "I do not have to lose weight as long as I can use CPAP at night."
- C. "A glass of wine in the evening will help me sleep through the night."
- D. "I will not have to take my blood pressure meds if I use CPAP at night."

## LARYNGITIS

### Epidemiology

Acute **laryngitis** is the most common disorder of the larynx. Causes of acute laryngitis include upper respiratory infection, environmental pollutants, gastroesophageal reflux disease (GERD), and the use of asthma inhalers. Vocal misuse or strain can also result in acute laryngitis. Vocal strain can occur from prolonged periods of talking, which may be seen in teachers or lawyers, for example; screaming or having to talk loudly as a result of environmental noise; or in attempts to communicate with someone with hearing loss. Attempts to maintain speech in the presence of laryngitis can further strain the vocal cords. Endotracheal intubation may also cause laryngeal edema resulting in acute laryngitis. Lung or throat cancer may manifest as laryngitis.

### Pathophysiology and Clinical Manifestations

Laryngitis is an inflammation of the mucous membranes of the larynx. The predominant symptom is hoarseness, but symptoms similar to those of an upper respiratory infection may also be present, such as cough, postnasal drip, fatigue, and malaise. The symptoms of acute laryngitis typically last 7 to 10 days. Extreme airway obstruction and **stridor**, a high-pitched, wheezing breath sound caused by turbulent airflow in the partially obstructed larynx, may occur in patients after endotracheal intubation.

## Management

### Medical Management

#### Diagnosis

The diagnosis of laryngitis is based on patient complaint of hoarseness related to a current or recent upper respiratory infection. In patients with risk factors for developing cancers of the throat and lungs, further diagnostic evaluation may be warranted. Patients may require visual examination of the larynx by an ear, nose, and throat specialist through the use of a **laryngeal mirror** or **fiberoptic laryngoscopy**. A flexible fiberoptic laryngoscopy involves inserting a thin,

flexible scope into the mouth or nose to the larynx to allow direct visualization. If polyps, inflammation, or tumors are present, x-rays or CT may be required.

### Treatment

Treatment consists of voice rest, adding moisture to the air in the home with a humidifier or vaporizer, and drinking plenty of fluids. Avoidance of smoking and exposure to second-hand smoke is also important. The use of antibiotics is indicated in the setting of bacterial infection. If laryngitis lasts greater than 5 days after appropriate treatment and voice rest, evaluation for the presence of malignancy should be considered.

## Nursing Management

### Assessment and Analysis

Symptoms of laryngitis are due to inflammation of the larynx resulting in vocal hoarseness or the absence of voice. Additional symptoms may include dry throat, difficulty swallowing and eating, fever, and cough.

### Nursing Diagnoses

- **Impaired verbal communication** related to the inflammatory process
- **Risk for infection** related to the inflammatory process
- **Risk for aspiration** related to the inflammatory process

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Temperature elevation may indicate an infection.*
- Assessment of throat structures  
*Increased edema of the throat structures could compromise the patency of the airway.*
- Assess for the presence of stridor after extubation.  
*Stridor indicates acute obstruction of the airway and is a medical emergency that may require reintubation.*

#### ■ Actions

- Administer humidification as prescribed.  
*Humidification may be ordered to reduce inflammation.*
- Administer antibiotics as ordered.  
*Antibiotics may be ordered to treat infection if present.*
- Have emergency airway equipment readily available, especially if laryngitis occurs after extubation.  
*Hoarseness and stridor after extubation indicate acute obstruction of the airway and are a medical emergency.*
- Provide alternatives for communication (pen and paper or a communication board with pictures).  
*Patients should be encouraged to rest the voice to prevent further trauma.*

#### ■ Teaching

- Instruct on medication use.  
*Complete all medications as prescribed.*

- Instruct patient on voice rest and the need to use alternative modes of communication.  
*Continued use of the voice will cause strain and delay the resolution of laryngitis.*
- Increase intake of fluids.  
*Fluids help soothe a sore throat.*
- Smoking cessation  
*Smoking irritates the larynx and can exacerbate symptoms.*

### Evaluating Care Outcomes

Voice rest, humidity, and increased oral intake help resolve laryngitis. Return of the patient's normal voice and resolution of accompanying symptoms reflect resolution of laryngitis and the effectiveness of treatment. Patients are encouraged to avoid activities that strain the larynx. If the laryngitis is a result of bacterial infection, the patient should take prescribed antibiotics as directed and use expectorant medication to manage secretions. In patients who develop acute laryngitis after extubation, resolution of stridor, ease of breathing, and adequate oxygenation levels indicate decreased obstruction and resolution of laryngitis.

### Connection Check 25.5

The nurse is aware that there are several causes of laryngitis. Which of the following can cause laryngitis? (Select all that apply.)

- Food allergies
- Upper respiratory infection
- Environmental pollutants
- Gastroesophageal reflux
- Obstructive sleep apnea

## LARYNGEAL CANCER

### Epidemiology

In 2018, the American Cancer Society reported an expected 13,150 new diagnoses of **laryngeal cancer**, with the diagnosis split into 10,490 cases in men and 2,660 cases in women. The number of deaths was estimated at 3,710. This reflects a decrease in the number of people diagnosed with laryngeal cancer because of the decrease in smoking.

Risk factors for the development of laryngeal cancer include tobacco and alcohol use, poor dietary habits, a compromised immune system, genetic syndromes, occupational hazards, gender, age, race, and GERD. In addition to being at higher risk for laryngeal cancer, patients with GERD are also at higher risk for cancer of the esophagus.

The use of tobacco in any form is the most important risk factor for the development of cancers of the head and neck, including the larynx. Cigarettes, pipes, cigars, and all forms of chewing tobacco raise the risk of laryngeal cancers because of the chemicals contained in tobacco products. Alcohol ingestion combined with tobacco use increases

the risk of developing laryngeal cancer up to 100 times as compared with people who do not use either product. In patients with a history of alcohol abuse, poor dietary habits are also often present, resulting in a lack of fiber intake and foods containing vitamins. Laryngeal cancers are more common in people who have compromised immune status as a result of immunosuppressant medications after organ transplant, hereditary diseases, or AIDS. People with genetic mutations resulting in syndromes such as *Fanconi anemia* and *dyskeratosis congenita* have an increased risk of developing cancer of the mouth and throat at an early age. Occupations where workers have intense and long exposure to certain chemicals; wood, coal or steel dust; paint fumes; and asbestos are at higher risk of laryngeal cancer. Laryngeal cancer is about four times more common in men than in women, although these statistics are changing as more women are smoking and using alcohol. Laryngeal cancer is slow growing, so more than half of the people with laryngeal cancer are over 65 years of age. It is more common in African Americans and Caucasians than among Latinos and Asians.

### Pathophysiology

The larynx is divided into three main parts. The supraglottis is the uppermost part of the larynx above the vocal cords and includes the epiglottis. The middle part is the glottis and is where the vocal cords are located. The lower part of the larynx is the subglottis and is the area located between the vocal cords and the trachea. Laryngeal cancer usually originates from the squamous cells that line the larynx and hypopharynx, the part of the pharynx behind the larynx, the entrance to the esophagus. Changes in the squamous cells from irritation, usually from heavy alcohol drinking and smoking, result in the squamous cells becoming precancerous. According to the American Cancer Society, most precancerous cells do not become cancers, especially if the irritant is removed, but some advance into cancer cells. See Figures 25.7A and B for an illustration of the normal structures of the larynx; Figure 25.7C illustrates laryngeal cancer.

### Clinical Manifestations

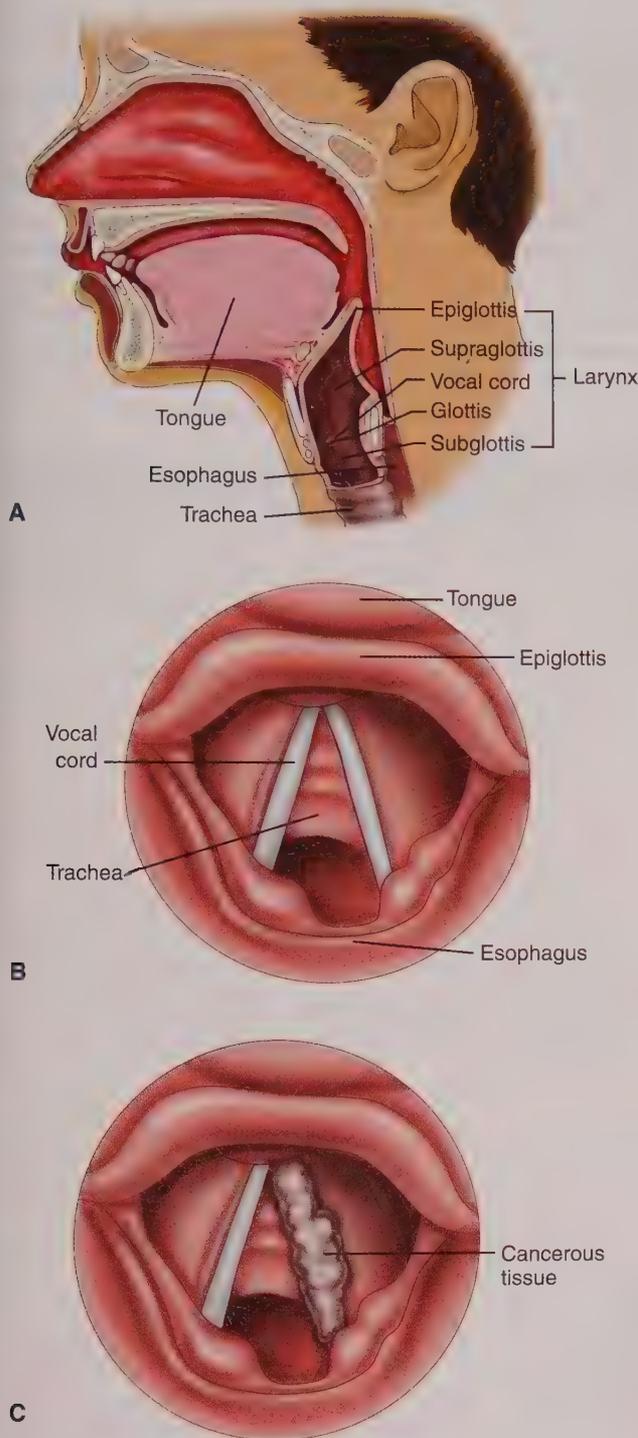

Clinical manifestations include hoarseness or a change in the voice that does not resolve in 2 weeks. Voice changes include lower-than-usual pitch and raspy and hoarse sounds. Additional symptoms include a persistent sore throat, constant cough, pain with swallowing, ear pain that does not go away, difficulty swallowing, trouble breathing, a lump or mass in the neck, and weight loss due to difficulty eating.

### Management

#### Medical Management

##### Diagnosis

Diagnosis starts with the completion of a thorough health history, including general health information, other medical conditions, onset of symptoms, risk factors, and family

**FIGURE 25.7** A and B, Normal structures of the larynx. C, Laryngeal cancer of the vocal cord.

**history:** Physical assessment of the neck, thyroid, lymph nodes, and muscle movement of the neck can indicate if tumor growth has invaded these structures. If these initial findings are suspicious for laryngeal cancer, a referral to an otolaryngologist (ear, nose, and throat specialist) or a head and neck surgeon is made.

Further diagnostic procedures include endoscopy and imaging. Visualization and examination of the pharynx

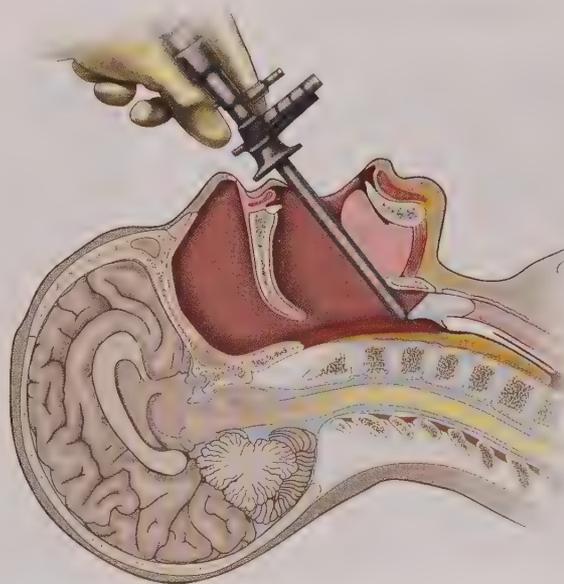

and larynx are performed by an otolaryngologist with the use of a direct laryngoscopy with a flexible endoscope. Laryngoscopy allows for assessment of the vocal folds and glottis for the presence of ulcerations, nodules, polyps, strictures, bleeding, or tumors. Laryngoscopy may also be performed under general anesthesia, at which time samples or biopsies of suspicious tissue are obtained for evaluation (Fig. 25.8).

Diagnostic imaging includes a barium swallow, chest x-ray, CT, MRI, and positron emission tomography (PET). A barium swallow evaluates the throat and the ability to swallow. Chest x-rays are obtained to evaluate the lungs for the presence of lung cancer. The CT, MRI, and PET scans are completed to determine the presence of metastasis into the surrounding and distant soft tissues and for regional adenopathy, or lymph node involvement. The information obtained through biopsy and diagnostic imaging is used to determine the stage of the tumor and disease progression. Stages of laryngeal cancer are based on the size of the tumor, the involvement of the lymph nodes, and whether the cancer has spread to other sites within the body.

Diagnostic laboratory testing is also done to provide information about the overall health status of the patient. A complete blood count, blood chemistry profile, coagulation studies, and urinalysis provide vital information about the potential spread of laryngeal cancer, nutritional status, and organ function, such as the kidneys and liver. At present, there is no specific blood test or marker to assist in diagnosing laryngeal cancer.

### Treatment

Treatment of laryngeal cancer is based on factors such as the stage of the disease, the location and size of the

**FIGURE 25.8** Laryngoscopy: direct visualization of the larynx.

tumor, and whether the current tumor is a recurrence. Treatment includes radiation therapy, surgery, and chemotherapy.

Radiation therapy is used to eliminate cancer cells and maintain the structure and function of the larynx. It is used to treat small tumors, to reduce tumor size prior to surgery, or in patients who are unable to undergo surgery. Radiation therapy is usually given 5 days a week for 6 to 8 weeks. Side effects of radiation include increased hoarseness; prolonged tissue healing; sore throat; difficulty swallowing; and if the salivary glands are involved, dry mouth (xerostomia).

Chemotherapy can be used in several different ways. It can be given at the same time as radiation therapy (chemoradiation) to improve the effectiveness of the radiation therapy. It can be given before radiation therapy to shrink larger tumors and make radiation therapy more effective. It can also be given prior to surgery to shrink larger tumors that are not easily excised. Finally, it can be used palliatively to help to control the cancer and relieve symptoms (palliative chemotherapy).

### Surgical Management

Surgical procedures used to treat laryngeal cancer include laser surgery, cordectomy, partial laryngectomy, and total laryngectomy. The goal of surgical treatment is to remove the tumor and maintain the function of the larynx, speech, swallowing ability, and breathing.

Laser microsurgery is used to treat early forms of glottic cancers and is now considered the standard approach at many institutions. It utilizes a beam of light to remove the tumor. A cost-effective alternative to an open surgical procedure, laser microsurgery results in good functional outcomes and causes minimal morbidity.

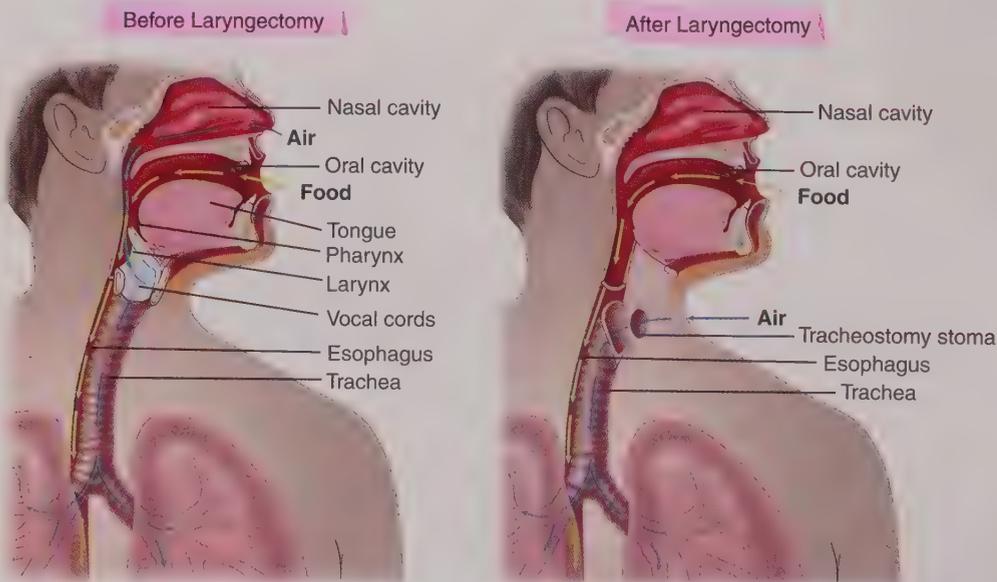

Cordectomy is the removal of part or all of a vocal cord through the use of a transoral laser. If laryngeal cancer is present unilaterally on the vocal cords and is in the early stages, this option may be considered.

Partial laryngectomy is performed to remove part of the larynx in the early stages of laryngeal cancer. This includes removal of part of the larynx, only one vocal cord, and the tumor. Preservation of the voice, which may be slightly altered or hoarse, is achieved because of the presence of the remaining structures. Patients will retain normal breathing and swallowing ability. A temporary tracheostomy may be required after partial laryngectomy to protect the airway.

Total laryngectomy is the complete removal of the larynx. In advanced stages of laryngeal cancer where the cancer has spread beyond the vocal cords, a total laryngectomy is a curative procedure. In this procedure, the larynx and several rings of the trachea are removed. Swallowing ability will remain normal after total laryngectomy, but the surgery results in the inability to speak. The creation of a tracheostomy is required for breathing and because of the risk of aspiration of fluids and food after the removal of the epiglottis (Fig. 25.9).

**Safety Alert** In patients with a tracheostomy, an obturator and a replacement tracheostomy tube should be kept at the bedside in the event of unexpected dislodgement of the tracheostomy tube. Ensure that the tube is secured in place with cloth tracheostomy ties or a Velcro tracheostomy tube holder. In addition, a suctioning unit and suctioning supplies should be at the bedside.

**FIGURE 25.9** Surgical removal of the larynx and the creation of a tracheostomy to protect the airway.

Laryngeal cancer prognosis is dependent on the stage of the disease; the size, location, and grade of the tumor; the presence of metastasis; and the general health status, immune function, and age. Early diagnosis of laryngeal cancer has a high cure rate, with a 5-year survival rate of 80% to 95%. Advanced staging at diagnosis has a 5-year survival rate of 25% to 50%. The presence of comorbidities such as diabetes, heart disease, or hypertension also has an impact on survival. Smoking cessation is another factor increasing survival (see Evidence-Based Practice: Smoking Cessation). Because of the age of patients diagnosed with laryngeal cancer, usually in the 60- to 70-year-old age group, the cause of death may be related to other factors.

## Evidence-Based Practice

### Smoking Cessation

#### Medication therapy

##### First line

- Nicotine replacement therapies (nicotine gum, patches, or lozenges)
- Non-nicotinic medications (Varenicline [Chantix] or bupropion [Zyban])

##### Second line

- Clonidine\* and nortriptyline\*

#### Behavioral/counseling therapy

- Providing support increases the likelihood of success and can be in the form of group or individual counseling or telephone conversations.

#### Physical activity

- Increasing physical activity decreases the cravings and symptoms of anxiety, depression, and stress that may be experienced during smoking cessation.
- Increasing physical activity and exercise also can reduce weight gain after smoking cessation.

\*Not approved by the U.S. Food and Drug Administration (FDA) for smoking cessation.

Rigotti, N. A. (2018). Patient education: Quitting smoking (beyond the basics). In J. K. Stoller & M. D. Aronson (Eds.), *UpToDate*. Retrieved from <https://www.uptodate.com/contents/quitting-smoking-beyond-the-basics#H16>

## Nursing Management

### Assessment and Analysis

The symptoms of laryngeal cancer are dependent on the location of the cancer. Laryngeal cancer affecting the vocal cords results in changes in voice quality and character or hoarseness. A lump in the neck, earache, or sore throat can be seen in tumors above the vocal cords.

## Nursing Diagnoses

- **Ineffective airway clearance** related to surgical removal of the glottis
- **Impaired swallowing** related to laryngectomy/tracheostomy tube
- **Impaired verbal communication** related to removal of the larynx
- **Impaired body image** related to the surgical procedure
- **Risk for infection** related to the surgical procedure
- **Grieving** related to the change in body image, role performance, and potential death
- **Risk for nutritional imbalance, less than body requirement**, related to impaired swallowing, poor appetite

## Nursing Interventions

### Assessments

- Complete a review of risk factors  
*Focus on risk factors for laryngeal cancer, such as smoking, alcohol use, and occupational exposure to chemicals.*
- Review of symptoms/complaints  
*Hoarseness, earache, and sore throat lasting several weeks need further evaluation.*
- Skin/vocal/swallowing assessment  
*Red, tender, peeling skin may result from radiation therapy. Radiation therapy may also cause worsening hoarseness and difficulty swallowing.*
- Laboratory assessments: electrolytes, white blood cell (WBC) and platelet count  
*Patients on chemotherapy may have alterations in their electrolyte balance. Also, they can become immunosuppressed, resulting in neutropenia, making them more susceptible to infection. Platelet counts may decrease, resulting in bleeding risk.*

### Postoperative

- Vital signs  
*Decreased blood pressure may occur with blood loss; increased heart rate may be due to hypovolemia or pain.*
- Oxygenation status  
*Edema and increased secretions postoperatively may cause shortness of breath and decreased oxygenation.*
- Patency of tracheostomy  
*Bleeding or edema may occur postoperatively, impairing the patency of the tracheostomy.*
- Weight, nutritional intake, calorie count  
*Swallowing impairments postoperatively may impact adequate nutritional intake.*

### Actions

- Administer chemotherapy as ordered.  
*Chemotherapy is used in combination with radiation and/or surgery in an effort to destroy cancer cells and reduce tumor size.*
- Institute bleeding precautions as necessary.  
*Chemotherapy may increase bleeding risk due to decreased platelet count.*

### Postoperative

- Tracheostomy care: use of humidified oxygen via a trach collar; pulmonary hygiene such as turning, coughing, deep breathing, and mobility; suctioning equipment, replacement tracheostomy tube (same size and one smaller), and obturator at bedside; tracheostomy care twice daily and as needed; management of oral secretions with a Yankauer suction tip (Fig. 25.10)

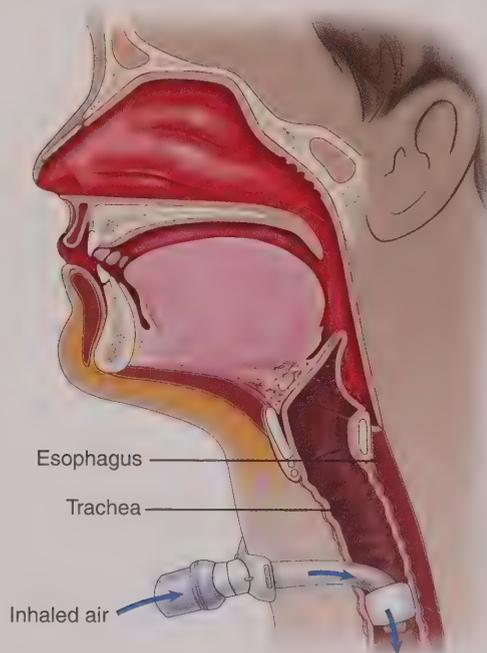

*Post-laryngectomy patients will have a permanent tracheostomy tube placed (Figs. 25.11 and 25.12). Good care is essential to maintain patency and decrease infection. Humidity, which will assist in moistening respiratory secretions, and pulmonary hygiene will facilitate secretion removal. Replacement equipment is necessary in case of unintended dislodgement of the tracheostomy. See Chapter 7 for more detailed information on tracheostomies.*

- Institute aspiration precautions.

*Postoperatively, the patient is at risk for aspiration because of the removal of upper airway structures/epiglottis.*

**FIGURE 25.10** Yankauer suction tip.

**FIGURE 25.11** Tracheostomy: artificial airway created in the neck to allow for ventilation.

**FIGURE 25.12** Essential components of the tracheostomy tube.

- Provide means for communication.

*Post-laryngectomy, the patient will not be able to speak due to the removal of the larynx. Provide pen and paper and a picture board.*

- Nutritional consultation

*Swallowing impairments may result in inadequate nutritional intake. Placement of a gastric or percutaneous esophageal gastrostomy tube may be required if the patient cannot maintain adequate nutritional intake.*

### ■ Teaching

- Diagnostic testing and interventions such as direct laryngoscopy

*Understanding the testing and interventions may ease anxiety and increase compliance.*

- Disease management

*Depending on the location of the laryngeal cancer, the patient may undergo various interventions (laser surgery, laryngectomy, **tracheotomy**). Understanding the outcomes, such as loss of speech and creation of a **tracheostomy**, is essential.*

- Tracheostomy management: suctioning and tracheostomy care with return demonstration  
*Skillful performance of suctioning and trach and stoma care is essential to keep the airway free from secretions and avoid infection.*

- Radiation therapy care:

- Skin care: avoid heating pad, ice pack, lotions or powders, sun exposure, extremes of temperature, and abrasive activities such as shaving at the radiation site; do not rub, scratch, or scrub the radiation treatment site; wear loose-fitting, soft clothing site; use a mild soap to clean the area.

*During radiation therapy, the skin can become red and tender and may peel. Radiation delays healing, so care must be taken to limit the additional potential for skin breakdown.*

- Oral care: use a soft-bristle toothbrush and brush and floss after each meal and at bedtime; suck on hard candy or chewing gum; examine the oral cavity for signs of infection, ulcerations, or bleeding.  
*A decrease in the production of saliva, which may be permanent, can occur with radiation therapy, resulting in dry mouth or xerostomia. Changes in taste sensation,*

halitosis, increased risk of dental cavities, and oral infections can occur as a result of decreased saliva production.

- Throat care: limit voice use; eat soft foods, drink plenty of fluids; sucking on ice chips or use of saline gargling may decrease the discomfort. The use of throat sprays or mouthwashes that contain a local topical anesthetic prescribed by the provider may assist in relieving the sore throat.

*With radiation therapy, vocal hoarseness may worsen, and difficulty in swallowing or a sore throat may develop.*

- Nutrition management: easy-to-eat, soft, nonspicy, non-acid-containing foods; small, frequent feedings; liquid nutritional supplements may be added. *Swallowing impairments may result in inadequate nutritional intake.*

- Chemotherapy management: take antiemetics prior to receiving chemotherapy and as needed; avoid crowds and persons with infections, and report any signs of infection immediately; report increases in bruising, presence of blood in the urine or stool, or increased fatigue.

*Chemotherapy may cause nausea and vomiting, immunosuppression, and decreased platelets.*

- Communication management: writing or picture boards, esophageal speech, electrolarynges. *Because of the loss of vocal cords with a laryngectomy, the ability to speak will be gone. Alternative forms of communication will be necessary. Esophageal speech occurs through the use of swallowed air to create words in the mouth. Electrolarynges are mechanical devices that are placed against the neck and use vibrated air to create words.*

### Evaluating Care Outcomes

The location, the treatment required (chemotherapy, radiation, surgery), and the presence of metastasis will determine the outcome of the patient with laryngeal cancer. In patients where early detection of laryngeal cancer has occurred, a complete recovery can be expected. If metastasis has occurred, the outcome is dependent on the metastasis site and the patient response to treatment. After laryngectomy, patients can return to normal activities using alternative means for communication. Patients are at risk for recurrence of laryngeal cancer if they continue to smoke and use alcohol.

### Connection Check 25.6

The nurse is aware that the greatest risk factor for laryngeal cancer is

- age.
- alcohol use.
- tobacco use.
- occupational hazards.

## LARYNGEAL TRAUMA

### Epidemiology

Laryngeal trauma is rare. One form of trauma, the laryngeal fracture, occurs in approximately 1 patient per 14,000 to 42,000 emergency department visits and accounts for less than 1% of all blunt traumas. This is partially due to the protected location of the larynx, with the hard, bony structure of the cervical spine posterior and the mandible in a superior and anterior position. Laryngeal trauma is sometimes seen in females because of their slimmer, longer necks, but overall, males present with the highest percentage of laryngeal trauma because of a greater participation in body-contact sports such as fighting.

### Pathophysiology

Laryngeal trauma occurs as a result of blunt or penetrating injuries, ingestion or inhalation of caustic agents to the neck, or pressure from prolonged endotracheal intubation. Blunt trauma can occur as a result of assaults, crush injuries, falls, motor vehicle crashes, sports, or strangulation. Penetrating injuries can occur from gunshots or stabbings. Patient outcomes are dependent on early recognition and maintenance of an adequate airway.

### Clinical Manifestations

Clinical manifestations of laryngeal trauma are dependent on the extent of the injury. They include hoarseness, pain, stridor, **dyspnea** (difficulty breathing), **dysphagia** (difficulty swallowing), and **hemoptysis** (bloody sputum). The airway can become obstructed from edema or fracture of the laryngeal structures or hematoma development.

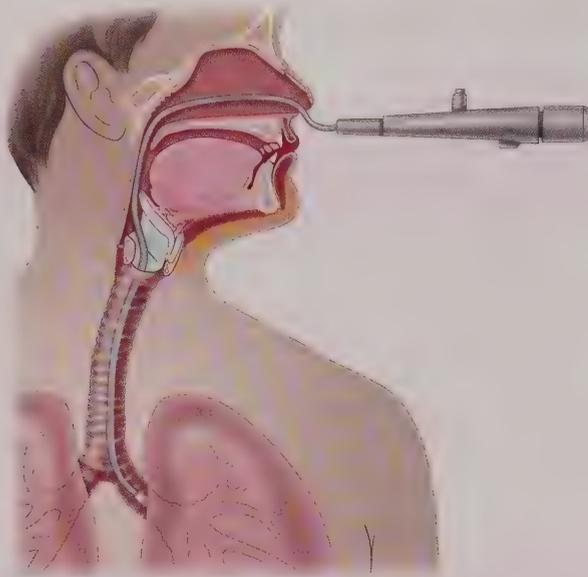

### Management

#### Diagnosis and Medical/Surgical Management

Diagnosis is completed by conducting a physical inspection of the neck for signs of swelling, discoloration, subcutaneous emphysema, tracheal deviation, and open wounds. Diagnostic studies include cervical CT, fiberoptic laryngoscopy, or flexible **bronchoscopy**. During a laryngoscopy or flexible bronchoscopy, the provider uses a flexible tube with a fiberoptic system to view structures in the upper and lower airways (Fig. 25.13).

The priority of care in patients with laryngeal trauma is to ensure and maintain a patent airway. Maintenance of the airway may include endotracheal intubation or tracheostomy. Because of the potential of cervical spine injury in addition to laryngeal trauma, stabilization of the cervical spine is vital. Diagnostics wait until the airway is protected and the cervical spine is stabilized.

Surgical interventions, if necessary, include evacuation of hematoma, repair of lacerations, and stabilization/repair of fractures.

**FIGURE 25.13** Flexible bronchoscopy allows for direct visualization of the upper and lower airways.

**Safety Alert** Patients who have experienced neck trauma are at high risk for airway occlusion or obstruction. Have an emergency tracheostomy insertion set at the bedside, and closely observe the patient for changes in respiratory rate, respiratory effort, and the development of adventitious breath sounds.

## Nursing Management

### Assessment and Analysis

Symptoms of laryngeal trauma are due to injury to the vocal cords and edema of the soft tissue of the neck. The patient may have a change in the quality and character of the voice or hoarseness, difficulty swallowing, or difficulty breathing. Discoloration and edema of the neck increase the suspicion of laryngeal trauma.

### Nursing Diagnoses

- **Ineffective airway clearance** related to edema
- **Impaired gas exchange** related to laryngeal trauma
- **Impaired swallowing** related to edema

### Nursing Interventions

#### Assessments

- Vital signs  
*Increases in respiratory and heart rates, decreased oxygen saturation, and tachypnea indicate respiratory distress.*
- Physical assessment of the neck and upper airway  
*Identify risk for laryngeal trauma if discoloration, change in voice, stridor, use of accessory muscles for breathing, or restlessness indicating hypoxia are present.*

#### Actions

- Have tracheostomy insertion tray and emergency equipment at the bedside.  
*The patient may have a sudden loss of the airway requiring emergency tracheostomy.*
- Provide humidified air via a face mask or face tent.  
*Cool humidified air will help decrease airway edema.*
- Keep the head of the bed elevated at 45 degrees or greater.  
*Elevation of the head of the bed will assist in decreasing edema and maintaining a patent airway.*
- Aspiration precautions  
*Maintain nothing-per-os (NPO) status to protect the airway in the presence of edema and/or bleeding. Also, maintain NPO status until the need for surgery has been evaluated.*

#### Teaching

- Symptoms to report to the healthcare provider and when to seek emergency medical care  
*A compromise in airway patency can quickly progress to airway occlusion and death.*
- Maintenance of voice rest  
*Limit talking to prevent an increase in trauma to the larynx and to prevent edema.*

### Evaluating Care Outcomes

In patients with laryngeal trauma, early recognition of airway compromise is key. The nurse provides close monitoring of respiratory rate, effort, breath sounds, and oxygen saturation. Keeping the head of the bed elevated and providing adequate humidification will assist in decreasing edema to the area. Encouraging the patient to observe voice rest helps minimize additional irritation and avoid airway compromise.

## Connection Check 25.7

In providing care for a patient with potential laryngeal trauma, a priority of care is

- monitoring oxygen saturation every 2 hours.
- having an emergency tracheostomy tray at the bedside.
- continuous cardiac monitoring.
- ensuring adequate oral intake of food.

## Making Connections

### CASE STUDY: WRAP-UP

Henry is found to have hypertension, with his blood pressure ranging from 150 to 170/90 to 100 mm Hg. His electrocardiogram shows sinus rhythm with frequent multifocal premature ventricular contractions. He is scheduled for a polysomnography (sleep study).

Henry's polysomnography study shows he has OSA. He is provided with a CPAP device with a nasal mask. He is started on hydrochlorothiazide 25 mg daily for his hypertension. Several months after diagnosis, he has lost 25 pounds. He reports that he is not as sleepy during the day and is more rested upon waking in the morning. His blood pressure currently is 130/82 mm Hg. His wife reports that he is less irritable and more energetic.

### Case Study Questions

- Henry is started on an antihypertensive after his diagnosis of hypertension. Which statement indicates Henry understands his education regarding the new medication?
  - "I can stop taking this medication when I start sleeping better."
  - "Sleeping through the night is the most important thing to consider."
  - "I'm glad we found out I had high blood pressure so that I can treat it!"
  - "This medication will help me sleep better."
- The nurse provided patient education regarding the sleep study. Which statement made by the patient indicates he understands the procedure?
  - "The study will occur in the cardiology department and will last 2 hours."
  - "The sleep study will help determine the amount of sleep I need each night."
  - "I will receive some sedation for the procedure and will need to have a ride home."
  - "The test determines how deeply and what type of sleep I have."
- After a sleep study confirms that Henry has OSA, the nurse is preparing to provide patient education regarding home management. The nurse includes which of the following instructions for Henry?
  - The use of albuterol nebulization treatments to promote bronchodilation
  - Use of nasal cannula oxygen delivery during sleep
  - Use of a CPAP machine during sleep
  - Keeping the head of the bed flat during sleep
- The nurse is providing patient education regarding the use of the CPAP machine to Henry and his wife. Which of the following statements regarding CPAP are correct? (*Select all that apply.*)
  - The machine utilizes a small compressor.
  - CPAP provides extra oxygen at night.
  - The face mask should snugly fit over the nose and mouth.
  - There is an adjustment period to using the CPAP machine.
  - You should use it only on nights you need to get up early in the morning.

- After 4 months of using the CPAP machine, Henry determines that he would like to try to sleep without it. He feels slightly claustrophobic and thinks the weight loss may have improved his OSA. What does the nurse ask Henry and his wife to monitor if he stops using the CPAP machine? (*Select all that apply.*)
  - Increased belching
  - Irritability
  - Snoring
  - Voice quality
  - Blood pressure

## CHAPTER SUMMARY

Rhinitis is caused by irritation and inflammation of the mucous membranes of the nose. Symptoms of rhinitis include nasal congestion; rhinorrhea; sneezing; and itching of the nose, eyes, and ears. Causes of rhinitis include allergies, temperature or humidity changes, and the common cold. Treatment is aimed at symptom relief through the use of a decongestant.

*Rhinosinusitis* is the current terminology for sinusitis. Rhinosinusitis can be bacterial or viral in nature. A deviated nasal septum, trauma to the nose, or tumors can interfere with nasal drainage and contribute to the development of acute rhinosinusitis. Symptoms of rhinosinusitis include purulent nasal drainage, a sense of pressure, and facial pain. Treatment is dependent on whether a bacterial infection is present. Antibiotics, corticosteroids, pain medications, and saline nasal irrigation are treatment modalities for rhinosinusitis. Complications of rhinosinusitis include orbital cellulitis, osteomyelitis, subdural abscess, meningitis, and sepsis.

Obstructive sleep apnea (OSA) occurs as the soft tissue and muscles of the upper airway relax during sleep, occluding the airway. This results in apnea, hypoxia, and hypercapnia. The patient awakens frequently during the night. Signs and symptoms of OSA are excessive daytime sleepiness, insomnia, loud snoring, personality changes, impotence, hypertension, and cardiac dysrhythmias. Because of the increased prevalence of obesity, the incidence of OSA has increased. Obstructive sleep apnea results in the cardiovascular consequences of hypertension, cardiac dysrhythmias, and myocardial infarction. Treatment of OSA is weight reduction and the use of continuous positive airway pressure (CPAP).

Laryngitis occurs as a result of inflammation of the mucous membranes of the larynx. Acute laryngitis is the most common disorder of the larynx. Causes of acute laryngitis include upper respiratory infection, environmental pollutants, gastroesophageal reflux disease (GERD), and the use of asthma inhalers. Lung or throat cancer may manifest as

laryngitis. If laryngitis is a result of infection, antibiotics are used. The patient is encouraged to rest her or his voice and increase oral fluid intake.

Risk factors for the development of laryngeal cancer include tobacco and alcohol use, poor dietary habits, a compromised immune system, genetic syndromes, occupational hazards, gender, age, race, and GERD. The use of tobacco in any form is the most important risk factor for the development of cancers of the head and neck, including the larynx. Diagnostic studies include flexible bronchoscopy, computed tomography, and laboratory studies. The treatment modalities

required will be determined on the basis of the site and whether the cancer has metastasized. Surgery, radiation, and chemotherapy may be used to treat laryngeal cancers.

Laryngeal trauma occurs as a result of blunt or penetrating injuries to the neck, cervical spine injuries, and esophageal injuries. Symptoms of laryngeal trauma are dependent on the extent of the injury and include hoarseness, pain, stridor, dyspnea, dysphagia, and hemoptysis. Patients are at risk for loss of a patent airway, so emergency tracheostomy or intubation equipment should be at the bedside.

# Chapter 26

## Coordinating Care for Patients With Lower Airway Disorders

*Adriana Glenn*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of lower airway disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Asthma
  - b. Chronic obstructive pulmonary disease
  - c. Cystic fibrosis
  - d. Lung cancer
3. Describing the diagnostic results used to confirm the diagnosis of lower airway disorders
4. Discussing the medical management of:
  - a. Asthma
  - b. Chronic obstructive pulmonary disease
  - c. Cystic fibrosis
  - d. Lung cancer
5. Developing a comprehensive plan of nursing care for patients with lower airway disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with lower airway disorders

### CONCEPTS

- Assessment
- Inflammation
- Medication
- Nursing Roles
- Oxygenation
- pH Regulation

### ESSENTIAL TERMS

Adjuvant therapy  
Asthma  
Bronchiectasis  
Chronic bronchitis  
Chronic obstructive pulmonary disease (COPD)  
Cystic fibrosis  
Emphysema  
Exacerbation  
Forced expiratory volume (FEV)  
Forced vital capacity (FVC)  
Neoadjuvant therapy  
Peak expiratory flow  
Pursed-lip breathing  
Spirometry  
Steatorrhea  
Tripod position  
Visual analog dyspnea scale

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Clifford Davis is a 39-year-old male with a history of asthma who presents to the emergency department with shortness of breath and inability to carry on a conversation. He is assuming a tripod position and exhibits pursed-lip breathing. He has a nonproductive cough. He woke up coughing, followed by chest tightness, which prompted a call to the rescue services. His vital signs are blood pressure (BP), 121/65 mm Hg; heart rate (HR), 150 bpm; respiratory rate (RR), 40. He has audible wheezes bilaterally. He has been a one-pack/day smoker for 15 years.

His medications include:

Hycodan cough elixir 1 to 2 tsp at bedtime (HS)

Zyrtec 5 mg bid

Advair 500/50 1 inhalation bid

Pulmicort Flexhaler 180 mcg bid

Tessalon Perles 200 mg tid

Ventolin 2 puffs prn...

## INTRODUCTION

All lower airway disorders negatively impact oxygenation, ventilation, and gas exchange, thus affecting tissue perfusion. Some lower airway disorders can be chronic and progressive such as asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis. Chronic and progressive lower airway disorders require meticulous management and lifestyle adjustments to achieve maximum wellness. Conversely, lung cancer can occur acutely and more often has a very poor 5-year survival rate. Lung cancer requires early detection and aggressive management to achieve maximum wellness. All patients attempting to optimally manage their lower airway disorders require thoughtful nursing care, support, and education.

## ASTHMA

### Epidemiology

Statistics updated in 2017 indicate asthma affects over 18 million Americans, including 6 million children. Approximately 8% of children and 8% of adults have asthma. In adults, it is more common in women than in men. In children, asthma is more common in boys. The rate of asthma among blacks is higher than in other racial or ethnic groups. Multiple-race, American Indian, or Native Alaskan people also have higher rates of asthma. Internationally, estimates of those who suffer from asthma are approximately

300 million people worldwide. This number is expected to increase by more than 100 million by 2025. The risk of death from asthma increases with age. Risk factors include a family history, frequent respiratory infections, eczema, and the presence of allergies such as rhinitis.

### Pathophysiology

**Asthma is a chronic lung disease characterized by an intermittent, reversible airway obstruction resulting from inflammation of the lung's airways and a tightening of the muscles that surround the airways. The condition affects the bronchial airways, not the alveoli. There is airway obstruction and bronchial hyperresponsiveness. The state of bronchial hyperresponsiveness and underlying inflammation of the small airways is easily triggered by exposure to irritants, exercise, cold weather, or risk factors. Irritants include cigarette smoke, mold, pollen, dust, animal dander, air pollutants, and occupational irritants. Risk factors include viral infections, nasal polyps, allergic rhinitis, food and medication allergies, and emotional stress.**

Exposure to triggers produces an inflammatory response. As a part of that immune activation, IgE antibodies bind to receptors on mast cells, causing degranulation and the release of inflammatory mediators, such as histamine and leukotrienes, which cause vasodilation and increase capillary permeability. There is edema of the airways and an increase in basophils, eosinophils, and neutrophils, which stimulate the production of mucus. The resulting thick, tenacious mucus causes a thickening of the airways and bronchial hyperresponsiveness. The release of histamine also causes constriction and spasm of the smooth muscles surrounding the bronchial tubes, causing bronchospasm of the bronchial tubes. The bronchospasms cause further narrowing of the airways. The bronchospasms, mucus production, and edema produce obstruction to the flow of air into and out of the lungs.

### Clinical Manifestations

After exposure to a trigger, the patient exhibits clinical manifestations such as wheezing, dyspnea, coughing, increased sputum, and increased respiratory rate. The patient may also experience chest tightness and tachycardia, which may be secondary to decreased oxygenation or anxiety or a side effect of treatment with bronchodilators. A classic sign of an asthma attack is the inability to speak in full sentences.

### Connection Check 26.1

A patient with asthma presents with which symptoms?

- Cough, elevated blood pressure
- Decreased respirations, fatigue
- Increased respirations, wheezes
- Increased sputum, decreased respirations

## Management

### Medical Management

#### Diagnosis

The diagnosis and assessment of asthma include a detailed patient history, pulmonary function tests, chest x-ray, and pulse oximetry and possibly arterial blood gases (ABGs). The detailed patient history should include childhood illnesses, family history of allergies or asthma, eczema, smoking history, occupational history, and exposure to environmental triggers. Additionally, the patient history should include the frequency of symptoms, whether they are triggered by any specific activity or time (day, evening, spring, or fall), how long the symptoms last, and mechanisms the patient uses to relieve the symptoms. The chest x-ray is needed to rule out any other respiratory conditions and to monitor progressive changes in the chest.

Pulmonary function tests (PFTs) are a predominant feature in evaluating asthma. PFTs are a group of tests used to evaluate the functioning of the respiratory system. Some of the more commonly used PFTs are spirometry, peak expiratory volume, and pulse oximetry. There are other PFTs available for use in confirming a diagnosis of asthma when routinely used tests or exams do not provide a clear diagnosis of asthma.

**Spirometry** is a test that measures airflow and lung volumes, such as the **forced expiratory volume (FEV)**. One of the major tests of pulmonary function is the forced expiratory volume in 1 second (FEV<sub>1</sub>). The FEV<sub>1</sub> measures the amount of air forced out of the lungs after a full inspiration. The volume is measured at 1 second. The measurement is compared to a normal person's predicted volume based on age and gender. A decrease in this test of 15% to 20% below the predicted value for age and gender is diagnostic of asthma. An increase of 12% after administration of a bronchodilator is also diagnostic of asthma.

**Peak expiratory flow** readings measure the maximum airflow expired during a forced expiration. The patient's peak flow readings are compared to the personal best reading with a reading obtained during an **exacerbation** or "asthma attack." Patients are encouraged to monitor their peak flow values. The reading done during an exacerbation as compared to a personal best allows the patient to recognize the severity of the respiratory distress. The patient's asthma action plan (discussed later) is based on the peak flow readings (Box 26.1).

Both noninvasive and invasive methods can be used to obtain oxygen saturation levels in the blood. Pulse oximetry is a noninvasive method of measuring oxygen saturation (SpO<sub>2</sub>). It can be used to help determine the severity of the respiratory distress. The normal pulse oximetry value is 95% to 100%. Pulse oximetry monitoring detects desaturation of the hemoglobin before the patient exhibits symptoms. Arterial blood gas monitoring is an invasive sampling of arterial blood to measure the oxygenation of the blood (PaO<sub>2</sub>), acid-base balance, and the partial pressure of carbon dioxide (PaCO<sub>2</sub>).

PaO<sub>2</sub> is an important term and component of ABGs. PaO<sub>2</sub> is the partial pressure of oxygen in arterial blood. PaO<sub>2</sub> reflects a more accurate measure of oxygen in the arterial

## Box 26.1 Patient Education: Peak Flow Meter

### Use of the Peak Flow Meter

- Before each use, make sure the sliding marker or arrow on the peak flow meter is at the bottom of the numbered scale (zero or the lowest number on the scale).
- Stand up straight. Remove gum or any food from your mouth. Take a deep breath (as deep as you can). Put the mouthpiece of the peak flow meter into your mouth. Close your lips tightly around the mouthpiece. Be sure breath, blow out as hard and as quickly as possible. Blow a "fast hard blast" rather than "slowly blowing" until you have emptied out nearly all of the air from your lungs.
- The force of the air coming out of your lungs causes the marker to move along the numbered scale. Note the number on a piece of paper.
- Repeat the entire routine three times. (You know you have done the routine correctly when the numbers from all three tries are very close together.)
- Record the highest of the three ratings. Do not calculate the average. This is very important. You cannot breathe out too much when using your peak flow meter, but you can breathe out too little.
- Measure your peak flow at close to the same time each day. You and your healthcare provider can determine the best times. One suggestion is to measure your peak flow rate twice daily between 7 and 9 a.m. and 6 and 8 p.m. You may want to measure your peak flow rate before or after using your medicine. Some people measure peak flow both before and after taking medication. Try to do it the same way each time.
- Keep a chart of your peak flow rates. Discuss the readings with your healthcare provider.

blood than SpO<sub>2</sub>. Once the PaO<sub>2</sub> in arterial blood falls below the threshold of 60 mm Hg, there is a steep reduction in SpO<sub>2</sub>. Although a PaO<sub>2</sub> of 60 mm Hg is considered acceptable, a more acceptable range for PaO<sub>2</sub> is 80 to 95 mm Hg. Arterial blood gases provide the best information with regard to identifying the patient's response to oxygen and ventilation therapy and medications. Once asthma is diagnosed, the disease is classified based on the frequency and severity of the symptoms. One approach through the Global Initiative for Asthma guidelines identifies the level of control and the treatment recommended for asthma. Asthma is classified as "mild asthma," "moderate asthma," "severe asthma," and "uncontrolled asthma." Asthma severity may be assessed retrospectively through close evaluation of the treatment required to manage symptoms.

### Treatment

The patient and healthcare provider develop an asthma action plan, which assists with decision making. The plan provides information and instructions on how the patient can manage his or her asthma based on peak expiratory flow readings, medications, an awareness or recognition of worsening symptoms and when to seek emergency care. The treatment of

asthma includes assessment, monitoring, control of environmental factors, pharmacological treatment, and education. The patient's frequency of symptoms and triggers should be noted. Pulmonary function tests should be conducted regularly to track the patient's response to therapy. During an acute exacerbation, peak flow readings, pulse oximetry, and ABGs (in a very severe attack) are used to determine the severity of the attack. Control of environmental factors is a necessary part of the education program for the patient with asthma. Irritant exposure should be reduced once the irritant has been identified. Patient history or sensitivity testing will often reveal the likely irritant. Environmental smoke is associated with increased symptoms and decreased lung function. Patients should be advised not to smoke and to avoid "second-hand" smoke exposure. The patient should be counseled on the importance of being aware of the levels of air pollution and to avoid outside activities if the level is high. There are many air-monitoring apps available to assist patients in becoming more informed about the air quality in their area. Patients should avoid fumes from wood-burning stoves, fireplaces, aerosol sprays, and strong perfumes. They should also remove animals and/or birds from their home if they are sensitive to the dander. Stress and depression may also be factors that can precipitate an asthma attack.

### Medications

Pharmacological treatment of the patient with asthma is based on the patient's response to previous treatment(s) and the level of engagement in the self-management plan. Patients are seen frequently when they begin a new medication (1–3 months) and when they experience an acute exacerbation (within a week). There are several classifications of medications that are used to treat asthma: anti-inflammatories, bronchodilators, anticholinergics, and leukotriene modifiers.

Anti-inflammatories, typically inhaled corticosteroids, reduce mucus production and swelling, making the airways less sensitive and less likely to react to asthma triggers that cause asthma symptoms. Bronchodilators such as beta<sub>2</sub>-adrenergic agonists relax the bronchial smooth muscle, helping to open the airway and decreasing obstruction. Anticholinergics are another group of bronchodilators. Different from beta<sub>2</sub>-adrenergic agonists, which relax the bronchioles or small airways, anticholinergics relax the muscles around the larger airways or bronchi. Leukotriene receptor antagonists are another class of medications that may be used to enhance asthma control if the usual medications are not effective. They are not steroids; they inhibit the leukotriene-mediated inflammatory process.

Medications also fall into two categories: long-term control medications and "rescue" medications. Long-term control medications are used daily regardless of the symptoms a patient is experiencing to achieve and maintain control of the asthma. The most effective long-term control medications for asthma are inhaled anti-inflammatories. Another long term control medication option for poorly controlled asthma or when inhaled glucocorticoids are difficult to manage, such as in young children, is oral theophylline, a bronchodilator with anti-inflammatory

effects. "Rescue" medications are those medications used once an asthma attack has started; these are usually short-acting bronchodilators. Short-acting beta<sub>2</sub>-adrenergic agonists are the gold standard because they are most effective. Short-acting beta<sub>2</sub>-adrenergic agonists should be used for acute exacerbations of asthma only. Studies have shown that regular use of short-acting beta<sub>2</sub>-adrenergic agonists results in more frequent and earlier exacerbations, tolerance, decreased baseline pulmonary function, and increased hyper-responsiveness. Oral anti-inflammatories such as prednisone may also be used in an acute exacerbation. As the attack subsides, oral anti-inflammatory medications are not abruptly stopped but decreased in dosage until they are discontinued.

New medications for poorly controlled asthma include anti-interleukin 5 (anti-IL5) and anti-immunoglobulin-E (anti-IgE) therapy. Anti-IL5 medications reduce the production and survival of eosinophils involved in the asthma attack. Anti-IgE medications help prevent the inflammatory response in allergic asthma. Figure 26.1 illustrates a stepwise approach to the treatment of asthma.

### Complications

Status asthmaticus is an acute exacerbation of asthma that is unresponsive to repeated doses or treatment with the typical rescue medications (bronchodilators). It can vary from mild to severe with bronchospasm, inflammation, and excessive mucus production with mucus plugging. Patients report chest tightness, wheezing, dry cough, shortness of breath, and severe respiratory distress. This results in carbon dioxide retention, hypoxemia, and ultimately respiratory failure. Typical triggers include the recent onset of a viral respiratory illness, exposure to a potent irritant or allergen, or exercising in the cold.

Status asthmaticus is a life-threatening emergency requiring a prompt medical response. Treatment includes oxygen, IV fluids, systemic bronchodilators, and steroids to open the airways and decrease inflammation. Endotracheal intubation may be necessary in severe cases until symptoms are under control.

#### Safety Alert

- Absent or diminished breath sounds signify a decrease in the movement of air due to increased obstruction or respiratory exhaustion.
- If a patient's wheezing decreases and he or she has little or no breath sounds, this indicates the patient is not able to move air throughout the system. This is a medical emergency! It indicates respiratory failure. The patient may require mechanical ventilation.

### Nursing Management

#### Assessment and Analysis

The symptoms the patient exhibits during an asthmatic attack are related to airway obstruction. These symptoms include:

- Dyspnea
- Use of accessory muscles of respiration

	<b>STEP 2</b>		<b>STEP 3</b>		<b>STEP 4</b>		<b>STEP 5</b>		
<b>Preferred Controller Choice</b>	STEP 1	Low dose ICS		Low dose ICS/LABA**		Med/high ICS/LABA		Refer for add-on treatment, e.g., tiotropium,†† anti-IgE, anti-IL5*	
Other controller options	Consider low dose ICS	Leukotriene receptor antagonists (LTRA) Low dose theophylline*		Med/high dose ICS Low dose ICS + LTRA (or + theoph*)		Add tiotropium†† Med/high dose ICS + LTRA (or 1 theoph*)		Add low dose OCS	
<b>Reliever</b>	As-needed short-acting beta <sup>2</sup> -agonist (SABA)			As-needed SABA or low dose ICS/formoterol#					

\*Not for children <12 years

\*\*For children 6–11 years, the preferred Step 3 treatment is medium dose ICS

#For patients prescribed BDP/formoterol or BUD/formoterol maintenance and reliever therapy

††Tiotropium by mist inhaler is an add-on treatment for patients ≥12 years with a history of exacerbations

**FIGURE 26.1** Stepwise approach for asthma treatment.

Key: ICS, inhaled corticosteroid; LABA, long acting inhaled beta2 agonist; SABA, short acting inhaled beta2 agonist; LTRA, leukotriene receptor antagonist; OCS, systemic oral corticosteroid; anti-IgE, anti-immunoglobulin E; anti-IL5, anti-interleukin 5; tiotropium = anticholinergic drug; theophylline = broncodilator; BDP/formoterol = combined LABA and ICS

- Wheezes
- Elevated pulse
- Elevated blood pressure
- Increased anxiety
- Inability to lie flat
- Inability to talk in complete sentences
- Decreased peak flow readings

### Nursing Diagnoses

- **Ineffective airway clearance** related to increased mucus production, bronchospasm, fatigue
- **Impaired gas exchange** related to dyspnea, fatigue
- **Ineffective breathing pattern** related to anxiety

### Nursing Interventions

#### Assessments

- **Vital signs**—pulse rate, temperature, respiratory rate, peak flow measurement  
*Increased pulse rate may be a sign of poor oxygenation or anxiety or a side effect of treatment with bronchodilators; increased temperature is a sign of infection; a respiratory rate greater than 30 breaths per minute is due to increased anxiety and increased work of breathing due to bronchial constriction; peak flow values indicate the severity of the asthma attack and help monitor recovery.*
- **Oxygen saturation**  
*Oxygen saturation of less than 90% indicates significant oxygenation problems. The goal is to maintain the SpO<sub>2</sub> at 90% or above. Hypoxemia causes restlessness, anxiety, and increased blood pressure and pulse rate.*
- **Arterial blood gas**  
*The patient initially exhibits respiratory alkalosis caused by hyperventilation (decreased PaCO<sub>2</sub>). As respiratory*

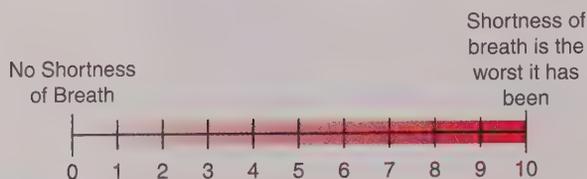

*difficulty increases, respiratory acidosis develops (increased PaCO<sub>2</sub>).*

- **Breath sounds**  
*The presence of wheezing indicates narrowing of the airway—expiratory first, then inspiratory. Absent or diminished breath sounds signify a decrease in the movement of air due to increased obstruction or respiratory exhaustion.*
- **Level of consciousness**  
*Changes in level of consciousness are indicators of hypoxemia.*
- **Ability to speak in full sentences**  
*This demonstrates the ability to move air throughout the tracheobronchial tree; inability to speak in full sentences is an indicator of respiratory distress.*
- **Cough**  
*Irritation causes stimulation of the cough receptors.*
- **Use of accessory muscles**  
*Use of accessory muscles demonstrates respiratory fatigue.*
- **Position—tripod position** (sitting upright with arms propped on a table) or semi-Fowler's position  
*The patient may assume the tripod position in an attempt to decrease the work of breathing.*
- **Monitor dyspnea**  
*Use of the visual analog dyspnea scale allows the patient to identify his or her own level of dyspnea because dyspnea is a subjective experience (Fig. 26.2).*
- **Previous intubation**  
*The need for intubation in past asthma attacks is an indicator of severity.*

#### Actions

- Provide oxygen.  
*Increase SpO<sub>2</sub> to 90% or greater.*

### Visual Analog Dyspnea Scale

**FIGURE 26.2** The visual analog dyspnea scale is a line that assesses the patient's degree of dyspnea. It is a 100-mm line that starts with "No shortness of breath" at one end and "Shortness of Breath is the worst it has been" on the opposite end. Only the patient can identify his or her perception of the dyspnea because dyspnea is a subjective experience. The patient identifies his or her dyspnea on the scale verbally by holding up his or her fingers or pointing to a point on the line. After treatment, the patient is reassessed using the same visual analog dyspnea scale.

- Administer bronchodilators as ordered.  
*Bronchial smooth muscle relaxants help open the airway.*
- Administer anti-inflammatory medication/steroids as ordered.  
*Anti-inflammatory medication decreases the inflammation causing the airway obstruction.*
- Administer anticholinergics as ordered.  
*Anticholinergics relax the muscles around the larger airways or bronchi.*

### Teaching

- Provide the patient with an individualized written asthma action plan (Fig. 26.3) that includes daily management of asthma and how to recognize symptoms of exacerbations.  
*Control of asthma over time requires regular assessment and consistent management.*
- Avoidance of risk factors  
*Identify factors that trigger an attack.*
- Pursed-lip breathing  
*Pursed-lip breathing keeps the airways open longer and prolongs exhalation, allowing increased time for oxygen and carbon dioxide exchange.*
- Medication education  
*Control symptoms and manage disease. Oral steroids used during an exacerbation should be tapered, not abruptly discontinued, to avoid adrenal insufficiency.*
- Peak flow meter (see Box 26.1)  
*Monitor pulmonary status—establish a baseline and reassess during an acute exacerbation to determine the severity of respiratory distress.*
- Smoking cessation  
*Smoking is the leading cause of pulmonary disease.*
- Proper inhaler technique (Box 26.2)  
*Proper technique ensures maximum effectiveness of the inhaled medication. If the patient has trouble coordinating the inhalation and exhalation necessary for proper inhaler technique, recommend the use of an AeroChamber.*
- Cleaning of respiratory equipment  
*Peak flow meters, nebulizers, metered-dose inhalers (MDIs), and AeroChambers must be kept clean to prevent infections.*

### Evaluating Care Outcomes

A well-managed patient with asthma has decreased visits to the emergency department and relies on the use of "rescue" medications less often. The patient has minimal symptoms during the day and night. Supporting positive patient outcomes requires the patient to have adequate knowledge to manage his or her disease. The patient uses control medications as ordered and limits or avoids exposure to the irritants triggering asthma exacerbation. The patient ceases smoking, makes the home and environment as "allergy-free" as possible, monitors peak flow readings twice a day, and adheres to the asthma management plan. When the patient follows the treatment plan, the patient delays the progression of the asthma, experiences fewer exacerbations, and enjoys longer durations of being asymptomatic.

### CASE STUDY: EPISODE 2

Clifford's SpO<sub>2</sub> reading upon arrival in the emergency department is 88%. He is started on nasal oxygen, which improves his saturation up to 96%. He is given prednisone by mouth after determining he has not taken his daily dose of anti-inflammatory medication. His peak flow reading is lower than his normal baseline. He is started on the first of three albuterol nebulizer treatments. His SpO<sub>2</sub> level maintains at 96%. He remains short of breath and tachycardic, with a heart rate of 135 bpm...

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE

### Epidemiology

Chronic obstructive pulmonary disease (COPD) is composed of two diseases: emphysema and chronic bronchitis. It is the fourth-leading cause of chronic morbidity and mortality in the United States. COPD is projected to be the third-leading cause of death by 2020. Additionally, it is projected to rank fifth in 2020 in diseases worldwide. In 2014, almost 16 million people in the United States 18 years and older were diagnosed with COPD, and another 12 million adults are thought to have undiagnosed COPD based on low pulmonary function tests. The prevalence of COPD is higher among women and Caucasians. The Centers for Disease Control and Prevention (CDC) reports that American Indians/Alaskan Natives and multiracial non-Hispanics, those with less than a high school education, current or former smokers, and people with a history of asthma have an increased incidence of COPD. The highest rates of COPD are found in the Southeast and Midwest regions of the United States (Kentucky, Tennessee, Mississippi, and Alabama) and Puerto Rico.

Cigarette smoking is the primary cause of COPD. Approximately 80% to 90% of COPD deaths are caused by smoking. Other risk factors include occupational dust and chemicals, outdoor air pollution, and second-hand smoke.

FIGURE 26.3 Sample asthma control plan.

Fewer than 5% of all COPD cases are caused by a deficiency of an enzyme called alpha-1 antitrypsin (AAT). AAT is produced in the liver and is present in the lungs. When present, it has lung-protectant properties. When deficient, there is an increased risk of developing emphysema. Both

parents must carry the defective gene to increase the risk of deficient AAT. About 100,000 Americans have the AAT deficiency. Alpha-1 antitrypsin deficiency should be considered if a young person develops emphysema and has no history of smoking or exposure to smoke.

## Box 26.2 Patient Education: Use of Metered-Dose Inhaler and Aerochamber

### Use of the Metered-Dose Inhaler (MDI)

1. Remove the cap and shake the inhaler.
2. Breathe out gently.
3. Put the mouthpiece in your mouth, and at the start of inspiration, which should be slow and deep, press the canister down and continue to inhale deeply.

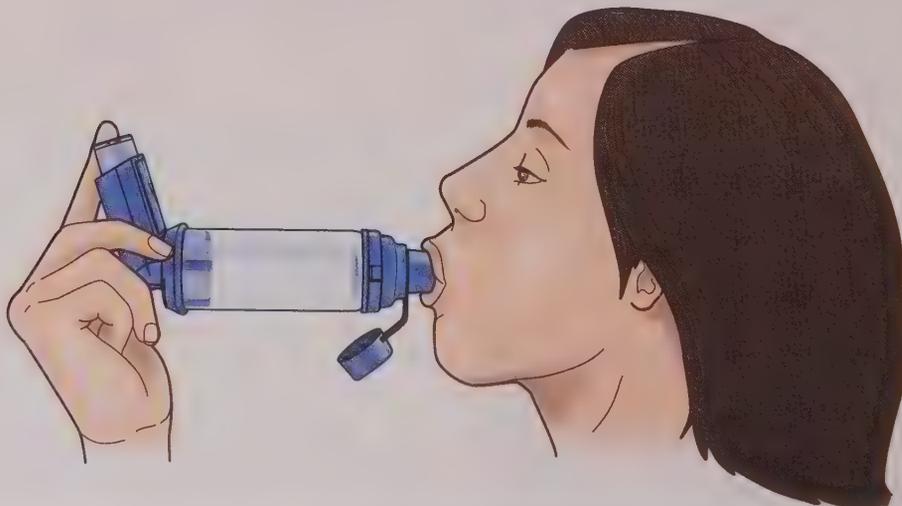

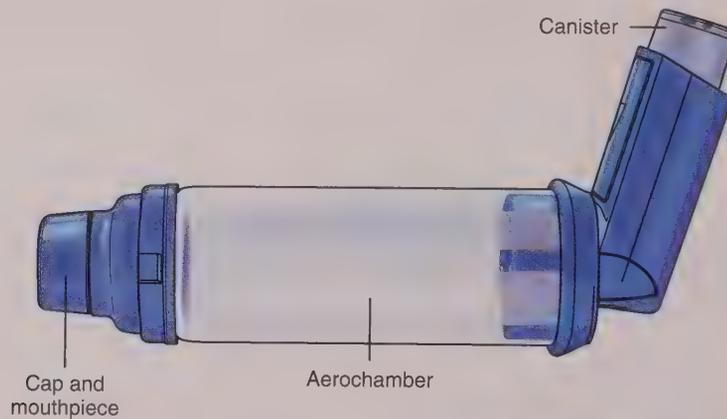

4. Hold the breath for 10 seconds or as long as possible, then breathe out slowly.
5. Wait for about a minute or as directed by your healthcare provider before repeating steps 2 through 4; if using a corticosteroid MDI, rinse mouth upon completion of doses.
6. Replace the cap on the MDI.

### Use of the Aerochamber

1. Remove cap from the MDI.
2. Shake inhaler and insert in back of aerochamber (opposite of the mouthpiece).
3. Breathe out completely and place mouthpiece of the chamber in your mouth and seal lips tightly around it.
4. Press canister once to release a dose of the medication.
5. Take a deep, slow breath in. (If you hear a whistling sound, you are breathing in too quickly.)

6. Hold breath for about 10 seconds (count slowly), and then breathe out through the mouthpiece.
7. Breathe in again but do not press canister.
8. Remove mouthpiece from mouth and breathe out.
9. Wait for about a minute or as directed by your healthcare provider before repeating steps 2 through 8; if using a corticosteroid MDI, rinse mouth upon completion of doses.
10. Replace the cap on the MDI.

## Pathophysiology

Chronic obstructive pulmonary disease is characterized by airflow limitations. The airflow limitation is progressive and is associated with an abnormal inflammatory response of the lung to noxious particles or gases. Both diseases in COPD cause obstruction to the airflow but in different ways (Fig. 26.4). **Emphysema** is a disease caused by the destruction of the alveoli. **Chronic bronchitis** affects the small airways and is defined as the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. Thus, the chronic airflow limitation is caused by a mixture of small-airway disease and destruction of the lung tissue.

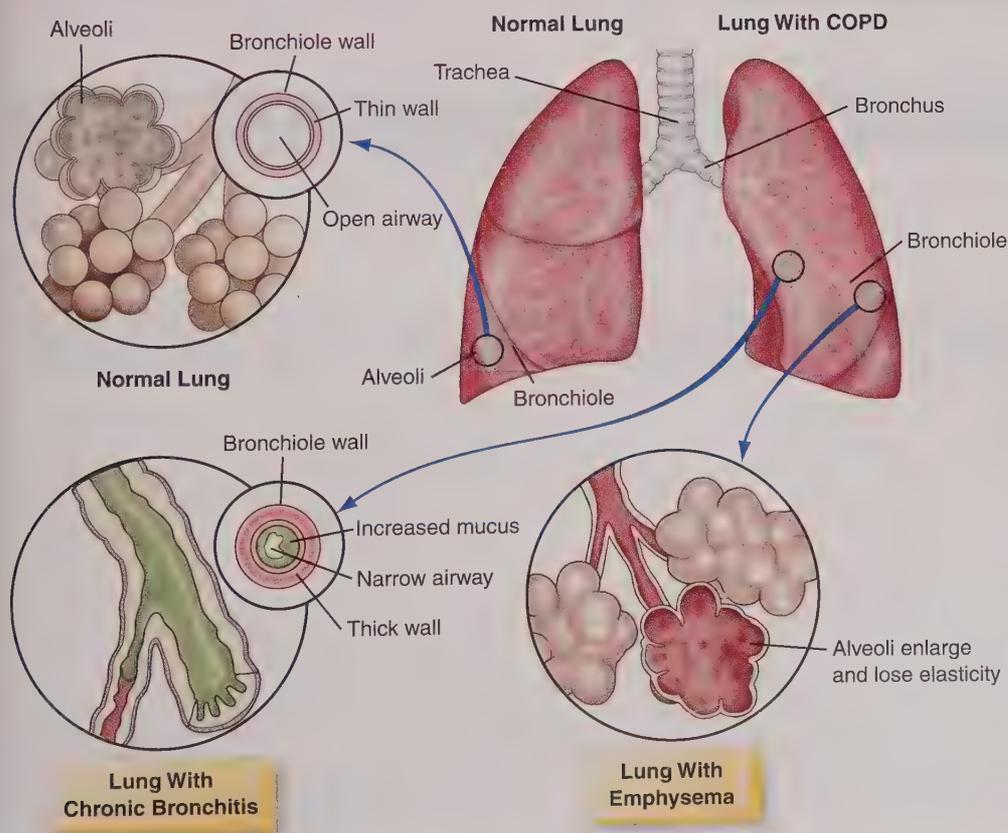

The patient with emphysema loses lung elasticity and develops hyperinflation of the alveoli. Inhaled pollutants (smoke, dust, chemicals, air pollution) result in the breakdown of elastin, which causes the alveoli to lose their elasticity and thus effective elastic recoil after exhalation. The small airways collapse prematurely, causing trapping of air in the alveoli and subsequent distention. Carbon dioxide cannot leave the alveoli, and oxygen cannot enter, resulting in an ineffective exchange of oxygen and carbon dioxide. The patient is hypoxemic, as evidenced by a low  $SpO_2$  and  $PaO_2$  (partial pressure of oxygen), and has carbon dioxide retention and chronic respiratory acidosis.

Chronic bronchitis is caused by inflammation of the bronchi and bronchioles by chronic exposure to smoke and environmental irritants. The inflammation causes an increase

in the production of mucus cells, which produce a large amount of thick mucus. The walls of the bronchus thicken, causing airway obstruction. The smaller airways are usually affected before the larger airways. Also identified is an asthma-COPD overlap syndrome (ACOS) which significantly impacts disease trajectory and quality of life (see Evidence-Based Practice).

## Clinical Manifestations

Clinical manifestations of the disease include increased work of breathing and shortness of breath. COPD is evidenced by the use of accessory muscles and the patient assuming the tripod position to help ease the work of breathing. The patient with emphysema often appears thin and has a “barrel chest,” in which the ratio of the anteroposterior (AP) diameter to the transverse diameter of the chest is 2:2 rather than the normal ratio of 1:2. Patients with emphysema sometimes have a reddish complexion and appear to be puffing when breathing; hence, they may be referred to as a “pink puffer.” Conversely, patients with chronic bronchitis are typically obese, have hypoxemia, and appear cyanotic and thus may be referred to as a “blue bloater”; they also have excessive mucus production with a productive cough. Additionally, patients with COPD are at risk for right heart failure due to chronic pulmonary hypertension resulting in right ventricular enlargement. This is referred to as cor pulmonale. Table 26.1 shows a comparison of chronic bronchitis, emphysema, and asthma.

**FIGURE 26.4** A normal lung versus a lung with COPD.

## Evidence-Based Practice

### ACOS

The term *asthma-COPD overlap syndrome (ACOS)* has been used to describe adults presenting with symptoms of both asthma and COPD. The prevalence rate is highly variable, from 15% to 55% depending on age and gender. These patients experience frequent exacerbations and a more rapid decline in lung function, with a correspondingly high mortality rate. They also consume a higher volume of healthcare resources than patients with COPD or asthma alone. There is a self-reported poor quality of life. Recognition of this diagnosis is key to successful management. The goals of treatment are similar to the goals for asthma and COPD: reduce exposure to risk factors; maintain lung function while reducing symptoms, prevent exacerbations, and maintain normal activity. Mainstays of treatment include anti-inflammatory medications and long-acting and short-acting rescue bronchodilators. Smoking cessation is essential.

Ding, B., & Small, M. (2017). Treatment trends in patients with asthma-COPD overlap syndrome in a COPD cohort: Findings from a real-world survey. *International Journal of Chronic Obstructive Pulmonary Disease*, 12, 1753–1763. doi:10.2147/COPD.S136314

Global Initiative for Chronic Obstructive Lung Disease. (2015). *Asthma-COPD overlap syndrome*. Retrieved from <http://www.goldcopd.org/uploads/users/files/AsthmaCOPDOverlap.pdf>

COPD is characterized by exacerbations occurring after exposure to pollutants such as smoke or respiratory infections such as a cold or flu. An exacerbation is a change in the natural course of the disease evidenced by a variation from the patient's daily baseline symptoms of dyspnea, cough, and/or sputum production. Exacerbations are typically acute in onset and may indicate the need for a change in usual patient management. Warning signs of an exacerbation include increasing shortness of breath, wheezing, more frequent or severe cough, anxiety, problems with sleep, and decreased appetite.

### Management

#### Medical Management

#### Diagnosis

The diagnosis of COPD is based on patient history, physical assessment, and spirometry. Generally, a chest x-ray is obtained to rule out other causes of respiratory distress. A computed tomography (CT) scan may be considered when the lungs need to be viewed in more detail. Pulmonary function tests also aid in diagnosis. The most commonly performed pulmonary function test (PFT) is spirometry. Spirometry is the measurement of lung volumes and airflow. The two tests done by spirometry are **forced vital capacity (FVC)** and **forced expiratory volume in 1 second (FEV<sub>1</sub>)**. Forced vital capacity is the maximum volume of air exhaled during a forced expiration; FEV<sub>1</sub> is the volume of air expired in the first second of maximal expiration after a maximal inspiration. It is a measurement of the lung's ability to empty quickly. Diagnosis is based on both the

	<b>Emphysema (“Pink Puffer”)</b>	<b>Bronchitis (“Blue Bloater”)</b>	<b>Asthma</b>
<b>Bronchospasms</b>	Premature closing of the airways with “air trapping”	Obstruction by thick, tenacious mucus	Airflow obstruction by inflammation and mucus
<b>Reversible</b>	Nonreversible	Nonreversible	Reversible
<b>Airway affected</b>	Alveoli are affected	Airways are affected	Airways are affected

value of  $FEV_1$  and  $FEV_1/FVC$ . Using normal values for the sex, age, and height of the patient, the  $FEV_1$  is measured, then calculated as a percentage of a normal value. The  $FEV_1/FVC$  is computed as a percentage of normal. Patients with COPD show a decrease in both the  $FEV_1$  and the  $FEV_1/FVC$ .

Chronic obstructive pulmonary disease is a progressive disease. As the disease progresses,  $FEV_1$  and  $FEV_1/FVC$  deteriorate, and exacerbations become more frequent and life threatening. The severity and progression of the disease correlate to the degree of abnormality of the tests. The Global Initiative for Obstructive Lung Disease has identified stages or grades of the disease: Grade I, mild; Grade II, moderate; Grade III, severe; and Grade IV, very severe. Table 26.2 describes the grades of COPD.

### Treatment

The management plan for COPD has four goals: assess and monitor the disease, reduce modifiable risk factors, manage stable COPD, and manage exacerbations. Assessment includes regular pulmonary function tests and chest x-rays with an exacerbation to identify other thoracic abnormalities or progressive changes within the structure of the lungs. Additional important biological measurements in the COPD management plan include pulse oximetry ( $SpO_2$ ) to determine the severity of hypoxemia during an exacerbation and

ABGs to measure the lungs' ability to clear carbon dioxide, as evidenced by  $PaCO_2$  and acid-base balance. The ABGs also evaluate oxygenation through  $PaO_2$  values and help identify the patient's response to oxygen therapy and medications. Finally, sputum cultures are assessed to identify organisms causing an infectious trigger to an exacerbation.

Reducing modifiable risk factors includes, if possible, decreasing or eliminating exposure to chemicals, dust, and air pollutants, especially smoke. The single most important modifiable risk factor is smoking cessation. Managing stable COPD includes health education regarding the risks and the warning signs of an exacerbation, oxygen therapy, moderate exercise as tolerated, and the mainstay of medical management: medications.

The cornerstone of pharmacological management is bronchodilators:  $\beta_2$ -adrenergic agonists and anticholinergics used individually or in combination on an as-needed or regular basis to control symptoms. A way to evaluate the effectiveness of treatment and determine a course of therapy is to administer a bronchodilator treatment after the initial spirometry and then repeat the test. This approach helps determine how the lungs respond to the bronchodilator or how the pulmonary obstruction is reversed with the medication. Medication management progresses as the disease progresses and begins with inhaled bronchodilators on an as-needed basis. As the disease

**Table 26.2 Gold Criteria for COPD Severity**

In patients with  $FEV_1/FVC$  less than 0.70:

<b>COPD Grade</b>	<b>Spirometry Values</b>	<b>Clinical Manifestations</b>
<b>Gold I Mild</b>	$FEV_1$ greater than or equal to 80% of predicted normal value	Patient usually unaware of presence of disease
<b>Gold II Moderate</b>	$FEV_1$ 50% to 79% of predicted normal value	Progressive shortness of breath with exertion
<b>GOLD III Severe</b>	$FEV_1$ 30% to 49% of predicted normal value	Worsening shortness of breath Frequent COPD exacerbations
<b>GOLD IV Very Severe</b>	$FEV_1$ less than 30% of predicted normal value	Shortness of breath extreme, impairing quality of life COPD exacerbations life threatening

COPD = Chronic obstructive pulmonary disease;  $FEV_1$  = forced expiratory volume at 1 second;  $FVC$  = forced vital capacity.

worsens, long-term bronchodilators are added. Inhaled glucocorticoids are added when and if the patient experiences frequent exacerbations.

Identifying and quickly managing exacerbations is essential because they can dramatically impair pulmonary function and accelerate disease progression. Inhaled bronchodilators and oral glucocorticoids are used, as well as antibiotics if the cause of the exacerbation is infection. Noninvasive positive-pressure ventilation can be used to improve oxygenation and ventilation as well as reduce the need for endotracheal intubation and ventilation.

### Complications

A complication of COPD is secondary spontaneous pneumothorax (SSP). SSP is a spontaneous pneumothorax that occurs in patients with underlying lung disease. Of all cases of SSP, 50% to 70% are attributed to COPD. It is typically caused by the rupture of the hyperinflated alveoli or blebs. Patients present with dyspnea and chest pain. The presentation is more severe than in primary spontaneous pneumothorax—spontaneous pneumothorax without underlying lung disease—due to the already-existing pulmonary dysfunction. Treatment priorities include supplemental oxygenation and chest tube placement to remove air from the pleural space to allow re-expansion of the affected lung. Care of the patient with a chest tube is discussed in Chapter 27.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations presented by the patient are due to increased airway resistance, increased work of breathing, and increased sputum production. They include:

- Cough
- Increased sputum production
- Dyspnea
- Use of accessory muscles
- Tripod positioning
- Inability to talk in full sentences
- Pursed-lip breathing
- Changes in skin coloring
- Anxiety

#### Nursing Diagnoses

- **Impaired gas exchange** related to altered oxygen delivery and alveoli destruction
- **Ineffective airway clearance** related to decreased energy, dyspnea, ineffective cough
- **Activity intolerance** related to fatigue and dyspnea
- **Anxiety** related to breathlessness

#### Nursing Interventions

##### Assessments

- Oxygen saturation

*An SpO<sub>2</sub> of less than 90% indicates a significant oxygenation problem. The goal is to maintain the SpO<sub>2</sub> at 90% or above.*

##### Respiratory rate

*Monitor respiratory rate to avoid hypoventilation—the respiratory drive in COPD is hypoxemia, not hypercapnia. See Safety Alert.*

##### Breath sounds

*The presence of crackles and wheezes may indicate airway obstruction. Crackles indicate the premature closing of the airways.*

##### Pursed-lip breathing

*Patients with COPD display pursed-lip breathing to keep the airways open longer and prolong exhalation, allowing for increased time for oxygen and carbon dioxide exchange.*

##### Cough

*Cough is a cardinal sign of pulmonary disease. It is a protective mechanism for the tracheobronchial tree.*

##### Temperature

*Increased temperature is a sign of an infectious trigger.*

##### Dyspnea

*Use of the visual analog dyspnea scale allows the patient to identify his or her own level of dyspnea because dyspnea is a subjective experience.*

##### Weight

*Monitoring weight identifies nutritional deficiencies—with prolonged increased work of breathing and decreased energy, the ability to eat decreases.*

#### Actions

- Administer bronchodilators as ordered.

*Bronchodilators are bronchial smooth muscle relaxants that help open the airway. Beta<sub>2</sub>-agonists (short-acting beta-agonists [SABAs] and long-acting beta-agonists [LABAs]) relax the smooth muscles of the airway by stimulating beta-adrenergic receptors, resulting in antagonism to bronchoconstriction. Anticholinergics relax and enlarge the airways in the lungs, making breathing easier. Anticholinergics can also protect the airways from bronchospasm and may reduce the amount of mucus produced by the airways.*

- Provide oxygen.

*Increase the SpO<sub>2</sub> to 90%. Patients may be placed on continuous oxygen therapy if the SpO<sub>2</sub> is less than or equal to 88% or the PaO<sub>2</sub> is less than or equal to 60 mm Hg.*

- Position—semi-Fowler's

*The semi-Fowler's position increases oxygenation by allowing adequate lung expansion.*

- Provide small, frequent meals with dietary supplements.
- Small, frequent meals take less energy to consume and avoid excessive pressure on the diaphragm that may be associated with a large meal.*

#### Teaching

- Breathing techniques—pursed-lip breathing (Box 26.3)
- Pursed-lip breathing keeps the airways open longer and prolongs exhalation, allowing for increased time for oxygen and carbon dioxide exchange.*
- Pacing of activities
- Pacing decreases the work of breathing and conserves energy.*

## Box 26.3 Pursed-Lip Breathing (PLB)

- Sit upright with neck and shoulders relaxed.
- Inhale through the nose slowly, counting “one, two.”
- Exhale through pursed lips as if you were blowing out a candle, slowly counting “one, two, three, four.”
- Exhalation should be twice as long as inhalation.
- Continue PLB until shortness of breath is controlled.

### • Smoking cessation program

*Smoking cessation is key to managing COPD and can change the course of the disease process.*

### • Nutritional needs

*Small, frequent meals decrease the work of breathing with less impact on the diaphragm.*

### • Medication regimen

*Knowledge regarding medications and their use; proper use of inhalers*

### • Vaccine prophylaxis

*Pneumococcal vaccination and an annual flu vaccine decrease the risk of disease exacerbations due to respiratory infections.*

### • Recognition of symptoms of exacerbation

*The patient and family should be aware of signs that signify the patient’s respiratory system is more impaired.*

### • Coping strategies

*The patient and family should be aware of the lifestyle changes that may occur because of COPD. These include an inability to maintain an active lifestyle, an inability to care for oneself, depression, denial, and social isolation. Strong support and effective coping strategies are essential to managing the life changes.*

is key. The patient should cease smoking and maintain healthy dietary habits by eating small, frequent meals.

## Connection Check 26.2

What is the primary difference between emphysema and chronic bronchitis?

- Chronic bronchitis predominately affects the large airways.
- Emphysema predominately affects the large airways.
- Emphysema predominately affects the alveoli.
- Chronic bronchitis predominately affects the alveoli.

## CYSTIC FIBROSIS

### Epidemiology

**Cystic fibrosis** is an inherited chronic disease that affects the lungs and digestive system. About 30,000 children and adults in the United States are affected with cystic fibrosis, with an estimated 1,000 new cases annually. There are approximately 70,000 affected individuals worldwide. Seventy percent of patients with cystic fibrosis are diagnosed by their second year of life. The disease most commonly affects Caucasians of North European descent. Males and females are equally affected. Blacks, Hispanics, Latinos, Asian Americans, and American Indians have lower incidence rates of cystic fibrosis. More than 10 million Americans are carriers of the defective cystic fibrosis gene.

Cystic fibrosis is the second most common life-shortening disorder occurring in childhood in the United States. The survival rate has increased since the 1950s and 1960s, when children were not expected to live into their teenage years. In the 1950s, children diagnosed with cystic fibrosis usually did not live long enough to attend school. Presently, more than 45% of patients with cystic fibrosis are over 18 years of age. The predicted median age of survival is the mid-30s. Due to the increased survival rate, more adults present with cystic fibrosis complications. Although other organs are affected, respiratory failure accounts for about 85% of the mortalities.

### Pathophysiology

Cystic fibrosis is a genetic disease of the exocrine glands (glands that secrete hormones into ducts, also called duct glands), such as the sweat, salivary, and pancreas glands. Cystic fibrosis is caused by a defective gene, the cystic fibrosis transmembrane conductance regulator, or *CFTR*, gene that is carried by both parents (see Genetic Connections). The *CFTR* gene is linked to the production of a protein called the cystic fibrosis transmembrane conductance regulator. This protein functions as a channel to facilitate the transport of negatively charged chloride ions into and out of the cell. It also inhibits sodium transport channels, inhibiting sodium transport into the cell. Due to

**Safety Alert** If a patient with COPD experiencing an exacerbation is on oxygen therapy, SpO<sub>2</sub> and respiratory rate must be monitored continuously until the condition is stabilized. If the patient is receiving too much oxygen, it may “blunt” the respiratory drive. The respiratory effort in a patient with COPD is triggered by the decrease in oxygen, not an increase in carbon dioxide, which is different from the patient with healthy lungs. Therefore, too much oxygen and high PaO<sub>2</sub> and SpO<sub>2</sub> may cause a decreased respiratory effort.

### Evaluating Care Outcomes

A well-managed patient with COPD has decreased visits to the emergency department and fewer hospitalizations. A critical aspect of supporting patients in managing the disease is making sure the patient has adequate knowledge regarding COPD management. Medications should be taken as ordered, and avoiding or reducing exposure to people with colds or flu that may increase the risk of exacerbations.

the extracellular ion concentration, water moves outside of the cell by osmosis, which maintains a thin layer of mucus on the epithelial cells. The genetic mutation disrupts the transport of chloride ions, sodium ions, and water, resulting in the production of a thick mucus that builds up on the epithelial cells (Fig. 26.5).

## Genetic Connections

### Cystic Fibrosis

Cystic fibrosis is a hereditary disease caused by a recessive defective gene. More than 10 million Americans are symptomless carriers of the defective cystic fibrosis gene. Genetic testing is performed to detect carriers. Each time two carriers of the defective gene have a child, the chances are:

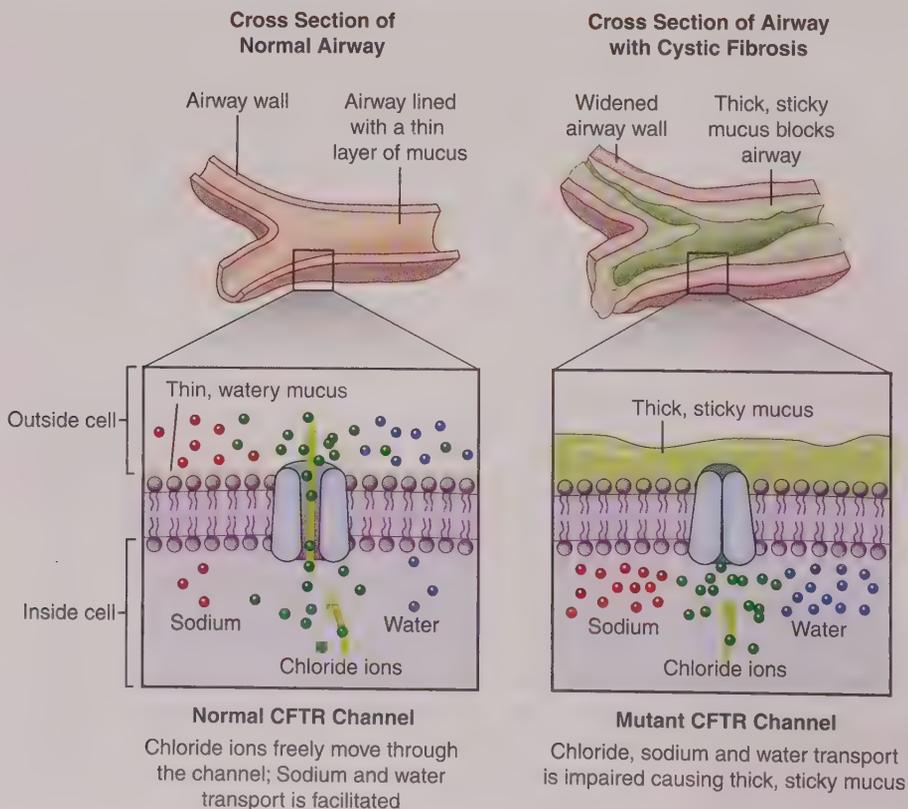

- 25% (1 in 4) their child will have cystic fibrosis
- 50% (1 in 2) their child will carry the defective gene and not have cystic fibrosis
- 25% (1 in 4) their child will not carry the defective gene and not have cystic fibrosis

Genetic counseling is important for couples who might be at risk of carrying the gene as well as for all couples who are planning to become pregnant.

Cystic fibrosis is a multisystem disease that produces increased amounts of thick mucus in the respiratory, gastrointestinal (GI), and reproductive systems. The disease is characterized by thick, viscous mucus that clogs the lungs and obstructs the pancreas. Other organs that are affected include the liver, salivary glands, and testes. The mucus build-up in the GI system and pancreas leads to an exocrine insufficiency, blocking the transport of pancreatic enzymes and resulting in decreased breakdown and absorption of food. The patient may also develop a pancreatic endocrine insufficiency (insufficient secretion of the hormone insulin into the bloodstream to target organs), which results in cystic fibrosis–related diabetes.

The increase in thick, sticky mucus production in the lungs leads to mucus plugging of the airways, inflammation, and **bronchiectasis** (chronic dilation of the bronchioles). Initially, the upper lobes are affected by the disease. Stasis of the mucus leads to chronic respiratory infections. The organisms that cause the infection are often *Staphylococcus aureus* and *Haemophilus influenzae* in childhood and *Pseudomonas aeruginosa* in adults. Pulmonary disease is the most challenging aspect of managing cystic fibrosis and is the leading cause of mortality.

There are often reproductive problems with males who have cystic fibrosis. The thick mucus production results in plugging and deterioration of the vas deferens before birth. The vas deferens transports sperm from the testes to join the semen. This deterioration results in sterility, but modern reproductive technology may allow these patients to reproduce.

**FIGURE 26.5** A genetic mutation of the *CFTR* gene disrupts the transport of chloride and sodium ions and water in cystic fibrosis, resulting in thick mucus deposits on the epithelial cells.

## Clinical Manifestations

The clinical manifestations are related to the organ systems affected and can vary significantly among patients. Respiratory symptoms include increased work of breathing, as evidenced by tachypnea and irregular breathing patterns. The patient presents with diaphoresis, nasal flaring, pursed-lip breathing, intercostal muscle retractions, and the use of accessory muscles. Other signs include a persistent cough that produces thick sputum, wheezing, a decreased ability to exercise, repeated lung infections, and inflamed nasal passages.

The GI effects are largely due to the accumulation of mucus in the pancreas, which hinders the release of pancreatic enzymes that help with the breakdown of food. Clinical manifestations of this include:

- Foul-smelling, greasy stools
- Poor weight gain and growth
- Intestinal blockage, particularly in newborns (meconium ileus)
- Severe constipation

## Management

### Medical Management

#### Diagnosis

Cystic fibrosis is primarily diagnosed through laboratory testing. The *CFTR* gene mutation in the sweat glands results in increased levels of chloride noted in the sweat because of the impairment of sodium chloride reabsorption. The sweat chloride test measures the concentration of chloride in the patient's sweat. A high level of chloride is an indication of cystic fibrosis. The normal value is less than 30 mEq/L. The test is positive for cystic fibrosis when the chloride level is greater than or equal to 60 mEq/L. Cystic fibrosis screening in newborns has been mandated throughout the United States since 2010. Newborn screening allows treatment to begin before symptoms develop.

#### Medications

The patient with cystic fibrosis takes the same medications as other patients with lower airway disorders, such as bronchodilators. In addition, the patient may take mucolytics to thin the mucus. Mucomyst (a mucolytic) and inhaled hypertonic saline increase the hydration of the airway to improve mucociliary clearance. The patient also takes anti-inflammatories such as ibuprofen to diminish the inflammatory response and slow the rate of decline in lung function.

Antibiotics are used for chronic pulmonary infections. The antibiotic most often used is tobramycin; its aerosolized form allows for minimal systemic effects. Azithromycin is another antibiotic frequently used. Fat-soluble vitamins (A, D, E, and K) are given as supplements because the long-term antibiotic therapy eradicates the normal flora of the GI tract. Pancreatic replacement enzymes are given to help with digestion and absorption of food. Patients, especially

children and teenagers, may also need supplemental calories to maintain their weight and improve energy levels.

The most recent addition to pharmacological management of cystic fibrosis is the use of CFTR modulators. CFTR modulators are medications targeting specific defects caused by mutations in the *CFTR* gene. These treatments do not correct errors in the *CFTR* gene but attempt to correct the malfunctioning protein made by the *CFTR* gene. There are many different mutations causing defects in the protein. The currently developed CFTR therapies are effective only in people with specific mutations.

### Surgical Management

Surgical management is an option for patients with cystic fibrosis. A lung or pancreas transplant or both may be considered. The transplant may extend the patient's life, but cystic fibrosis patients often have problems with other organs, which makes them a poor risk for the surgery. Also, transplantation does not cure the disease; the defective gene is still present. The patient may experience a reduction of symptoms initially but will then experience a gradual redevelopment of the disease.

### Nursing Management

#### Assessment and Analysis

The patient with cystic fibrosis usually presents with a variety of symptoms related to the issues with blocked ducts in the sweat and pancreatic glands and the respiratory system. They include:

- Thick, sticky mucus
- Persistent coughing
- Tachypnea
- Frequent lung infections
- Wheezing or shortness of breath
- Poor growth or slow weight gain
- **Steatorrhea** (frequent greasy, bulky, fatty stools) or difficult bowel movements
- Very salty-tasting skin

#### Nursing Diagnoses

- **Ineffective airway clearance** related to increased sputum production
- **Impaired gas exchange** related to increased sputum
- **Fatigue** related to dyspnea
- **Risk for infection** related to stasis of mucus
- **Imbalanced nutrition:** less than body requirements related to impaired digestive process and absorption of nutrients, increased work of breathing

#### Nursing Interventions

##### ■ Assessments

- Oxygen saturation  
*Mucus plugging leads to decreased airflow and impaired gas exchange.*
- Temperature  
*Increased temperature is indicative of an infection.*

- Respiratory rate  
*Increased work of breathing causes an increase in the respiratory rate.*
- Breath sounds  
*Mucus plugging causes wheezing and crackles because of blockage of the airways and air trapping of the bronchioles.*
- Weight  
*Weight loss occurs because of the impaired pancreatic enzyme absorption disrupting the breakdown and absorption of food.*
- Sputum for culture and sensitivities  
*These tests identify the organism and appropriate antibiotic to ensure adequate therapy.*

### ■ Actions

- Airway clearance techniques such as postural drainage and percussion  
*The airway must be clear of secretions to maintain patency.*
- Administer medications as ordered:
  - Bronchodilators  
*Bronchial smooth muscle relaxants help open the airway and ease the work of breathing.*
  - Antibiotics  
*Manage respiratory infections*
  - Mucolytics  
*Thin secretions, facilitating airway clearance*
  - CFTR modulators  
*The medications correct the function of the defective protein made by the cystic fibrosis gene (they do not correct the gene itself).*
  - Pancreatic enzymes  
*Pancreatic enzymes aid in the breakdown and absorption of food.*
  - Nutritional supplements  
*Increase caloric and vitamin intake to increase energy and increase weight*

### ■ Teaching

- Airway clearance techniques, the use of supplements to meet nutritional needs, taking medications as prescribed, and being aware of and avoiding risk factors of an exacerbation  
*Most therapy for cystic fibrosis is performed on a daily basis in the home. In order to manage the disease, the patient and family need a strong understanding of the disease and effective treatment.*
- Genetic screening  
*The American College of Obstetricians and Gynecologists (ACOG) suggests all couples should be offered screening to identify if they are cystic fibrosis carriers (not just people considered “at risk” like Caucasians and individuals with a family history of cystic fibrosis) because the increasing diversity of the population makes it harder to assign a person to just one ethnicity.*
- Genetic counseling  
*Counseling should be offered to all couples who are planning to become pregnant.*

## Evaluating Care Outcomes

Well-managed patients with cystic fibrosis and their caregivers have adequate knowledge to manage the disease through airway clearance techniques and reduced exposure to risk factors for pulmonary infections; they are active participants in the plan of care. The patient presents with a well-controlled respiratory status and free from infection. The patient maintains adequate nutritional status by utilizing pancreatic enzymes, adequate diet, and nutritional supplements. The patient and/or the caregivers can identify changes that suggest an exacerbation of the condition in order to intervene as quickly as possible. These patients and their families use community resources that are available for information and support.

### Connection Check 26.3

What is the priority treatment for a patient with cystic fibrosis?

- Nutritional counseling
- Airway clearance
- Medication administration
- Patient education

## LUNG CANCER

### Epidemiology

American Cancer Society (ACS) statistics for 2018 indicate that lung cancer remains the second most common cancer in both men and women. It is also the number one cancer killer in the United States for both men and women (about 154,050 deaths; 83,550 in men and 70,500 in women). The ACS estimated approximately 234,030 new cases of lung cancer for 2018.

Black men have a higher incidence of lung cancer than white men, whereas white women have a higher incidence than black women. Women have an overall lower incidence than men. Survival rates vary based the stage of disease at diagnosis. If diagnosed with stage 1A lung cancer, the survival rate is 49%; if diagnosed with stage IV lung cancer, the survival rate is 1%. When diagnosed with stage IV lung cancer, the disease has already spread to lymph nodes and other organs.

Lung cancer is most prevalent in persons over age 65. The major cause (90%) of lung cancer (and the most preventable) is smoking. The risk of developing lung cancer increases as the number of cigarettes smoked and the length of time spent smoking increase. Other risk factors include “second-hand” smoke, radon, occupational pollutants, and asbestos.

### Pathophysiology

The uncontrolled growth of abnormal cells in the lungs causes lung cancer. There are two major types of lung cancer: non-small cell and small cell. Non-small-cell cancer represents 85% of lung cancers and consists of three different

types of cells. They are squamous-cell carcinoma, adenocarcinoma, and large-cell carcinoma. The 5-year survival rate for those diagnosed with non-small-cell cancer if diagnosed in the early stages is good.

Small-cell cancer, also called oat-cell cancer, represents 15% of lung cancers. It grows quickly and metastasizes to other organs in the body. Independent of the stage at diagnosis, survival statistics are poor. Only 5% to 10% of those developing small-cell cancers survive for 5 years.

## Clinical Manifestations

The symptoms of lung cancer are not typically evident early in the disease but become apparent as the disease advances. Symptoms include a new cough that does not go away or changes in a chronic cough, hemoptysis, shortness of breath, wheezing, hoarseness, and chest pain. Headache and bone pain may also be present. Weight loss is common. As the disease progresses, the symptoms worsen.

## Management

### Medical Management

#### Diagnosis

Diagnosis is made through several methods:

- Chest x-ray
- Computed tomography (CT) scan of the chest
- Sputum for cytology
- Bronchoscopy
- Positron emission tomography (PET) scans
- Bone scans and abdominal scans
- Mediastinoscopy

A chest x-ray or a CT scan of the chest may identify a pulmonary lesion. A cytology test on sputum may identify specific tumor cells. Bronchoscopy or mediastinoscopy allows direct visualization of the tissues to aid in the diagnosis of lung cancer. Bronchoscopy is the assessment of the larger airways, the trachea and bronchi, through a scope inserted through the mouth or nose. Mediastinoscopy is a surgical procedure that allows for direct visualization of the mediastinum. A scope is inserted through an incision in the chest that allows direct examination and collection of samples for biopsy. Bone scans and abdominal scans are performed to look for metastatic lesions. The PET scan is used to identify changes in the body's metabolism and function rather than structure. A PET scan can detect areas of increased metabolic activity as occurs with rapidly dividing cancer cells.

#### Nonsurgical Management

The treatment for lung cancer is interprofessional and is dependent on the type, size, location, and stage of the tumor. The components of nonsurgical treatment typically consist of a combination of radiation and chemotherapy. Pain management is also an important focus in treatment.

The chemotherapeutic agent used to treat lung cancer is dependent on the type and/or size of the tumor. It may be

used in conjunction with surgery (discussed in the following section), or it may be the primary treatment option for more advanced cancers or if the patient is too ill for surgery.

Radiation therapy used in lung cancer treatment has great versatility. In situations where surgery is not an option, radiation can be used. Radiation can also be used palliatively to relieve symptoms or for pain control.

Pain control is a major component in lung cancer management. A pain relief ladder developed by the World Health Organization is helpful as a guideline for pain control (see Chapter 11, Fig. 11.7). Step 1 involves the use of nonopioid analgesics (acetaminophen or NSAIDs) for mild to moderate pain. Step 2 consists of a moderately potent opioid (codeine, hydrocodone, and oxycodone) plus a nonopioid for persistent pain or pain not controlled by Step 1. Step 3 includes the use of stronger opioids (morphine, fentanyl) plus a nonopioid for uncontrolled or severe pain. The use of adjuvant or additional medications is important to consider at all levels of treatment to relieve patient anxiety. Pain medication needs to be administered around the clock rather than on demand to avoid peaks of pain.

Palliative care services are appropriate to consider with the diagnosis of a life-threatening illness like lung cancer. Palliative care improves the quality of life of patients and their families. In addition to providing pain relief, palliative care can also help in the management of other distressing and debilitating symptoms, such as shortness of breath, nausea, and vomiting.

### Surgical Management

Surgery is the preferred treatment if there is no metastasis. Surgery is primarily used for non-small-cell tumors. There are several types of pulmonary surgery depending on the tumor site and size (Fig. 26.6):

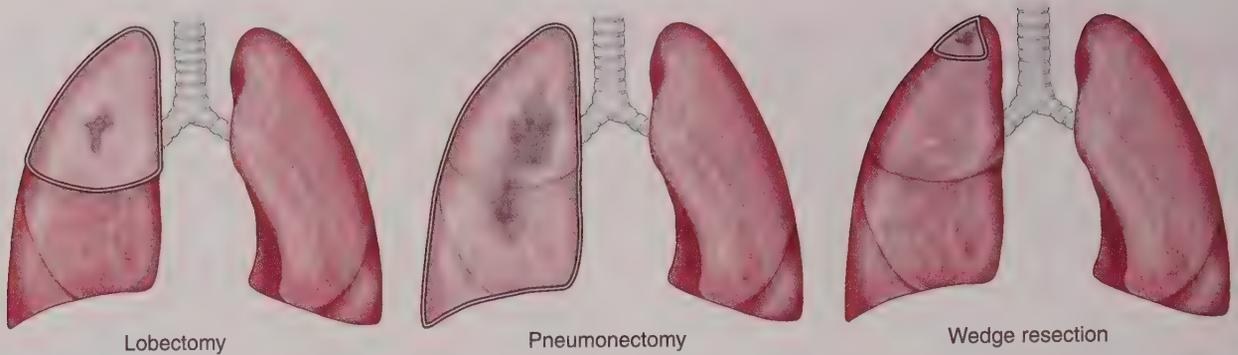

- Lobectomy is the removal of an entire lobe of the lung.
- Pneumonectomy is the removal of the entire lung.
- Wedge resection is the removal of a small section of a lobe of the lung.

Chemotherapy may be administered prior to surgery to reduce the size of the tumor to aid in resection. The administration of a chemotherapeutic agent in an effort to shrink the tumor prior to surgery is a type of **neoadjuvant therapy**. Additionally, chemotherapy can be used as **adjuvant therapy** after surgery to kill any remaining cancer cells. Similar to chemotherapy, radiation is also used to shrink the tumor prior to surgery or after surgery to kill any remaining cancer cells.

## Connection Check 26.4

When should palliative care be initiated for patients diagnosed with lung cancer?

- A. Upon diagnosis
- B. After chemotherapy
- C. After surgery
- D. Upon patient request

**FIGURE 26.6** Types of surgeries for lung cancer: lobectomy to remove cancer cells localized in one lobe, a wedge resection for cancer localized in one small area of the lung, and a pneumonectomy for cancer cells spread diffusely in the lung.

## Nursing Management

### Assessment and Analysis

The patient with lung cancer presents with the following characteristics as a result of abnormal cell growth and tumors in the lungs causing impaired chest movement and air exchange; they usually occur in the late stages of the disease:

- Persistent cough
- Dyspnea
- Wheezing
- Hemoptysis
- Chest pain
- Frequent episodes of pneumonia or bronchitis

### Nursing Diagnoses

- **Ineffective gas exchange** related to disruption of pulmonary cells secondary to lung cancer
- **Anxiety** related to the inability to breathe effectively
- **Activity intolerance** related to fatigue and dyspnea

### Nursing Interventions

#### Assessments

- Oxygen saturation  
*Decreased SpO<sub>2</sub> is due to poor gas exchange. An SpO<sub>2</sub> of less than 90% indicates significant oxygenation problems.*
- Temperature  
*Increased temperature is a sign of infection.*
- Breath sounds  
*The presence of wheezes may indicate airway obstruction. Rhonchi indicate increased secretions in the upper airways.*
- Cough  
*Cough indicates an irritation of the tracheobronchial tree. The presence of hemoptysis indicates the rupture of small blood vessels.*
- Pain  
*Pain increases respiratory rate; anxiety decreases quality of life.*
- Appetite/weight  
*Appetite may be decreased because of the side effects of chemotherapy or loss of energy due to increased work of breathing. Monitoring the weight helps to identify nutritional deficiencies.*

#### Focused postoperative assessment:

- Vital signs  
*Hypotension and/or tachycardia may indicate excessive blood or fluid loss.*
- Breath sounds  
*Diminished or absent breath sounds may indicate postoperative atelectasis.*
- Suture line  
*A suture line that is reddened, warm to touch, and/or draining thick, yellow drainage indicates infection.*
- Chest tube
  - Monitor amount and color of chest tube drainage.  
*Excessive bloody drainage may indicate a bleed within the chest. Cloudy drainage may indicate infection.*
  - Monitor water-seal chamber.  
*Persistent bubbling in the water-seal chamber indicates an air leak in the chest tube system.*  
*See Chapter 27 for a detailed description of chest tube care.*

#### Actions

- Provide oxygen.  
*Increase the SpO<sub>2</sub> to 90%.*
- Administer medications as ordered.
  - Pain medications/Anti-anxiety medications  
*Pain and anti-anxiety medications provide relief from both pain and anxiety, allowing better relaxation, increased expansion of the lungs to improve oxygenation, and improved quality of life.*
  - Bronchodilators  
*Bronchodilators, bronchial smooth muscle relaxants, open the airway and decrease the work of breathing.*
- Provide small, frequent meals with dietary supplements.  
*Small, frequent meals avoid excessive pressure on the diaphragm associated with a large meal. Dietary supplements increase nutritional caloric intake, providing energy for the work of breathing.*
- Position—semi-Fowler's  
*The semi-Fowler's position increases oxygenation by allowing full lung expansion.*

- Focused postoperative actions
    - Maintain a closed chest tube system.  
*A closed system prevents any inadvertent air leaks.*
    - Never clamp the chest tube.  
*Clamping the chest tube may result in increased air or fluid in the pleural space, worsening the pneumothorax, and may lead to a tension pneumothorax.*
- See Chapter 27 for a detailed description of chest tube care.

### Teaching

- Breathing techniques  
*Controlled breathing techniques help to increase the clearance of sputum and reduce the sense of breathlessness. Pursed-lip breathing encourages the exchange of oxygen and carbon dioxide.*
- Pacing activities  
*Pacing conserves energy and decreases the work of breathing.*
- Smoking cessation program  
*Smoking cessation can change the course of the disease process.*
- Nutritional needs  
*Small, frequent meals decrease the work of breathing with less impact on the diaphragm.*
- Medication regimen  
*Knowledge regarding medications and their use, such as proper use of inhalers, increases the ability to manage the disease.*
- Use of pain medications around the clock  
*Improves patient comfort and quality of life by maintaining a level of pain control rather than suffering peaks of discomfort*

### Evaluating Care Outcomes

A well-managed patient with lung cancer has the pain under control, sufficient appetite and weight, and adequate oxygenation. Positive outcomes are achieved through around-the-clock pain medication; small, frequent meals; and appropriate use of oxygen and bronchodilators. Regular provider follow-up and palliative care referrals are essential to maintaining an optimal quality of life.

### Connection Check 26.5

The nursing plan of care for a patient diagnosed with lung cancer includes which of the following? (Select all that apply.)

- Education about disease management
- Frequent assessment of pain levels
- Reminders that recovery is coming soon
- Frequent assessment of oxygenation
- Weaning from oxygen because the disease is terminal

## Making Connections

### CASE STUDY: WRAP-UP

Clifford continues to be short of breath and to wheeze. His SpO<sub>2</sub> remains acceptable while he receives oxygen via the nasal cannula. After the first three nebulizer treatments, his peak flow reading is repeated. It is slightly improved but not back to baseline. Clifford then receives Prednisone 60 mg intramuscularly (IM). The symptoms slowly begin to subside. A repeat of the peak flow reading reveals continued improvement. When Clifford's symptoms are fully resolved, he is discharged from the emergency department with a prescription for an oral prednisone taper. Before he leaves, hospital personnel ensure that he has an appointment with his primary care provider to review this hospital visit and update his asthma action plan.

### Case Study Questions

- What is the most important component of the medical management of Mr. Davis?
  - Breathing techniques
  - Disease management through education
  - Use of "rescue" medications
  - Use of a peak flow meter
- If there are no wheezes and diminished breath sounds upon reassessment, what conclusion can the nurse make?
  - Mr. Davis has resolved his respiratory condition.
  - Mr. Davis has responded to the bronchodilator therapy.
  - Mr. Davis has a partially obstructed airway.
  - Mr. Davis needs another nebulizer treatment.
- What does the nurse recognize as the priority for Mr. Davis when a partially obstructed airway is suspected?
  - Airway management
  - Medication administration
  - IV line insertion
  - Patient education
- What is a major component of the treatment program for Mr. Davis?
  - A smoking cessation program
  - A physical exercise program
  - Genetic counseling
  - Dietary counseling

5. Which statement about Mr. Davis's medications indicates the need for further teaching?
- "I use my albuterol (Proventil) when I am having difficulty breathing."
  - "I wait 5 minutes between my inhalation puffs."
  - "I will be able to discontinue all of my medications when my asthma is under control."
  - "I should not suddenly stop taking the prednisone."

## CHAPTER SUMMARY

Asthma is a chronic lung disease characterized by intermittent, reversible airway obstruction resulting from inflammation of the lung's airways and a tightening of the muscles that surround the airways. The patient with asthma presents with the symptoms of increased sputum, increased respirations, and wheezes. Effective treatment of asthma involves assessment and control of environmental triggers, monitoring of symptoms, pharmacological treatment, and education. Pharmacological management typically falls into two categories: long-term control medications and "rescue" medications. Long-term control medications are used daily to maintain control of the asthma. "Rescue" medications are those medications used once an asthma attack has started.

Chronic obstructive pulmonary disease is composed of two pulmonary diseases: emphysema and chronic bronchitis. Both diseases cause obstruction to the airflow but in different ways. The patient with emphysema has airway obstruction due to overdistention and air trapping of the alveoli. Chronic bronchitis results when there is inflammation of the bronchi and bronchioles. The inflammation causes an increase in the production of thick mucus. The walls of the bronchus thicken and cause airway obstruction. The management plan for COPD has four goals: monitor

the disease, reduce exposure to risk factors, manage stable COPD, and manage exacerbations. The major components of pharmacological management are bronchodilators: beta<sub>2</sub>-adrenergic agonists and anticholinergics used individually or in combination on an as-needed or regular basis to control symptoms.

The major diagnostic test for both asthma and COPD as well as other lower airway disorders is the pulmonary function test (FEV<sub>1</sub>), which measures the amount of air that is moved in and out of the tracheobronchial tree. The FEV<sub>1</sub> is the amount of air forcefully exhaled within 1 second after a forced inhalation.

Cystic fibrosis is a genetic disease of the exocrine glands, such as the sweat, salivary, or pancreas glands. It is a multi-system disease that produces increased amounts of thick mucus in the respiratory, GI, and reproductive systems. The increase in thick, sticky mucus production leads to mucus plugging of the airways. It also blocks the pancreatic enzymes from breaking down and absorbing food. Medication management includes bronchodilators, mucolytics to thin the mucus, anti-inflammatories to diminish the inflammatory response, CFTR modulators, and antibiotics in the case of infection. Patients also require pancreatic replacement enzymes to help with digestion and absorption of food as well as supplemental calories to maintain weight.

Lung cancer is caused by the uncontrolled growth of abnormal cells in the lungs. There are two major types of lung cancer: non-small cell and small cell. The survival rate for those diagnosed with non-small-cell cancer is good at 5 years. Small-cell cancer grows quickly and metastasizes to other organs in the body. Only 5% to 10% of those developing small-cell cancers survive for 5 years. Treatment is multidisciplinary and is dependent on the type, size, location, and stage of the tumor. Medical management of lung cancer typically consists of a combination of surgery, radiation, chemotherapy, and pain management. Palliative care services are appropriate to consider from diagnosis through the course of the illness because they can improve the quality of life of patients and their families.

# Chapter 27

## Coordinating Care for Critically Ill Patients With Respiratory Dysfunction

*Deborah Ennis*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing respiratory conditions that require management in the critical care setting
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Pulmonary embolism
  - b. Acute respiratory failure
  - c. Acute respiratory distress syndrome
  - d. Chest trauma
3. Describing the diagnostic results used in the management of critically ill patients with respiratory dysfunction
4. Discussing the medical management of:
  - a. Pulmonary embolism
  - b. Acute respiratory failure
  - c. Acute respiratory distress syndrome
  - d. Chest trauma
5. Describing the indications, management, and complications associated with mechanical ventilation in the critically ill patient
6. Developing a comprehensive plan of nursing care for critically ill patients with respiratory dysfunction
7. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with complications of respiratory dysfunction

### CONCEPTS

- Assessment
- Clotting
- Medications
- Oxygenation
- pH Regulation

### ESSENTIAL TERMS

Acute respiratory distress syndrome (ARDS)  
Acute respiratory failure  
Alveolar-capillary membrane (ACM)  
Alveolar hypoventilation  
Barotrauma  
Cardiac tamponade  
Dead-space ventilation  
Deep vein thrombosis (DVT)  
Embolectomy  
Exudative phase  
Fibrotic phase  
Flail chest  
Hemothorax  
Hypercapnia  
Hypercapnic respiratory failure  
Hypoxemia  
Hypoxemic respiratory failure  
Hypoxia  
Intrapulmonary shunt  
Noninvasive positive-pressure ventilation (NPPV)  
PaO<sub>2</sub>/FIO<sub>2</sub> ratio  
Pneumomediastinum  
Pneumothorax  
Proliferative phase  
Pulmonary embolism (PE)  
Tension pneumothorax  
Tidal volume  
Ventilation-perfusion mismatch (V/Q mismatch)  
Ventilator-induced lung injury (VILI)  
Virchow's triad

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

J.T. Winters is a 19-year-old male admitted to the emergency department after sustaining injuries in a motor vehicle collision (MVC). He was traveling at a high rate of speed when he lost control and went off the road. It is estimated that his car struck a tree at 35 miles per hour. He was not wearing a seat belt, but his air bag did deploy. He was conscious at the scene.

Upon his arrival to the emergency department, J.T.'s vital signs are as follows:

HR—115 bpm

SpO<sub>2</sub>—93% (on 2 L N/C)

Temp—99.3°F (37.4°C)

BP—106/54 mm Hg

RR—32 breaths/minute

Pain—10/10

J.T. is complaining of pain across his sternum and on his left side. Inspection reveals a broad ecchymotic area across the front of his chest and a deformity along his left side in the region of his fifth through eighth ribs. With each inhalation, this part of his thorax moves inward. Someone uses the phrase “paradoxical movement” to describe what is observed. Upon auscultation, no breath sounds are heard on the left side. A chest tube is inserted, and 400 mL of blood is rapidly drained...

## PULMONARY EMBOLISM

A **pulmonary embolism (PE)** is defined as the obstruction of one or more of the branches of the pulmonary artery by particulate matter that has an origin elsewhere in the body. A pulmonary embolus is most commonly caused by a thrombus. A pulmonary embolus can also be caused by a piece of tumor, amniotic fluid, air, or fat, referred to as a nonthrombotic pulmonary embolus (NTPE; Table 27.1). It is important to note that an amniotic fluid pulmonary embolus is fatal to the mother in two-thirds of the cases, with 70% of newborns surviving.

### Epidemiology

There are many risk factors for PE, but by far, the greatest risk factor is the presence of a **deep vein thrombosis (DVT)**. **Virchow's triad** of venous stasis, vessel wall damage, and hypercoagulability is the major predisposing factor for the development of a DVT. The most common cause of DVT is prolonged immobility (Table 27.2).

**Table 27.1 Sources of Pulmonary Emboli**

Type	Source
<b>Deep vein thrombus</b>	Clot breaks loose from site of origin, most often from the deep veins of the leg or pelvis, then travels to the pulmonary vasculature.
<b>Fat</b>	Long-bone fracture Osteomyelitis Liposuction
<b>Air</b>	Central venous catheter (CVC) insertion—negative intrathoracic pressure can allow air to enter a CVC on insertion or if disconnected from a fluid source. Cardiopulmonary bypass Hemodialysis
<b>Amniotic fluid</b>	Amniotic fluid can move into the vascular space during delivery through placental vessels.
<b>Tumor</b>	Tumor sloughs off, and tumor particles travel to the pulmonary vasculature.

**Table 27.2 Virchow's Triad**

Predisposing Factor	Causes
<b>Hypercoagulability</b>	<ul style="list-style-type: none"> <li>● Cancer</li> <li>● Oral contraceptives</li> <li>● Dehydration/hemoconcentration               <ol style="list-style-type: none"> <li>1. Sickle cell anemia</li> <li>2. Polycythemia vera</li> <li>3. Abrupt discontinuation of anticoagulants</li> </ol> </li> </ul>
<b>Venous stasis</b>	<ul style="list-style-type: none"> <li>● Prolonged bedrest/immobility</li> <li>● Obesity</li> <li>● Burns</li> <li>● Pregnancy</li> <li>● Vasculitis/thrombophlebitis</li> <li>● Bacterial endocarditis</li> <li>● Any postoperative patient</li> </ul>
<b>Intimal damage of vessels</b>	<ul style="list-style-type: none"> <li>● Trauma</li> <li>● IV drug use</li> <li>● Atherosclerosis</li> </ul>

Other risk factors for DVT include:

- Obesity
- Smoking
- Chronic heart disease

- Fracture (hip or leg)
- Hip or knee replacement
- Major surgery
- Major trauma
- Spinal cord injury
- History of previous venous thromboembolism
- Malignancy

The incidence of PE is approximately 1 to 2 per 1,000 persons in the United States. Annually, 50,000 to 100,000 patients die from PE. More than 40% of patients diagnosed with PE also have diagnosed DVT. Pulmonary embolism is the third most common cause of death in patients who are hospitalized for other reasons.

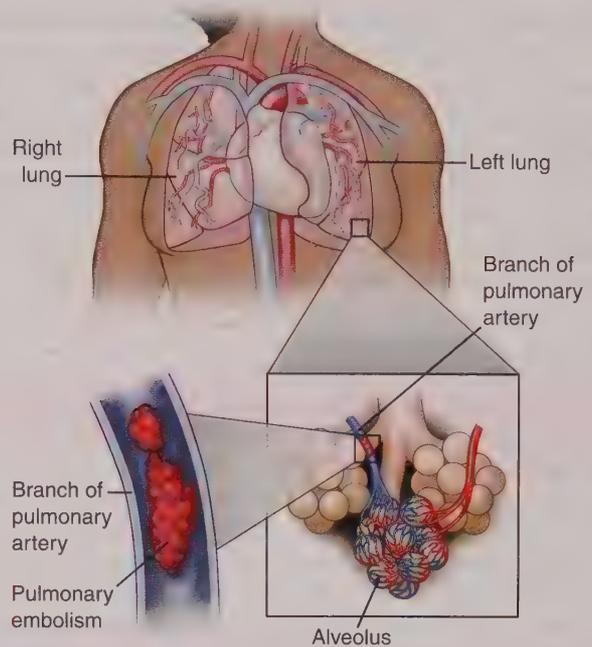

**Safety Alert** Elderly patients are the most likely recipients of knee or hip replacement surgery.

Due to the fact that many of these patients experience limited mobility due to the pain from their disease and have a higher risk for DVT due to aging changes, these patients are at high risk for PE. The nursing assessment must be aimed at early identification of PE as a possible postoperative complication.

## Pathophysiology

When a blood clot or other particulate matter travels to the lungs, it lodges in the pulmonary artery and blocks blood flow (Fig. 27.1). This obstruction results in an impaired ventilation-to-perfusion ratio ( $V/Q$  ratio) described as decreased or blocked blood flow or perfusion to functioning alveoli. This is called a **ventilation-perfusion mismatch ( $V/Q$  mismatch)**, a decreased blood flow to functioning alveoli or areas of the lung where gas exchange can take place if perfusion is adequate. A PE results in a high-ventilation/low-perfusion scenario—a high  $V/Q$  mismatch. This prevents gas exchange at the alveolar level, leading to **hypoxemia** (low blood oxygen levels) and local vasoconstriction in the affected pulmonary vascular bed. The PE also results in an increase in pulmonary vascular resistance (PVR) because blood flow cannot move past the venous obstruction. If the right ventricle cannot overcome this increased PVR, then left ventricular preload (blood flow to the left ventricle) is reduced. This leads to decreased oxygenation, decreased cardiac output, and hypotension. The combination of decreased oxygenation and reduced cardiac output results in inadequate tissue perfusion and **hypoxia** (inadequate oxygenation at the cellular level). The increased PVR also leads to pulmonary hypertension (high pressures in the pulmonary vasculature), causing a backflow of blood into the right ventricle and right heart failure. This can exacerbate if the vascular obstruction continues to grow.

Acute pulmonary emboli are classified as massive, submassive, or low risk (Table 27.3). Massive pulmonary emboli occur abruptly, with a sudden onset of symptoms

**FIGURE 27.1** Pulmonary embolism.

**Table 27.3 Pulmonary Embolism Classification**

Type	Manifestations
<b>Massive</b>	Acute pulmonary embolism with: <ul style="list-style-type: none"> <li>• Prolonged hypotension requiring pharmacological support</li> <li>• Right and left ventricular dysfunction</li> <li>• Shock and/or cardiac arrest</li> </ul>
<b>Submassive</b>	Acute pulmonary embolism with: <ul style="list-style-type: none"> <li>• Normal blood pressure</li> <li>• Right ventricular dysfunction—evidenced by echocardiogram</li> <li>• Myocardial necrosis, indicated by elevated troponin I and elevated brain natriuretic peptide (BNP)</li> </ul>
<b>Low risk</b>	Acute pulmonary embolism with: <ul style="list-style-type: none"> <li>• Normal blood pressure</li> <li>• No right ventricular dysfunction</li> <li>• No elevated biomarkers (troponin or BNP)</li> </ul>

following obstruction. An acute massive PE can cause rapidly developing right ventricular heart failure and death. A massive PE is present if more than 50% of the blood flow through the pulmonary artery is obstructed. A submassive PE is present when there is right heart dysfunction but no hemodynamic instability. A low-risk PE presents with no indications of heart dysfunction, elevated biomarkers, or hypotension. Pulmonary emboli are further categorized by

the placement of the embolus. A saddle pulmonary embolism is one that straddles the bifurcation of the pulmonary artery, either fully or partially obstructing both branches of the pulmonary artery. This type of PE very often results in sudden death. A central pulmonary embolism is an embolus or emboli found in the main branch of the pulmonary artery or in either the right or left branch of the pulmonary artery. A peripheral pulmonary embolism is an embolism or emboli found in the peripheral or smaller branches of the pulmonary arteries.

## Clinical Manifestations

The sudden onset of intense dyspnea, pleuritic chest pain, and tachypnea is usually the first indication that the patient has an acute PE (Box 27.1). Pulmonary embolism should be suspected in any postoperative patient, especially those following long-bone surgeries with a new onset of shortness of breath. The pain is attributed to the inflammatory mediators that have been released. In the cases of massive PE, acute right ventricular failure may present with jugular venous distention (JVD). Because of the decreased cardiac output, the patient may become hypotensive and tachycardic. The patient may also become tachycardic because of the hypoxemia caused by the increase in **dead-space ventilation** (nonperfused functioning alveoli). Cerebral perfusion may become compromised, making the patient anxious, restless, and/or confused. If pulmonary infarction has occurred because of hypoxia of pulmonary tissue, the patient may have hemoptysis (bloody sputum).

## Management

### Medical Management

#### Diagnosis

#### Imaging Studies

The diagnosis of PE is done through imaging studies and laboratory studies. The initial study for any patient presenting with chest pain is an electrocardiogram (ECG) to rule

out a myocardial infarction. There may be ECG changes in the case of massive PE, but they are nonspecific and not sensitive. Ischemic changes may be seen as inverted T waves and ST changes. Damage to the myocardium is represented by new Q waves and right bundle branch blocks. The predominant value of the ECG is to rule out myocardial infarction (MI).

An initial chest x-ray is done preliminarily to rule out other causes of the respiratory distress. It may show atelectatic changes similar to those of pneumonia and infiltrates at the area of the embolism.

The chest, spiral computed tomography (CT) scan with contrast is the most commonly ordered test to diagnose a PE. The scan can effectively identify central as well as peripheral emboli.

The ventilation-perfusion scan (V/Q scan) can be utilized if a CT scan is not available. A V/Q scan can identify areas of the lungs that are ventilated but not perfusing effectively. This is an indication of obstruction of the pulmonary vasculature or PE. The phrase “high probability” indicates that there is a V/Q mismatch.

The most definitive study for the diagnosis of PE is pulmonary angiography. This test allows for visualization of the pulmonary vasculature and therefore the detection of any obstruction. The invasive nature of this examination, coupled with the time it takes to perform the examination, limits its use when the patient is unstable. It also exposes the patient to more radiation than CT. This test is completed only if other studies are not conclusive and only in a stable patient.

Once the patient with an acute PE has been stabilized, a lower extremity venous ultrasound is usually conducted to determine the presence and extent of any DVT. Recurrent PE is a major cause of mortality for patients who have endured an acute PE. Discovery of a DVT helps guide inpatient and post-discharge therapy and education.

#### Laboratory Studies

A plasma D-dimer level is a very specific indicator of the possibility of the presence of a thrombus in the body. This level increases as the body removes clots through lysis as part of the normal clot-removal process. The D-dimer is the fibrin left behind from that lysis. A negative D-dimer rules out the possibility of a clot. A positive D-dimer indicates the presence of a clot but requires further testing. This test may be one of the first blood studies done for a patient with acute symptoms of a PE.

Laboratory studies very often include arterial blood gases (ABGs). Evaluation of ABGs in the presence of a PE will most likely reveal hypoxemia (PaO<sub>2</sub> less than 80 mm Hg) and respiratory alkalosis (PaCO<sub>2</sub> less than 35) due to the patient's increased respiratory rate. The hypoxemia is more profound in direct relation to the amount of pulmonary vessel obstruction the patient is experiencing. The ABGs may later reveal metabolic acidosis due to the hypoxemia because the body switches to anaerobic metabolism in the face of hypoxemia in the later stages of a PE.

### Box 27.1 Common Signs and Symptoms of Pulmonary Embolism

- Dyspnea
- Accessory muscle use
- Pleuritic chest pain
- Tachycardia
- Tachypnea
- Crackles upon auscultation
- Cough
- Hemoptysis
- Unilateral lower extremity edema due to the presence of a deep vein thrombus (DVT); pain in extremity, with redness and warmth

As discussed previously, an acute PE may have cardiac manifestations. Because of the strain on the ventricles brought on by the PE, B-type natriuretic peptide (BNP) may be elevated. This peptide is released by overstretched ventricles under physiological stress. Levels above 100 pg/mL indicate heart failure. B-type natriuretic peptide is an insensitive test because not all patients with an acute PE have heart failure. Troponin I and troponin T may also rise, but this elevation is transient when compared with MI.

### Treatment

Medication therapy when treating a patient with acute PE is primarily anticoagulation. Anticoagulation does not reduce the clot; it keeps the clot from getting larger and also helps to reduce the formation of other clots. In nonsymptomatic patients with a low-risk clot, anticoagulation usually consists of initiation of an oral factor Xa inhibitor that inhibits the conversion of prothrombin to thrombin. These medications require no laboratory monitoring as in the case of coumadin, but there is no reversal agent available. These patients do not require hospitalization. Intravenous heparin therapy is initiated with a symptomatic patient with any type of PE—blood clot, air, fat, or other particulate matter—because blood clots will adhere to any of those substances, making them larger and able to obstruct more blood flow. Typically, patients are started on IV heparin with a bolus followed by a continuous drip. The dosages are based on the patient's weight. Heparin therapy is monitored through the activated partial thromboplastin time (aPTT). Prior to the initiation of therapy, an aPTT is drawn and then repeated every 4 to 6 hours to monitor therapy. The therapeutic goal is 1.5 to 2.5 times the normal value, or 40 to 90 seconds. If the initial aPTT is below the designated therapeutic level, an additional heparin bolus may be given along with an increase in the rate of the infusion. If the aPTT is above therapeutic, the rate of the infusion will be reduced. In the cases of very high aPTT levels, the infusion may be held for a specified period of time before restarting the infusion at a lower rate. Once the aPTT is in the therapeutic range for two consecutive iterations, it is evaluated once every 12 or 24 hours. Each facility has established protocols for the assessment of aPTT for a patient receiving heparin. Reaching a therapeutic aPTT level within 24 hours has been shown to have better outcomes. Protamine sulfate is the reversal agent to heparin and must be readily available if active bleeding occurs. Subcutaneous low-molecular-weight heparin, fondaparinux, or unfractionated heparin may be prescribed in lieu of instituting a weight-based heparin protocol.

Anticoagulation continues after discharge with warfarin. Warfarin (Coumadin) therapy is monitored through the international normalized ratio (INR). The therapeutic anticoagulation goal is an INR of 2.0 to 3.0. It takes approximately 3 to 5 days to reach a therapeutic level, so initially, the two medications, heparin and warfarin, are prescribed concurrently. Warfarin may be continued following a PE, depending on severity, for 3 to 6 months. A factor Xa

inhibitor could also be used on discharge rather than warfarin depending on patient and provider preference.

If a patient is hemodynamically compromised, thrombolytic therapy (alteplase) should be considered. Contrary to anticoagulation, systemic thrombolysis is responsible for lysis or removal of the clot from the pulmonary artery. The adverse effects of systemic thrombolytic agents may preclude their use. The risk of bleeding is of paramount concern. The main concern in the elderly patient is cerebral hemorrhage. Patients typically have IV heparin administration discontinued during the alteplase infusion. It is restarted after the infusion is complete. Absolute and relative contraindications must be taken into account before initiating this therapy (Table 27.4). Patients who are hemodynamically unstable may be candidates for catheter-directed thrombolysis (CDT) using a low-dose hourly infusion of tissue plasminogen activator (tPa) or urokinase. This therapy will administer the medication directly to the clot at the site, resulting in lysis of the clot and reducing the risk of bleeding complications. This therapy is considered safe and beneficial for patients with massive PE and those with submassive PE.

Intravenous isotonic fluid is used to decrease the viscosity of the blood. Caution must be exercised to ensure that the patient is not fluid-overloaded. In cases of recognized right ventricular compromise, IV fluid may be held, and an inotropic pharmacological agent that increases cardiac contractility, such as dobutamine, may be administered in order to overcome PVR and allow the left ventricle to maximize cardiac output. Hypotension can be managed with norepinephrine and vasopressin if it is not resolved with single-medication therapy.

### Surgical Management

Surgical management is considered for acute massive PE resulting in hemodynamic instability where thrombolytic agents are contraindicated. The procedure is an

**Table 27.4 Contraindications to Thrombolytic Therapy**

Absolute	Relative
History of hemorrhagic stroke	Severe hypertension (SBP greater than 200 mm Hg or DBP greater than 110 mm Hg)
Active intracranial neoplasm	Nonhemorrhagic stroke (within 2 months)
Recent surgery	Surgery in past 10 days
Recent trauma (less than or equal to 2 months)	Thrombocytopenia (platelets less than 100,000)
Active or recent internal bleeding (6 months)	History of bleeding tendencies

DBP, Diastolic blood pressure; SBP, systolic blood pressure.

**embolectomy**, or physical removal of the clot. There are two types of embolectomy, catheter or surgical. In addition to the CDT discussed above, rheolytic or rotational catheter embolectomy may be an option. In a rheolytic catheter embolectomy, pressurized saline is used to erode the clot. It requires a large venous catheter or sheath, so bleeding is a major risk. Another type of catheter embolectomy is the rotational embolectomy. A rotating tool is used to break down the clot. A standard cardiac catheter is used, so there is less risk to the patient. In general, catheter embolectomy is used for clots in the main and segmented or lobar pulmonary artery branches. The efficacy of catheter embolectomy is still being studied, but each method has a mortality rate of approximately 20%.

The more common type of embolectomy is the surgical embolectomy. This is a complex thoracic surgical procedure that requires cardiopulmonary bypass. Again, this procedure is usually performed when the patient has systemic hypotension and the use of thrombolytics is contraindicated. New studies indicate that the use of CDT could be an appropriate choice in lieu of a surgical approach, especially in the face of severe hemodynamic instability. The major determinant of the success of these procedures is when they can be performed prior to the onset of cardiogenic shock or cardiac arrest.

Inferior vena cava (IVC) filters are placed to prevent recurrent PEs (Fig. 27.2). The indications for IVC filter placement are active bleeding that disqualifies anticoagulation therapy, recurrent PE despite adequate anticoagulation

therapy, or evidence that hemodynamic or respiratory dysfunction is severe enough that another PE could be fatal. The filter allows for blood passage but is designed to trap any further emboli originating in the lower extremities. Complications of IVC filter placement are rare but include filter migration, erosion of the vena cava wall, obstruction due to filter thrombosis, and procedural complications. Retrievable IVC filters are now available, with the goal being the removal of the IVC when anticoagulation is again advisable.

## Nursing Management

### Assessment and Analysis

Assessment of a patient at risk for an acute PE requires astute monitoring. The clinical manifestations are non-specific. Sudden onset of pleuritic chest pain, dyspnea, and tachypnea are the most common initial assessment findings. The presence of a PE has two distinct cardiac manifestations. If PVR is elevated, the early signs of right ventricular failure, such as JVD, may be seen. With a massive PE, preload to the left side of the heart may be dramatically reduced, causing a decrease in cardiac output and hypotension. A sudden change in mental status may occur if cerebral perfusion pressure is compromised. The patient may become anxious or express feelings of impending doom.

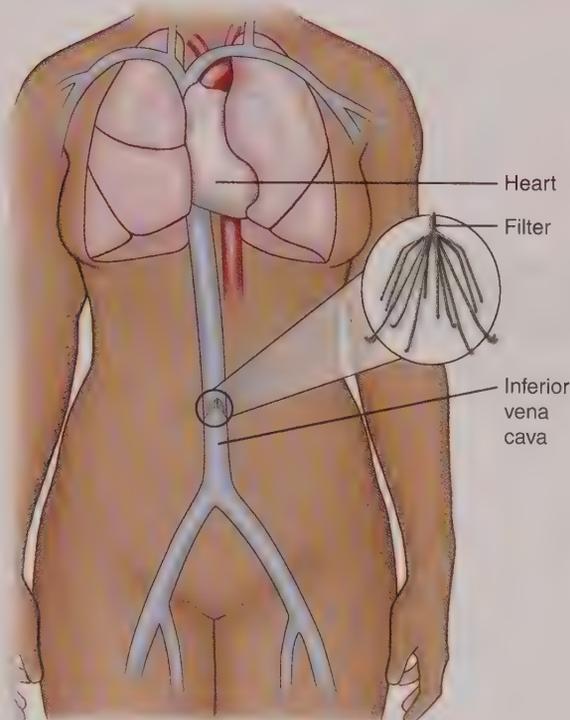

### Nursing Diagnoses

- **Impaired gas exchange** related to interruption of pulmonary blood flow
- **Ineffective breathing pattern:** tachypnea related to pain and hypoxemia
- **Decreased cardiac output** related to increased PVR
- **Risk for bleeding** related to anticoagulant/thrombolytic therapy

### Nursing Interventions

#### ■ Assessments

- **Airway**  
*Is breathing effective to maintain oxygenation? Is the patient breathing comfortably or in respiratory distress? Mechanical ventilation may be required.*
- **Oxygenation**  
*The pulse oximetry reading decreases from baseline as a result of increased dead-space ventilation; blood is not properly oxygenated in the lungs.*
- **Frequent vital signs**  
*The pulse increases because of hypoxemia; blood pressure may decrease from baseline in cases of massive PE because of decreased left heart preload; tachypnea may occur due to decreased oxygenation and pain; fever may develop because of the inflammatory response.*
- **Chest pain**  
*Sudden-onset chest (pleuritic) pain with dyspnea and tachypnea is usually the first sign of acute PE, resulting from the release of inflammatory mediators.*
- **Laboratory values**
  - ABGs (onset)  
*Tachypnea causes respiratory alkalosis; PaO<sub>2</sub> is reduced because of increased dead-space ventilation.*

**FIGURE 27.2** Inferior vena cava (IVC) filter placement. The filter allows for blood passage but traps emboli originating in the lower extremities, preventing travel to the heart and lungs.

- ABGs (as disease progresses)  
*Metabolic acidosis results from hypoxia and the subsequent transition to anaerobic metabolism.*
- Lactic acid levels  
*An increase confirms anaerobic metabolism.*
- Coagulation studies  
*APTT levels are monitored if the patient is on heparin; the prothrombin time (PT)/INR is followed if the patient is on warfarin.*
- Monitor urine output.  
*Urine output less than 0.5 mL/kg/hr is an early sign of shock.*

### ■ Actions

- Elevate the head of the bed.  
*Allows the diaphragm to drop, facilitating less work of breathing and better oxygenation*
- Administer IV fluids.  
*Decrease viscosity of blood; caution must be used in cases of right ventricular overload.*
- Administer anticoagulation medications as ordered.  
*Heparin infusion, warfarin, and factor Xa inhibitors limit the growth of PE and DVT and decrease the formation of new clots.*
- Administer thrombolytic medications if ordered.  
*Thrombolytics degrade the clot; if not contraindicated, they are used when patients are hemodynamically compromised.*
- Administer inotropic agents if ordered.  
*Inotropic agents increase cardiac contractility in an effort to augment cardiac output if the patient is hemodynamically unstable.*
- Administer norepinephrine or vasopressin as ordered.  
*These vasoconstrictive medications are given, if necessary, to maintain a systolic BP of at least 80 mm Hg.*
- Institute bleeding precautions.  
*The use of anticoagulants and/or thrombolytics can result in bleeding; minimize venipunctures; watch for blood in urine, stool, and sputum; watch for unusual bruising.*
- Be prepared for intubation and resuscitation.  
*Massive PE may result in cardiogenic shock and sudden death.*

### ■ Teaching

- Disease process/lifestyle modifications  
*The patient should understand the risks of PE and how to avoid future occurrences via lifestyle modifications.*
  - Exercise regimen that includes aerobic exercise  
*Exercise strengthens the patient's heart and cardiovascular system, improves venous return to the heart, and assists in the loss of weight.*
  - Cardiac-prudent diet that minimizes saturated fats  
*Heart-healthy diet to reduce damage to vasculature*
  - Adequate fluid intake; at least eight 8-ounce glasses of water spread across each day  
*Maintains hydration; decreases blood viscosity*
  - Smoking cessation  
*Reduces intimal damage to vasculature; decreases vasoconstriction caused by smoking, which decreases risk of clot formation in vasoconstricted vessels; improves overall health*

### • Medications

*Explain the mechanism of action of anticoagulants and thrombolytics; the patient will be required to have follow-up laboratory samples drawn if on warfarin to determine effective dosing of outpatient anticoagulants. Regular laboratory testing not necessary for patients on factor Xa inhibitors.*

### • Bleeding precautions

*Encourage the use of electric razors; use soft toothbrushes, no flossing. Avoid activities with a risk of bleeding, such as football.*

### • Diet

*Limit foods high in vitamin K; these foods interfere with the efficacy of warfarin.*

### • Signs and symptoms of a recurrent PE/DVT

*Be aware of the occurrence of unilateral lower extremity edema and pain in the extremity, with redness and warmth, which may be due to the presence of a DVT. Pleuritic chest pain and dyspnea may indicate recurrent PE.*

### Evaluating Care Outcomes

Patients who have suffered from a PE have an increased incidence of recurrent PE. By adhering to a medication regimen, improving diet, beginning an exercise program, staying adequately hydrated, and quitting smoking, the patient should remain free of a recurrence of a PE as well as reducing the most common cause, DVT of the lower extremities.

### Connection Check 27.1

After oxygen has been administered, the next priority intervention the nurse would initiate for a patient with a pulmonary embolus is the administration of which of these therapies?

- Normal saline IV fluid
- IV heparin
- Platelet administration
- Antibiotics for inflammatory fever

## ACUTE RESPIRATORY FAILURE

### Epidemiology

**Acute respiratory failure** is when one or both of the gas-exchange functions of the lungs are compromised. The gas-exchange functions of the lungs are oxygenation and ventilation or carbon dioxide (CO<sub>2</sub>) removal. Compromise of these functions leads to hypoxemia and/or **hypercapnia**, also referred to as hypercarbia (increased PaCO<sub>2</sub>). There are two types of respiratory failure: type I, or **hypoxemic respiratory failure**, and type II, or **hypercapnic respiratory failure**.

Hypoxemic respiratory failure (type I) is characterized by a PaO<sub>2</sub> of less than 60 mm Hg despite increased inspired oxygen with a normal or low PaCO<sub>2</sub>. Hypercapnic respiratory failure (type II) is characterized by a respiratory acidosis, a PaCO<sub>2</sub> greater than 50 mm Hg and pH less than 7.35. Hypoxemia may or may not be present.

The prevalence of acute respiratory failure varies depending on the definition, but it is a life-threatening disorder

with a high mortality rate. Risk factors for hypoxemic respiratory failure include disease processes that produce a V/Q mismatch or impair oxygen diffusion at the alveolar level, such as pulmonary edema, pneumonia, or pulmonary embolus. Risk factors for hypercapnic respiratory failure include diseases that impair ventilation or cause hypoventilation. This type of respiratory failure is seen in patients with impaired chest-wall movement and thus impaired ventilation, such as acute asthma and narcotic overdose, or in patients with peripheral nervous system disorders that impair chest-wall movement, such as myasthenia gravis. This may also be seen in patients with chest-wall injury due to trauma that results in ventilatory impairment. Typically, these patients also present with hypoxemia if the cause is not quickly reversed. Risk factors are noted in Table 27.5.

### Pathophysiology

In hypoxemic respiratory failure, gas exchange and oxygenation do not occur because of a V/Q mismatch, a shunt, or impaired diffusion. In the case of V/Q mismatch, one scenario is that the lungs are adequately ventilated but not perfused (dead-space ventilation), as in the case of a patient suffering from a PE (high V/Q); air is entering the lung, but the blood is blocked from reaching the alveoli due to the embolism, and thus no gas exchange occurs. The second scenario is when the lungs are perfused but inadequately ventilated (shunt), as in the case of the patient with atelectasis or pneumonia (low V/Q; Fig. 27.3). Blood is perfusing the lungs, but air cannot get to the alveoli due to fluid or exudate in the air spaces. An extreme V/Q mismatch is an **intrapulmonary shunt**, where there is no gas exchange at all because of a shunting of blood past collapsed alveoli, as in the case of atelectasis. Impaired diffusion occurs at the alveolar level. Either the distance for diffusion (gas exchange) is increased or the permeability of the **alveolar-capillary membrane (ACM)** is reduced. This is due to either collapsed alveoli; fluid in the alveoli or small airways, such as in pulmonary edema; or exudate in the small airways and/or alveoli, such as in pneumonia. The primary result is hypoxemia.

In hypercapnic respiratory failure, impaired ventilation occurs when there is a reduced ability of the lungs and respiratory apparatus to adequately expand (hypoventilation). The amount of air moved by the lungs is suboptimal. This means that the elimination of CO<sub>2</sub> does not take place adequately. Hypercarbia is the initial result, but hypoxemia eventually occurs without adequate treatment.

### Clinical Manifestations

Acute respiratory failure results in hypercapnia and hypoxemia. Hypercapnia can produce headache, confusion, and a decreased level of consciousness or increased somnolence. The patient may be tachycardic and tachypneic and may also appear dizzy and flushed, with a pink coloring to the skin. In hypoxemia, clinical manifestations include increases in heart rate, respiratory rate, and blood pressure in an effort to increase oxygenation and perfusion. As the patient becomes more hypoxemic, there is less cerebral perfusion. This may manifest as restlessness, confusion, and/or anxiety. Eventually, without adequate treatment, the patient will present cyanotic with a greatly decreased level of consciousness or coma. It is important to remember that the patient will present not only with the clinical manifestations of respiratory failure but also with the clinical manifestations of the underlying cause or disease process (Table 27.6).

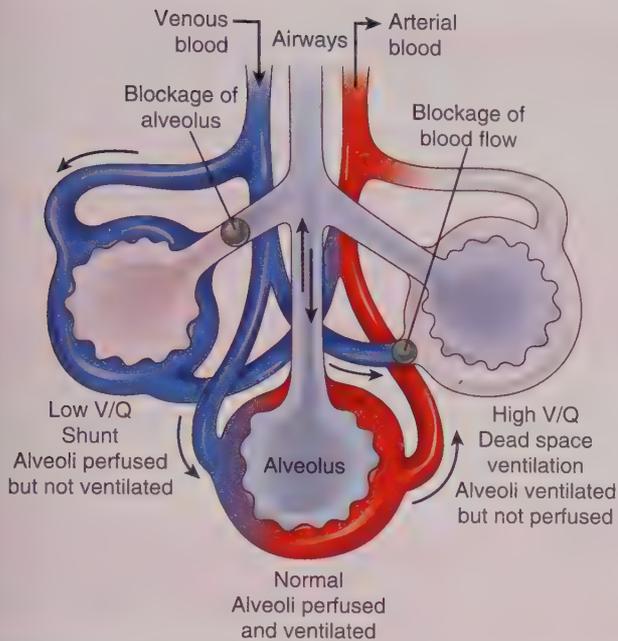

### Connection Check 27.2

- A patient with a diagnosis of pneumonia complains of a new onset of slight shortness of breath. For which of the following assessment findings would the nurse call the primary care provider immediately? (*Select all that apply.*)
- The patient is voiding, but the amounts are decreasing.
  - The patient is sleeping more than usual.
  - There is a pink coloration to the skin.
  - The patient's secretions are thin and milky colored.
  - The patient thought it was the 3rd instead of the 5th of the month.

**Table 27.5 Risk Factors for Acute Respiratory Failure**

Impaired Ventilation (Hypoventilation)	Ventilation-Perfusion Mismatch	Impaired Diffusion (Alveolar)
<ul style="list-style-type: none"> <li>● Airway obstruction</li> <li>● Respiratory muscle weakness/paralysis that can occur with neuromuscular disease such as myasthenia gravis</li> <li>● Chest-wall injury</li> <li>● Anesthesia</li> <li>● Opioid administration</li> </ul>	<ul style="list-style-type: none"> <li>● COPD</li> <li>● Restrictive lung diseases (sarcoidosis, pulmonary fibrosis)</li> <li>● Atelectasis</li> <li>● Pulmonary embolus</li> <li>● Pneumothorax</li> <li>● ARDS</li> </ul>	<ul style="list-style-type: none"> <li>● Pulmonary edema</li> <li>● ARDS</li> </ul>

<ul style="list-style-type: none"> <li>• Dyspnea</li> <li>• Restlessness</li> <li>• Anxiety</li> <li>• Fatigue</li> <li>• Increased blood pressure (from baseline)</li> <li>• Tachycardia</li> </ul>	<ul style="list-style-type: none"> <li>• Confusion</li> <li>• Lethargy (due to increased <math>\text{CO}_2</math>)</li> <li>• Pink skin coloration (due to increased <math>\text{CO}_2</math>)</li> </ul>	<ul style="list-style-type: none"> <li>• Cyanosis</li> <li>• Coma</li> </ul>

## Management

### Medical Management

#### Diagnosis

Laboratory and diagnostic tests include ABGs, venous oxygen saturation, hemoglobin and hematocrit, chest x-ray, and sputum cultures. Arterial blood gases are an excellent tool to assess the adequacy of both oxygenation and ventilation in the lungs. Hypoxemic respiratory failure has an initial period of respiratory alkalosis due to hyperventilation along with hypoxemia. Once the initial blood gases have been analyzed and treatment has been initiated, pulse oximetry can be used to monitor oxygenation. The goal is to have an  $\text{SpO}_2$  greater than 94% (which correlates to a  $\text{PaO}_2$  of approximately 80 mm Hg). Special care is taken for the patient with chronic obstructive pulmonary disease (COPD) because of the hypoxic drive to breathe (see Safety Alert).

**Safety Alert** Normal ventilation is stimulated by the buildup of  $\text{CO}_2$  in the blood. Chemoreceptors detect a hypercapnic (elevated  $\text{CO}_2$ ) state, and the respiratory cycle is stimulated to breathe faster and more deeply. This is called the “hypercapnic drive.” In some patients with COPD, the body’s chemoreceptors become less sensitive to  $\text{CO}_2$  because it is retained at higher levels as a result of the disease process. Over time, the patient with COPD develops a “hypoxic drive” to breathe. It is the lack of oxygen in the blood that causes these patients to breathe. It is because of this hypoxic drive that patients with known COPD may not tolerate high oxygen concentrations when being given supplemental oxygen therapy. **The increased amount of oxygen may cause the patient to stop breathing. Careful, continuous monitoring must be used when providing increased oxygen levels to these patients.**

Hypercarbic respiratory failure results in ABGs with a pH of less than 7.35 and a  $\text{PaCO}_2$  of greater than 45 mm Hg. The  $\text{PaO}_2$  may or may not be decreased initially but will eventually decrease without adequate treatment.

Venous oxygen saturation measures the amount of oxygenated blood returning to the heart to determine the adequacy of perfusion at the tissue level. It is correlated with perfusion failure or increased tissue oxygen demands. A normal venous oxygen saturation is 60% to 80%. A decreased venous oxygen saturation indicates inadequate cardiac output; the tissues are extracting more oxygen than normal because of the decreased oxygen delivery. A more detailed description of venous oxygen saturation and hemodynamic monitoring is given in Chapter 32.

The patient’s hemoglobin and hematocrit should be analyzed to make certain that there are enough binding sites for oxygen to ensure adequate oxygen-carrying capacity. Red blood cells carry oxygen to the cells for cellular oxygenation. If there are not sufficient red blood cells, the oxygen-carrying capacity of the blood is diminished.

A chest x-ray may show an underlying pathology, such as heart failure, pulmonary congestion, pneumonia, or pneumothorax, that can explain the respiratory failure. As discussed earlier, PE as a cause of respiratory failure is diagnosed through laboratory testing and a CT scan. A sputum culture should be obtained to rule out a pathogenic (i.e., bacterial or viral) cause of the failure.

#### Treatment

Respiratory failure is not a disease—it is a condition caused by another disease or disorder. It is vital to treat not only the respiratory failure but also the underlying cause. If the cause is pulmonary edema, then that issue must be addressed as well as the oxygenation issues associated with the resulting respiratory failure. Careful attention to nutrition is also imperative to provide calories and energy for the increased work of breathing, as well as adequate hydration to keep secretions thin.

The treatment of respiratory failure begins with oxygen. In many cases of respiratory distress, minimal supplemental oxygen may help the patient's hypoxemic status. The use of a nasal cannula or Venturi mask may provide adequate support. This is not the case when a patient is suffering from respiratory failure. The patient in acute respiratory failure who has not responded to traditional methods of oxygen administration may be placed on a nonrebreather mask with 100% FIO<sub>2</sub>. The mask is placed over the patient's nose and mouth and then secured to the patient using the elastic band. The oxygen flow meter is then turned on to its maximum setting. The reservoir bag of the mask should be inflated to ensure that the patient is receiving 100% oxygen.

In cases of severe V/Q mismatches where shunting of blood is occurring past nonfunctioning alveoli, supplemental oxygenation may not be sufficient to improve the patient's oxygenation status. In these cases, noninvasive or invasive positive-pressure ventilation may be necessary to open the alveoli to allow gas exchange. **Noninvasive positive-pressure ventilation (NPPV)**, such as bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP), administered via a tight-fitting face mask, can be used to help increase oxygenation. In BiPAP, the patient receives two different pressures. A higher pressure during inhalation assists with the opening of the alveoli, and a lower pressure during exhalation keeps the alveoli from collapsing during/at the end of exhalation but also allows ease of exhalation. In contrast, CPAP maintains one continuous pressure throughout the respiratory cycle to help keep the alveoli open through inspiration and expiration.

Invasive positive-pressure ventilation requires an advanced airway, such as an endotracheal tube (ETT) or a tracheostomy tube, and mechanical ventilation. As with CPAP, during mechanical ventilation, positive pressure is maintained throughout the ventilatory cycle in the form of positive end-expiratory pressure (PEEP). The pressure is measured at the end of expiration, thus the name, but as stated, the positive pressure is maintained throughout the cycle. Mechanical ventilation is discussed in detail in Chapter 7.

### Connection Check 27.3

The nurse understands that oxygen therapy for a patient with COPD requires close monitoring because of which of the following?

- A. Hypoxic respiratory drive
- B. Hypercapnic respiratory drive
- C. Acidotic respiratory drive
- D. Alkalotic respiratory drive

### Medications

Medications such as inhaled bronchodilators, inhaled steroids, diuretics, sedation, and antibiotics are used in cases of acute respiratory failure. Bronchodilators open the airways by stimulating beta-2 receptors within the lungs. This helps to improve airflow because of an increase in the

diameter of the airways. Inhaled steroids help decrease the inflammatory response, decreasing bronchoconstriction and increasing the airway diameter. The combination of bronchodilators and steroids provides a more therapeutic response than either medication alone. This is known as a synergistic response. Diuretics are used to decrease pulmonary congestion, especially in cases where pulmonary edema is the underlying cause of failure. Sedation is used to control agitation and anxiety that increase the work of breathing and oxygen consumption, and it is especially needed if the patient requires mechanical ventilation. Antibiotics may be initially broad spectrum to treat a suspected pneumonia and are adjusted if the sputum culture is positive for a bacterial infection.

### Complications

If supplemental oxygen, mechanical ventilation, and medications do not halt the progression of respiratory failure, the patient is at high risk for cardiac failure, multiple organ dysfunction, and death.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations are due to the hypoxemia and hypercapnia of acute respiratory failure. Arterial blood gas analysis reveals a decreasing oxygenation status and/or increased CO<sub>2</sub> levels due to impaired oxygenation or ventilation. Changes in mental status may indicate a decrease in cerebral perfusion. Agitation indicates hypoxia; somnolence indicates hypercarbia. New-onset dyspnea, increased work of breathing, and tachypnea are early indicators of impending respiratory compromise. Tachycardia and hypertension are present initially as a compensatory response.

#### Nursing Diagnoses

- **Impaired gas exchange** related to **alveolar hypoventilation**, V/Q mismatching, and/or intrapulmonary shunting
- **Ineffective breathing pattern** related to muscular fatigue and/or neurological impairment

#### Nursing Interventions

##### ■ Assessments

- **Airway**  
*Is the airway patent? Is the patient breathing comfortably, or is there increased work of breathing? Does the patient require suctioning or assistance with airway secretions?*
- **Vital signs and oxygen saturation**  
*Blood pressure, pulse, and respiratory rate increase as a compensatory mechanism in an attempt to increase oxygenation in the presence of hypoxemia; fever may develop because of inflammation and/or infection. The pulse oximetry reading decreases from baseline because of the V/Q mismatch, impaired diffusion, and/or **alveolar hypoventilation**.*
- **ABGs**  
*Hypoventilation of type II failure results in CO<sub>2</sub> retention, acidosis, and ultimately, decreased PaO<sub>2</sub>; V/Q mismatch or diffusion defects of type I failure result in a decreased PaO<sub>2</sub>.*

- **Cardiac monitoring**

*Hypoxia and increased oxygen demand due to tachycardia may lead to dysrhythmias.*

- **Neurological assessment**

*A change in mental status may be an early indication of impending respiratory failure.*

- **Agitation**

*Agitation is caused by hypoxemia.*

- **Somnolence**

*Somnolence is caused by hypercapnia.*

- **Breath sounds**

*The underlying cause of respiratory failure may result in crackles (pulmonary edema) or rhonchi (pneumonia, COPD) or diminished or absent breath sounds (hypoventilation).*

- **Skin coloration**

*Careful monitoring of skin coloration can be helpful in identifying changes in the patient.*

*Cyanosis may be visible in the nail beds and around the mouth in the initial stages of hypoxemia; as central cyanosis sets in, the body may take on a blue or gray tinge.*

*A deep pink coloration to the skin is highly indicative of increased CO<sub>2</sub> levels.*

## ■ Actions

- **Administer oxygen (with humidity) as ordered.**

*Supplemental oxygen is necessary to treat hypoxemia.*

*Humidity helps to prevent mucosal drying and helps keep secretions thin so that they can be more easily coughed or suctioned up.*

- **Medication administration**

- **Administer bronchodilating medications as ordered.**

*Bronchial smooth muscle relaxants help open the airways.*

- **Administer steroids as ordered.**

*Reduce inflammation; synergistic effect with bronchodilating agents (administer bronchodilator medications first, then inhaled steroids to allow the steroids to be inhaled more easily into the bronchial tree)*

- **Administer diuretics as ordered.**

*Diuretics help decrease the pulmonary congestion that impairs ventilation.*

- **Administer sedation as ordered (typically only in mechanically ventilated patients).**

*Sedation helps decrease anxiety and agitation, helping to decrease the work of breathing and oxygen consumption.*

- **Elevate the head of the bed; sit the patient up in a chair.**

*Positioning with the head elevated optimizes gas exchange, aids in the work of breathing, and decreases the risk of aspiration*

- **Position patient with the “good lung down.”**

*If the underlying disease is unilateral, positioning with the good lung down improves gas exchange by optimizing the V/Q ratio; gravity ensures the healthy lung maintains adequate blood flow to optimize ventilation to perfusion.*

- **Chest physical therapy and suctioning; ambulate as able.**  
*If excessive sputum is part of the underlying cause, positioning, postural therapy, percussion, vibration, and ambulation combined with assisted coughing or suctioning help mobilize and clear secretions.*

- **Administer IV fluids/hydration.**

*Decreases viscosity of secretions; helps maintain intravascular volume.*

- **Administer nutritional support.**

*The patient’s metabolic needs must be met to promote healing.*

- **Be prepared for noninvasive or invasive positive-pressure ventilatory support.**

*A severe V/Q mismatch may require the addition of positive pressure to adequately promote gas exchange.*

## ■ Teaching

- **Disease process**

*The patient should understand the risk factors and causes of acute respiratory failure and how to avoid future occurrences.*

- **Medications**

*Explain the mechanism of action and the rationale for each medication. Dosing instructions, missed dosing, and the treatment regimen must be addressed.*

- **Pulmonary rehabilitation**

- **Breathing techniques**

*Techniques such as pursed-lip breathing and diaphragmatic breathing allow for better alveolar ventilation and improve gas exchange.*

- **Energy conservation**

*Work with the patient to determine priorities in daily living.*

- **Exercise**

*Aerobic exercise helps improve respiratory status.*

- **Infection prevention**

*Hand washing and pneumococcal and influenza vaccinations help decrease the likelihood of infection.*

- **Diet and adequate hydration**

*Adequate caloric intake is necessary for healing; adequate hydration helps ensure thin secretions.*

- **Smoking cessation**

*Improves overall health and respiratory functioning; reduces incidences of pulmonary disease and cancer*

## Evaluating Care Outcomes

The initial goal of treatment for the patient with acute respiratory failure is to improve gas exchange. Pulmonary rehabilitation in the form of exercise training, nutritional counseling, and breathing strategies should be implemented to assist in the recovery from respiratory failure. The patient successfully treated is able to return to baseline respiratory function. Except in cases where the use of supplemental oxygen is the patient’s underlying norm, a well-managed patient should not require supplemental oxygenation upon discharge. The patient should be able to return to baseline activities of daily living, work, and social commitments.

**CASE STUDY: EPISODE 2**

After stabilization of his injuries, J.T. is admitted to the intensive care unit (ICU). The bleeding into the thoracic cavity has stopped, but the lung has not fully expanded. On the second day in the unit, it is noted that his pulse oximetry readings continue to decline in spite of increased  $\text{FIO}_2$  via 100% nonrebreather. He is tachypneic and tachycardic. A chest x-ray shows diffuse infiltrates bilaterally. An ABG shows the following: pH 7.50,  $\text{PaCO}_2$  of 32,  $\text{PaO}_2$  of 50, and  $\text{HCO}_3^-$  of 28 while on 70%  $\text{FIO}_2$ . It is determined that J.T. has developed ARDS. J.T. is intubated, and mechanical ventilation is initiated...

## ACUTE RESPIRATORY DISTRESS SYNDROME

### Epidemiology

There are approximately 190,000 new cases of **acute respiratory distress syndrome (ARDS)** annually. Research shows that the prevalence of ARDS is between 15% and 18% of all mechanically ventilated patients. Despite the most modern technology and after numerous studies, mortality rates for ARDS remain high. Death is not usually due to respiratory failure but due to multiple organ dysfunction brought on by hypoxia and/or infection.

There are more than 50 causes for the development of ARDS. The most common cause is sepsis. Other causes include pneumonia, severe trauma, aspiration, massive transfusions, cigarette smoking, cardiopulmonary bypass, pneumonectomy, PE, and drug/alcohol overdose. A way of classifying ARDS is to determine if the cause is due to direct or indirect injury. Direct injury refers to damage or disruption of the respiratory system. Indirect causes are those processes or disorders that occur outside the respiratory system but have a deleterious effect on the lungs. Table 27.7 outlines a partial list of causes of ARDS; it is not meant to be a complete list.

### Pathophysiology and Clinical Manifestations

Acute respiratory distress syndrome is defined by the following characteristics: acute onset of less than 7 days, refractory hypoxemia, and bilateral infiltrates ruling out cardiac pulmonary edema as the cause. It is further classified in terms of severity through evaluation of the  **$\text{PaO}_2/\text{FIO}_2$  ratio**, the ratio of the partial pressure of oxygen over the fraction of inspired oxygen. To determine this ratio, divide  $\text{PaO}_2$  by  $\text{FIO}_2$ . In a healthy individual, the  $\text{PaO}_2$  averages 90 mm Hg (normal is 80 to 100). Breathing room air, the  $\text{FIO}_2$  is 21% (or 0.21), so the equation is  $90/0.21$  or a  $\text{PaO}_2/\text{FIO}_2$  ratio of approximately 428. If a patient has a

**Table 27.7 Direct and Indirect Causes of ARDS**

Direct Injury	Indirect Injury
Aspiration	Sepsis, shock
Chest trauma	Pancreatitis
Pneumonia (infectious or aspiration)	Burns
Pulmonary contusion	Multiple blood transfusions; transfusion-related acute lung injury (TRALI)
Inhalation injury (smoke; toxins)	Cardiopulmonary bypass
Pulmonary embolus	Drug/alcohol overdose

ARDS, Acute respiratory distress syndrome.

$\text{PaO}_2$  of 70 mm Hg while receiving 70% (0.7)  $\text{FIO}_2$ , the ratio is 100, which is diagnostic for severe ARDS (Table 27.8).

There are three phases of ARDS: exudative, proliferative, and fibrotic. The **exudative phase** typically occurs within 24 to 48 hours after injury. In this phase, as a result of the activation and release of inflammatory mediators, there is a disruption of the alveolar-capillary membrane (ACM). The ACM becomes dilated due to the inflammatory mediators, and this disturbance allows fluid to move from the capillaries into the interstitial space and into the alveoli. The disruption of the ACM also allows protein to move from the vascular space.

The presence of protein in the vascular space helps to maintain the colloid oncotic pressure. Loss of protein from the vascular space lessens the oncotic forces, worsening the movement of fluid into the alveoli. The alveolar and interstitial edema results in a severe V/Q mismatch, inadequate ventilation occurring in the face of adequate perfusion or blood flow, which results in hypoxemia; blood is shunted past the fluid-filled alveoli without being oxygenated.

In addition to the alveolar and interstitial edema, there is damage to the alveolar cells that produce surfactant. Surfactant is responsible for maintaining alveolar surface tension. Alveolar surface tension keeps the alveoli from fully collapsing at the end of expiration. If alveolar surface tension is lost, then the alveoli collapse. This is referred to as *atelectasis*.

Clinical manifestations in this phase include hyperventilation and tachycardia as a compensatory response to hypoxemia. Arterial blood gases reveal a respiratory alkalosis due to the hyperventilation. Cardiac output increases in an attempt to increase blood flow through the lungs. The chest x-ray reveals the increased alveolar fluid as bilateral infiltrates and is referred to as *pulmonary edema*. Unlike the pulmonary edema associated with a heart failure exacerbation (see Chapter 30), there is no evidence of increased left atrial or ventricular pressure, which would indicate left heart failure. This is referred to as *noncardiogenic pulmonary edema*.

**Table 27.8 ARDS Severity**

Level of ARDS	PaO <sub>2</sub> /FIO <sub>2</sub> Ratio	Mortality Rate
<b>Mild ARDS</b>	200–300 on ventilator settings that include positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) $\geq$ 5 cm H <sub>2</sub> O	27%
<b>Moderate ARDS</b>	100–200 on ventilator settings that include PEEP $\geq$ 5 cm H <sub>2</sub> O	32%
<b>Severe ARDS</b>	Less than 100 on ventilator settings that include PEEP $\geq$ 5 cm H <sub>2</sub> O	45%

ARDS, Acute respiratory distress syndrome.

In the **proliferative phase**, neutrophils and other inflammatory mediators cross the damaged ACM and release toxic mediators that further damage both the alveolar and capillary epithelium. Diffusion defects result. The V/Q mismatch worsens, and pulmonary hypertension occurs because of locally occurring vasoconstriction in the lung caused by the hypoxemia. This results in right-sided heart failure due to the increase in PVR or high vascular pressures in the lung. Widespread fibrotic changes occur throughout the diseased lung tissue. The lungs become stiff and non-compliant, increasing the work of breathing.

Clinical manifestations in this phase include hypercarbia and worsening hypoxemia. As the process continues, PaCO<sub>2</sub> begins to rise despite hyperventilation. Increases in delivered oxygen do not alleviate the dropping PaO<sub>2</sub> caused by the increasingly impaired oxygen exchange across the fluid-filled and damaged ACM. This is refractory hypoxemia, meaning that in spite of increasing oxygen delivery to the patient, the hypoxemia does not improve and will eventually worsen. Lung compliance continues to deteriorate, continuing to increase the work of breathing. If the patient is on a ventilator, peak inspiratory pressures rise because of decreased compliance within the lung, requiring more pressure to deliver ventilatory volume.

In the **fibrotic phase**, there is diffuse fibrosis and scarring, resulting in greatly impaired gas exchange and compliance. Pulmonary hypertension worsens, as does the accompanying right-sided heart failure.

Clinical manifestations in this phase include a decreased left-heart preload due to the right heart failure and reduced capacity of the right ventricle to deliver blood to the lungs and on to the left side of the heart. This results in decreased blood pressure and cardiac output. The severe V/Q mismatch, diffusion defects, and intrapulmonary shunting result in refractory hypoxemia. The overall result is severe tissue hypoxia and lactic acidosis.

### Connection Check 27.4

The pulmonary edema associated with ARDS is caused by

- increased permeability of the ACM.
- right ventricular failure with pulmonary hypertension.
- left ventricular failure due to poor oxygenation.
- fluid overload related to resuscitation in the first phase.

## Management

### Medical Management

#### Diagnosis

#### Imaging Studies

The key imaging procedure to help identify and guide treatment for ARDS is the chest x-ray. During the early phases of ARDS, serial chest x-rays can be used to identify the bilateral infiltrates that are the hallmark sign of this disease process. This is sometimes described as a “ground-glass appearance” and is also characterized as a “snow-screen effect” or whiteout effect on the chest x-ray.

#### Laboratory Testing

Laboratory testing includes ABGs; complete blood count (CBC) with differential; sputum, blood, and urine cultures; coagulation studies; electrolyte panels; and liver function tests. Arterial blood gases initially show hypoxemia and hypocapnia as alveolar compromise develops. A CBC with differential is done to determine if the cause is infection. An abnormally high white blood cell count (above 10,000) is indicative of an infectious process. Sputum, blood, and urine cultures are used to determine the source of any infection. Comprehensive metabolic panels, coagulation studies, and liver and renal function tests may be used to determine the cause of ARDS but are also used to determine if the hypoxia from the disease process is affecting other body systems. In some cases of ARDS, there is a disruption of the normal clotting cascade, resulting in impaired fibrinolysis. This can result in disseminated intravascular coagulopathy, discussed in Chapter 14.

## Treatment

### Mechanical Ventilation

Mechanical ventilation is the primary treatment for the refractory hypoxemia of ARDS. It is initiated as lung compliance decreases, work of breathing increases, and oxygenation continues to be refractory regardless of interventions such as NPPV and other oxygen therapies. There are several modes of ventilation used in ARDS. The most common is conventional ventilation using reduced tidal volumes and PEEP. Because of the loss of lung compliance, research has demonstrated that using lower **tidal volumes**—the volume of air moved with one breath, one

inhalation and exhalation—with mechanical ventilation can help improve oxygenation while also reducing the occurrence of **ventilator-induced lung injury (VILI)**, lung damage due to mechanical ventilation such as inflammatory-cell infiltrates, increased vascular permeability, pulmonary edema, and **barotrauma** such as alveolar rupture. The reduced tidal volumes result in hypercapnia, which is accepted as a side effect. Permissive hypercapnia, although not fully understood, has been demonstrated to have some protective effects for the lungs. Hypercapnia should be carefully monitored or avoided in a patient with increased intracranial pressure because it results in vasodilation, which increases cerebral blood flow. The use of a low tidal volume is combined with higher PEEP. This allows the alveoli to open and remain open while at the same time keeping peak airway pressures low. As discussed earlier, PEEP keeps the alveoli from collapsing, allowing maximum gas exchange to continue throughout the respiratory cycle.

Other ventilatory modes sometimes used in the treatment of ARDS are high-frequency oscillating ventilation and airway pressure-release ventilation (APRV). High-frequency oscillating ventilation delivers very small tidal volumes at high frequencies. It avoids lung overdistention and VILI while facilitating alveoli recruitment. Airway pressure-release ventilation utilizes an inverse inspiratory/expiratory ratio (longer inspiration than expiration) to facilitate oxygenation and gas exchange. It is a form of elevated or higher-than-baseline CPAP that has timed, regular, brief reductions in the set airway pressure or CPAP level. Oxygenation is supported during the timed, higher pressure. Removal of CO<sub>2</sub> is facilitated during the timed reduction in pressure. This mode of ventilation allows for spontaneous breathing, reduces the need for sedation or neuromuscular blockade, and reduces VILI.

Partial liquid ventilation is another form of ventilatory support where the lungs are filled with perfluorocarbon liquid to a volume less than or equivalent to functional residual capacity and then ventilated using a standard conventional mechanical ventilator. Perfluorocarbon has surfactant-like properties and good oxygen-carrying capacity. This mode of ventilation has been shown to decrease the shunt associated with ARDS and redistribute blood flow from dependent areas of the lung to nondependent areas. This form of ventilation has promise; research is ongoing to evaluate its safety and efficacy.

Another mode of oxygenation showing some promise is high-flow nasal cannulas (HFNCs). There is much research testing this treatment in the early phase of ARDS and in mild ARDS as a form of noninvasive ventilation (NIV). In this form of oxygenation, high-flow oxygen is humidified, warmed, and delivered through soft, wide-bore nasal prongs. The high flow rate results in a “washout” of nasopharyngeal dead space, optimizing alveolar ventilation, and also increases nasopharyngeal airway pressure, producing a CPAP effect. The use of HFNC can improve oxygenation, decrease the work of breathing, and decrease the risk

of nosocomial infection associated with invasive ventilation modes. As with other forms of NIV, some studies have shown a failure rate as high as 40%, requiring intubation and mechanical ventilation, indicating more research is required.

Another treatment to support gas exchange in severe ARDS is extracorporeal membrane oxygenation (ECMO). This technique uses a pump to circulate blood through an artificial lung outside of the body (extracorporeal), where oxygenation and CO<sub>2</sub> removal takes place. Blood is then returned into the bloodstream. This is a very invasive form of therapy with many inherent risks and complications, but recent technological improvements have made it safer, increasing its use. More research is needed to determine more clearly what subset of patients will benefit from this therapy.

### Positioning

Patient positioning can be utilized as an adjunctive therapy in ARDS—specifically, placing the patient in a prone position. The proning of a patient while on mechanical ventilation may improve oxygenation through increased recruitment of collapsed posterior alveolar units and reduction in the V/Q mismatch. Via gravity, blood flow is directed to the better-aerated anterior portion of the lungs. It is best used in patients with severe ARDS if other ventilator strategies have not been successful. Careful, well-planned teamwork is required to successfully and safely put a critically ill patient with many IV lines and tubes in a prone position (see Evidence-Based Practice: The Use of Prone Positioning in the Patient with ARDS).

## Evidence-Based Practice

### The Use of Prone Positioning in the Patient With ARDS

#### Benefits:

- Dorsal lung reexpansion with improved oxygenation
- Aiding in secretion and extravascular water distribution, which decreases stress on the soft tissues of the lung
- Improved lung recruitment—opens more alveoli, improving oxygenation
- Reducing the need for higher PEEP and FIO<sub>2</sub>, decreasing ventilator-induced lung injury (VILI)
- Overall effects reduce mortality in the ARDS patient.

#### Implementation:

- Should be implemented within 72 hours of diagnosis
- Up to 20 hours per day in the prone position is recommended for the best results.
- Can be accomplished by manually turning the patient in bed or by using a mechanical device that can turn

the patient as needed and place the patient in the Trendelenburg or reverse Trendelenburg position as needed

#### Contraindications:

- Spine instability
- Conditions that increase intracranial pressure
- Pregnancy—possible concerns
- Abdominal wounds—possible concerns
- Unstable peripheral fractures or rib fractures—possible concerns
- Need for frequent airway access—possible concerns

#### Nursing Considerations:

- Any change in baseline oxygenation parameters after proning should be cause for a new ABG determination.
- Eye and facial skin care must be an integral part of the patient's ongoing care, including eye lubricant and padding of areas of the face as required.
- Sedation may be required due to patient anxiety during the process.
- Enteral feedings should be stopped at least 1 hour before proning, and parenteral feeding may need to be considered.
- Ensure all tubes are free of compromise during the proning procedure and evaluated frequently during the process.
- Have a plan in place for a rapid return to the supine position in the case of hemodynamic compromise or cardiac arrest.
- Educate the family members on this process—including the pros and the cons—and answer all questions related to this treatment modality

ABG, Arterial blood gas; ARDS, acute respiratory distress syndrome; PEEP, positive end-expiratory pressure.

Drahnak, D. M. (2015). Prone positioning of patients with acute respiratory distress syndrome. *Critical Care Nurse*, 35(6), 29–37. doi:10.4037/ccn2015753

Munshi, L., Del Sorbo, L., Adhikari, N. K., Hodgson, C. L., Wunsch, H., Meade, M. O., . . . Fan, E. (2017). Prone position for acute respiratory distress syndrome. A systematic review and meta-analysis. *Annals of the American Thoracic Society*, 14(Suppl. 4), S280–S288.

#### Medications

If the cause of ARDS is infection, antibiotics are administered, broad spectrum initially, then narrow spectrum after the causative pathogen is identified. Corticosteroids are also used to decrease the inflammatory response, but their use for the treatment of a patient with ARDS is controversial. There is no evidence that the use of steroids improves

mortality and morbidity, but the anti-inflammatory properties are thought to reduce the migration of white blood cells to the affected areas of the lung. There is also some research that shows that there are less fibrotic changes in the lung during the fibrotic phase of the process. On the negative side, the use of corticosteroids can blunt the body's inflammatory response, making the patient more susceptible to secondary infections. Research regarding steroid use in ARDS is ongoing.

Neuromuscular blocking agents or paralytics are sometimes used when patients are mechanically ventilated. Neuromuscular blocking agents reduce the risk of barotrauma because of controlled patient–ventilator synchrony; the patient cannot take a breath out of sync with the ventilator. They also reduce oxygen demand by limiting muscle movement. If neuromuscular blocking agents are used, the patient must also receive pain and sedative medication to ensure optimum comfort during treatment. As stated earlier, the patient can be managed with the judicious use of sedatives without the use of paralyzing medications if on APRV mechanical ventilation. Paralytic agents are most often used for patients with severe ARDS, and their use must be reevaluated daily for each patient.

#### Hydration

Fluid management is an important component in the care of a patient with ARDS. Adequate hydration is necessary to maintain circulatory volume and also avoid issues with thick, dry secretions that may be difficult to clear and potentially cause plugged airways. Complicating the management of fluid balance is a decrease in venous return to the right side of the heart because of the increased intrathoracic pressure associated with the use of PEEP. This results in a decrease in cardiac output and systemic blood pressure, potentially requiring fluid resuscitation. If too much fluid is given, ARDS can worsen because of the increased permeability of the ACM. If an insufficient amount of fluid is administered, preload and blood pressure may decrease, resulting in decreased perfusion to the brain and other vital organs. The patient's urine output and hemodynamic volume status should be carefully monitored via a central venous or pulmonary artery (PA) catheter. Hemodynamic monitoring is discussed in detail in Chapter 32.

#### Nutrition

Adequate nutrition is a very important component of care for a critically ill patient with ARDS. Acute respiratory distress syndrome is associated with a proinflammatory, hypermetabolic state. Without adequate nutrition, malnutrition, loss of body mass, and reduced respiratory muscle strength can result. Enteral (nasogastric tube feedings through the gastrointestinal tract [GI]) or parenteral (IV nutrition via a peripheral or central venous catheter) nutrition should be initiated within 48 to 72 hours of the initiation of mechanical ventilation. Enteral nutrition is the

preferred method unless contraindicated because of GI issues. Both have risks associated with them. Tube feedings are associated with aspiration, so care must be given to ensure that the feeding tube is properly placed, the head of the bed is elevated, and the tube feeding is turned off during those times when the patient is completely supine. Parenteral nutrition is associated with increased infections via the venous catheter.

## Complications

### Barotrauma

Acute respiratory distress syndrome results in a stiffening of the lungs and a loss of compliance (elasticity), requiring careful application of tidal volume and PEEP to maximize oxygenation without causing barotrauma. The patient is at risk for alveolar or lung rupture, resulting in **pneumomediastinum** (air in the mediastinal space) or **pneumothorax** (air in the pleural space), causing further hypoxemia.

### Renal Failure/Multisystem Organ-Dysfunction Syndrome

Renal failure is a frequent complication of ARDS due to hypotension and the use of nephrotoxic medications to treat infection. It also may indicate the progression of ARDS to multisystem organ-dysfunction syndrome (MODS). Multisystem organ-dysfunction syndrome results from prolonged refractory hypoxemia, hemodynamic instability, and the inflammation associated with sepsis. Multisystem organ-dysfunction syndrome is discussed in detail in Chapter 14.

### Ventilator-Associated Pneumonia

Any patient on mechanical ventilation is at risk for ventilator-associated pneumonia (VAP). When a patient has an artificial airway in place, normal mechanisms to protect the patient from pneumonia are compromised. The primary risks for pneumonia include the inability of the epiglottis to close and the potential drying out of the trachea and upper airways. Ventilator-associated pneumonia is difficult to detect when a patient is already ventilated because of ARDS, but there are some assessment findings that indicate its occurrence. Development of fever, leukocytosis, increased respiratory effort, and purulent secretions are hallmark signs of VAP. Sputum cultures will indicate infection. The earlier VAP is diagnosed, the earlier it can be treated.

Ventilator-associated pneumonia can be prevented by instituting some basic preventive techniques, such as regular mouth care (see Evidence-Based Practice: Preventing Ventilator-Associated Pneumonia). Suctioning of the ETT must be performed routinely as needed, as well as oropharyngeal suctioning to remove secretions from the mouth and throat. The ventilator circuit should be changed per hospital protocol, and care must be taken to avoid water buildup in the circuit. Sterile water should be used for the humidification of the air being delivered to the patient.

## Evidence-Based Practice

### Preventing Ventilator-Associated Pneumonia (VAP)

Important interventions to prevent VAP:

- Perform mouth care every 2 hours.
- Brush teeth every 12 hours with chlorhexidine.
- Keep the head of the bed elevated at all times at 30 degrees to prevent gastric aspiration.
- Conventional endotracheal tubes (ETTs) should be replaced with ETTs with subglottic secretion drainage. These are ETTs that have an extra port above the inflated cuff that is connected to low continuous suctioning. This prevents secretions that sit above the cuff from becoming infected with bacteria and then oozing down around the cuff into the airway, infecting the airway.

Prevention of ventilator-associated pneumonia in adults. (2017). *Critical Care Nurse*, 37(3), e22–e25. doi:10.4037/ccn2017460

## Nursing Management

### Assessment and Analysis

The clinical manifestations of ARDS are due to the refractory hypoxemia, pulmonary edema, and lung parenchymal changes of ARDS. The patient's increased work of breathing, evidenced by dyspnea, tachypnea, and accessory muscle use, may be the first indication present. Auscultation of breath sounds reveals crackles associated with pulmonary edema. Later, breath sounds may be diminished or absent because of the fibrotic lung changes and atelectasis. Anxiety and agitation may result from hypoxemia. The SpO<sub>2</sub> continues to decrease despite increasing FIO<sub>2</sub> levels. Initially, the ABGs demonstrate respiratory alkalosis due to the hyperventilation. Later, respiratory acidosis develops.

### Nursing Diagnoses

- **Impaired gas exchange** related to disrupted pulmonary function as evidenced by increased work of breathing, refractory hypoxemia, and increased oxygen demand
- **Anxiety** related to hypoxemia, lack of cerebral perfusion, and loss of personal control
- **Imbalanced nutrition, less than body requirements**, related to increased metabolic demand

### Nursing Interventions

#### ■ Assessments

- Hemodynamic monitoring
  - Vital signs

*The pulse increases because of hypoxemia; this is a compensatory mechanism of the sympathetic nervous system in an attempt to increase oxygenation. The respiratory rate increases also in an attempt to increase oxygenation. Blood pressure may be decreased because of right-side heart failure and the increased intrathoracic pressure, thus the decreased venous return associated with PEEP.*

- SpO<sub>2</sub>/pulse oximetry  
*The pulse oximetry reading may be low because of the V/Q mismatch and intrapulmonary shunting.*
  - Central venous pressure (CVP) or pulmonary artery (PA) pressure monitoring  
*The CVP or PA pressure may be variable. They may be decreased because of the decreased venous return related to increased intrathoracic pressure. They may also be increased due to increased vasoconstriction in the lung.*
  - Neurologic assessment: level of consciousness (LOC) and pupillary assessment must be done at least every 1 to 2 hours.  
*The patient with ARDS is at risk for neurological compromise due to the refractory hypoxemia and potential increase in PaCO<sub>2</sub> that can result in cerebral vasodilation. Frequent checks are necessary, especially if the patient is heavily sedated and chemically paralyzed or has a decreased ability to communicate due to intubation and mechanical ventilation.*
  - Respiratory assessment  
*Crackles may be auscultated because of fluid buildup in the alveoli due to increased capillary permeability. Later, they may be diminished because of atelectasis and fibrotic changes in the lungs.*
  - Monitor urine output.  
*A decreased urine output is an early sign of poor oxygen delivery to the tissues and shock.*
  - Monitor mechanical ventilation.  
*Frequent monitoring of airway pressure on the ventilator is vital. Increases in airway pressure may indicate the presence of secretions or worsening lung compliance. Decreases in airway pressure may indicate a leak in the system.*
  - Monitor the ECG.  
*Hypoxemia can lead to cardiac dysrhythmias.*
  - Laboratory tests
    - ABGs  
*Initially, hypoxemia and respiratory alkalosis secondary to poor gas exchange and hyperventilation are present. Later, respiratory acidosis may occur because of increased PaCO<sub>2</sub> levels and the permissive hypercapnia of low-tidal-volume ventilation. Later, metabolic acidosis may be present because of worsening hypoxemia and decreased oxygen delivery to the tissues, signaling the transition to anaerobic metabolism.*
    - Serum lactate level  
*Increased serum lactate confirms anaerobic metabolism.*
    - Liver/renal function blood tests  
*Abnormal renal and liver values indicate the progression of ARDS to MODS.*
    - Blood/sputum cultures/CBC  
*Positive cultures may indicate the cause of ARDS. Later, positive cultures may be present because of complications associated with critical illness, such as indwelling lines and catheters or VAP. A CBC indicating an increased white blood cell count is another indicator of infection.*
  - Skin assessment  
*Patients are at increased risk for skin breakdown due to immobility and hypoxemia/hypoxia.*
  - Chest x-ray  
*Daily chest x-rays are done to monitor the progression or improvement of ARDS.*
- **Actions**
- Airway suctioning when indicated by the presence of secretions to ensure that the ETT is clear  
*The ETT must remain clear of secretions to facilitate the delivery of ventilatory volume; increased secretions require increased pressure to deliver the preset volume or may actually block the ETT. Secretions are also a source of infection.*
  - Medication administration
    - Administer paralytic agents, analgesics, and sedative medications as ordered.  
*Allows for maximum patient comfort during mechanical ventilation. Respiratory effort and patient-ventilator synchrony must be optimized to avoid barotrauma.*
    - Administer inotropic/vasoactive agents as ordered.  
*Inotropic medications are used to augment cardiac output; vasoactive medications may be necessary to support blood pressure.*
    - Administer antibiotics as ordered.  
*Antibiotics are necessary to treat infection if that is the cause or a complication of the critical illness.*
  - Patient positioning/activity
    - Placing the patient in the prone position—proning  
*Proning allows for better oxygenation and alveolar recruitment by having the “good” side down. Proning increases the recruitment of collapsed posterior alveolar units and reduces the V/Q mismatch via gravity as blood flow is directed to the better-aerated anterior portion of the lungs.*
    - Elevate the head of the bed.  
*Elevating the head of the bed allows for better lung expansion and reduces the risk of aspiration.*
    - Frequent position changes  
*Frequent changes of position (as tolerated) help prevent skin breakdown.*
    - Range-of-motion (ROM) exercises  
*Range-of-motion exercises are necessary in the sedated or medically paralyzed bed-bound patient to preserve limb functioning and decrease contracture (severe joint stiffness).*
  - Infection protection/prevention
    - Hand washing  
*Hand washing is the number one intervention in the effort to prevent infection.*
    - Monitoring and care of central IV lines  
*Central lines are a significant source of infection. Maintenance of strict sterile technique on insertion is key to infection prevention. Routine monitoring for redness or drainage at the insertion site, dressing changes per hospital protocol, IV tubing changes per hospital protocol, and evaluation of the continued need for many invasive lines are also key to preventing central line infection.*
    - Foley catheter care  
*Increased risk for iatrogenic infections such as urinary tract infection (due to Foley catheter) requires routine Foley catheter care and evaluation of necessity of continued use.*

- Diligent mouth care  
*Increased risk for VAP due to intubation requires mouth care every 2 hours.*

### ■ Teaching

- Disease process  
*The patient and the patient's support system should understand the pathophysiology of ARDS, the severity of the disease, and the treatment required. Understanding the medications, invasive lines, and mechanical ventilation may help decrease anxiety and provide some sense of control. Providing time for visiting as possible may help the family stay engaged and involved in the family member's care. Visiting also provides tremendous support for the patient.*

### Evaluating Care Outcomes

Successful treatment of a patient with ARDS should be considered a victory because of the high mortality rate. The optimal outcome for a patient with ARDS is to return to baseline respiratory function and a return to a lifestyle similar to that prior to the illness. Ideally, there are no long-term respiratory issues, but in reality, ARDS can do significant damage to the lungs and thereby impacts the patient's life post-discharge. The physical weakness, early fatigue, and change in lifestyle can take a tremendous toll on the patient. Helping the patient mentally adjust to any residual physical limitations is something that should be stressed for both family members and the healthcare team. Counseling may be required. Consistent medical follow-up and a realistic rehabilitation regimen maximize the patient's recovery.

## CHEST TRAUMA

### Epidemiology

Thoracic (chest) trauma accounts for approximately 16,000 deaths annually. Thoracic trauma is the direct cause in 20% to 25% of all trauma-related deaths and is a contributory cause for an additional 20% to 25% of deaths. Motor vehicle collisions (MVCs) are the most prevalent cause of thoracic injuries seen in emergency departments and trauma centers. In 2016, there were 34,439 MVCs resulting in fatality, with an overall number of 37,461 fatalities. These numbers have been decreasing over the past few years, most likely because of the increase in air bags in new cars and the improvement in car manufacturing to decrease crash fatalities. Older drivers (greater than 60 years of age) are more susceptible to injury. Other risk factors for injury include rate of speed, size of the vehicle, and seat-belt use or lack thereof. At speeds greater than 25 miles per hour, the vehicle's occupants are more likely to be injured. At greater speeds, driver reaction time is increased, meaning it takes longer to process and react to danger; there is a greater collision impact and a higher chance that objects may enter the passenger compartment on impact. This is called *intrusion* and can cause injury secondary to the collision. In a vehicle-to-vehicle collision, a smaller car provides limited protection, especially if struck by a larger vehicle. Finally,

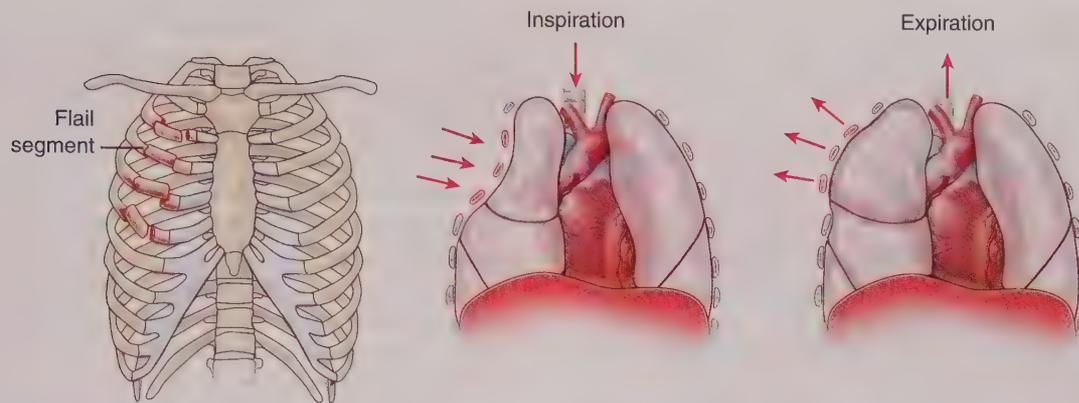

not wearing a seat belt puts drivers and passengers at risk of injury because of the collision with hard surfaces in the car, such as the dash, steering wheel, or windshield.

### Pathophysiology

Chest trauma is divided into two types: blunt-force and penetrating trauma. Blunt chest trauma is the result of a blunt object hitting the chest or the chest striking a blunt surface such as a steering wheel. Blunt-force injuries can be further characterized as acceleration or deceleration injuries. Deceleration is when the movement of the body is suddenly stopped but the internal organs remain in motion and collide with the chest wall. Acceleration injury occurs when the body is abruptly set in motion (rear-end collisions) or when the body is hit by a rapidly moving object. When either occurs, chest organs and tissues are subject to impact and shearing forces. Blunt-force trauma is more diffuse than penetrating trauma and may cause injuries that may not be obvious at the time of initial assessment. Penetrating trauma is the result of sharp objects such as knives or bullets entering the chest and causing damage to internal structures or organs. Other causes of penetrating injury are objects that enter a motor vehicle during a collision (intrusion) or shrapnel from explosions. The depth, angle, and location of the penetration can differentiate whether the penetrating trauma is a superficial wound or is potentially life threatening. A gunshot wound into the lateral right chest, missing all major vessels, may be superficial. A gunshot wound to the middle of the left chest is life threatening.

Common injuries occurring as a result of chest trauma include fractured ribs, pneumothorax, and hemothorax. Fractured ribs are the most common injury associated with chest trauma. Normal chest wall movement—the diaphragm moving downward and the external intercostal muscles moving the rib cage up and outward—assists in generating the negative pressure required for inspiration and effective ventilation. When ribs are fractured, the integrity of the entire thorax and chest-wall movement are compromised. The patient cannot take deep, effective breaths, largely because of pain, effectively limiting the ability to maintain normal tidal volumes with each breath. Also, depending on the location of the rib fractures, there may be collateral penetrating damage to organs and vessels located near the site of injury, such as the liver.

A **flail chest** is defined as three or more adjacent ribs that have been fractured in two or more places as a result of blunt or crush chest trauma, resulting in a “free” segment of the ribs. “Paradoxical” chest-wall movement is the hallmark sign associated with a flail chest. With each inhalation, the damaged area moves inward; on exhalation, this section of the chest wall moves outward (Fig. 27.4). As with rib fractures as described previously, chest-wall movement is compromised largely because of pain and may result in respiratory insufficiency. The severity of the injury and the treatment are determined by the extent of the underlying lung injury or contusion more so than by the fractures themselves.

**FIGURE 27.4** Flail chest. Paradoxical chest wall movement; on inhalation, the damaged area moves inward; on exhalation, the damaged area moves outward.

A pneumothorax may result from severe blunt or penetrating chest trauma where there is a disruption of the integrity of the lung parenchyma (Fig. 27.5). Pneumothorax is defined as the collection of air in the pleural space. A normal lung inflates during inspiration because of negative thoracic pressure in relationship to atmospheric pressure. As the diaphragm descends, the lung expands; air enters the airways and eventually fills the alveoli via the terminal bronchioles. When a pneumothorax occurs, there is a reduction in the negative thoracic pressure because of the presence of air in the pleural space. This makes inspiration more difficult, and the lung cannot adequately expand. This results in a reduction of gas exchange at the alveolar level, resulting in hypoxemia.

Different from a pneumothorax, a **hemothorax** is the presence of blood in the pleural space. It occurs if there has been a laceration of a pulmonary vessel with blunt or penetrating trauma. A hemothorax may result in two problems for the patient. As with pneumothorax, as blood fills the pleural space, the negative pressure is lost, limiting the lung's ability to expand. Second, the loss of blood from the

vascular space may result in hemodynamic compromise. Drainage greater than 1,500 mL is considered massive, and the patient may become hemodynamically unstable.

### Clinical Manifestations

With all chest trauma, clinical manifestations may include decreased oxygenation and ventilation. Because of the inability to fully inflate the lungs, gas exchange is compromised, resulting in decreased oxygenation. Initially, hyperventilation occurs in an effort to increase oxygen availability to the tissues, but eventually, as the patient tires,  $\text{CO}_2$  will begin to rise. Initial ABGs may indicate respiratory alkalosis due to hyperventilation, but respiratory acidosis will develop rapidly as  $\text{CO}_2$  is not exchanged. An early sign of hypoxemia is agitation and anxiety, then a decreased level of consciousness. The patient typically reports shortness of breath. Subcutaneous emphysema, or air in the tissues under the skin, may occur with blunt trauma and pneumothorax. Pain is also a common clinical manifestation, further compromising chest-wall expansion and thus oxygenation and ventilation. The patient may exhibit splinting, assuming a protective posture around the site of injury. The arm on the affected side is held tightly against the body, and the patient bends to that side. This position further compromises lung expansion on the side of injury, and pneumonia may ultimately result.

### Management

#### Medical Management

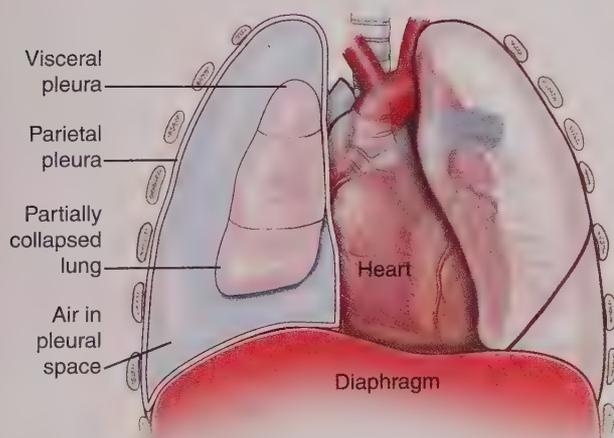

#### Diagnosis

#### Imaging Studies

Diagnostic evaluation following chest trauma includes several imaging studies, such as:

- Chest x-ray
- Ultrasonography
- Chest CT

A chest x-ray is done to evaluate the skeletal features of the chest and to evaluate the integrity of the lungs. The x-ray is viewed to look for fractures, lung expansion, or

**FIGURE 27.5** Pneumothorax. There is a reduction in the negative thoracic pressure because of air in the pleural space, resulting in an inability of the lung to fully expand.

mediastinal damage. A pneumothorax or hemothorax is visible on x-ray.

Ultrasound, also known as focused assessment with sonography in trauma (FAST), is a valuable tool for a quick assessment in an emergency situation. It can be used to rule out a **cardiac tamponade** (blood in the pericardium resulting in compression of the heart, to be discussed under complications), a life-threatening injury if not quickly treated. In addition, FAST is more sensitive and specific in diagnosing pneumothorax and hemothorax.

Chest CT may be performed upon a patient's arrival to the emergency department in the case of high-impact thoracic trauma. High-impact trauma involves rapid deceleration and may result in chest-wall deformities, multiple rib fractures, pneumothorax, or hemothorax. An abnormal chest x-ray indicating any of these conditions requires subsequent evaluation using CT. It is extremely useful in determining damage to the mediastinum or the aorta.

### Laboratory Studies

Laboratory analysis includes:

- ABGs
- Serum lactate
- Hemoglobin/hematocrit
- CBC and complete metabolic profile, coagulation studies, and a type and crossmatch in the event that the patient needs a blood transfusion

Arterial blood gases are used to determine whether hypoxemia and abnormalities in the acid-base balance exist. As noted earlier, initial ABGs may indicate respiratory alkalosis due to hyperventilation, but the patient will quickly develop respiratory acidosis because of ineffective gas exchange and tiring.

A serum lactate level may be drawn to determine the adequacy of oxygen delivery to the tissues. If the respiratory system is significantly compromised, resulting in insufficient oxygen for cellular metabolism, anaerobic metabolism results. This causes the production of lactic acids, resulting in a rise in lactate levels within hours.

The hematocrit and hemoglobin may be reduced if there is any bleeding. This is important because the bleeding may be internal and not readily observable. Diagnostic imaging assists in identifying any bleeding within the chest.

Routine laboratories are drawn in any trauma situation. They include electrolyte panels, CBC, and coagulation studies as well as patient-specific tests. For example, if the patient is known to have heart failure, a B-type natriuretic peptide (BNP) and cardiac enzymes (myoglobin, troponin, and creatine kinase-muscle/brain [CK-MB]) may also be drawn.

### Treatment

Treatment is guided by the common acronym ABC (airway, breathing, and circulation).

**Airway:** Evaluate the airway—Is the airway patent? Does the patient show any sign of respiratory compromise or obstruction? Partial or complete obstruction is a

medical emergency and should be fully evaluated. Intubation may be necessary to provide an adequate airway.

**Breathing:** Does the patient demonstrate the ability to breathe without any compromise in gas exchange? Is there chest-wall damage or other signs of respiratory compromise as indicated by abnormal ABGs, increased work of breathing, or signs of hypoxemia or hypercapnia? If not severe and the patient is able to protect the airway, the application of oxygen may be sufficient. If not, intubation and assisted ventilation may be necessary. If a pneumothorax or hemothorax is present, chest tube insertion may be required to facilitate breathing and adequate oxygenation (Box 27.2).

**Circulation:** Is circulation sufficient? Does the patient have adequate pulses and skin color? Is the blood pressure within normal limits? If not, IV fluid resuscitation may be required to maintain hemodynamic stability. If the injury has resulted in blood loss, as in the case of a hemothorax, blood transfusions may be indicated.

**Safety Alert** If the chest tube becomes disconnected from the drainage system, immediately submerge the end of the chest tube in sterile water to preserve the water seal. This prevents air from entering through the disconnected chest tube and reaccumulating in the pleural space. As quickly as possible, reconnect to a new chest tube system. Be aware of hospital policy. Some hospitals have protocols that allow the immediate reconnection to the original system.

If the chest tube becomes dislodged from the chest, apply a Vaseline gauze dressing and notify the provider immediately. Prepare for insertion of a new chest tube.

## Box 27.2 Chest Tube Placement

Chest tube placement is indicated if a pneumo- or hemothorax occurs as the result of chest trauma. In the case of a pneumothorax, because air rises, the chest tube is placed high, usually in the second intercostal space at the mid-clavicular line. For a hemothorax, due to the effects of gravity, the chest tube is placed lower, between the ribs at the fifth or sixth intercostal space at the midaxillary line, in order to drain blood and fluid from the pleural space.

Chest tube placement allows for the expulsion of air and/or fluid while allowing the lung to reexpand. The chest tube is connected to a chest-drainage system. Essential components of the chest-drainage system include a collection chamber, water seal, and suction. The collection chamber allows for the accumulation of blood and fluid. The water seal acts like a one-way valve, allowing for the removal of the air/blood over time without the introduction of air back into the pleural space. Initially, suction is applied to assist in the reexpansion of the lung. The suction is discontinued as the lung reexpands.

### Medications

Medications used for the patient suffering from chest trauma are primarily analgesic. A patient in extreme pain may not breathe deeply enough to avoid atelectasis. Initially, IV narcotic analgesia such as morphine is prescribed. A regional block or epidural analgesia may be administered to reduce pain without the narcotic side effects. This allows the patient to breathe more effectively. If there has been penetrating trauma, the patient is at an increased risk for an infection, so prophylactic broad-spectrum antibiotics may be prescribed.

### Connection Check 27.5

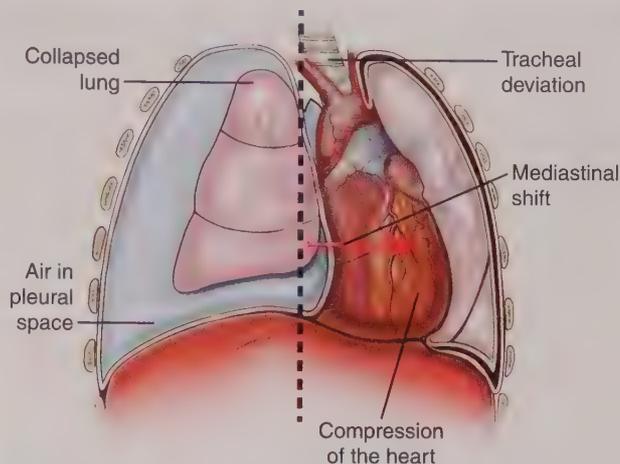

The nurse understands that the priority action for a patient with a chest tube that has come disconnected from the chest-drainage system is which of the following?

- Immediately cover the end of the chest tube with a sterile dressing.
- Immediately submerge the end of the chest tube in sterile water.
- Immediately reconnect the end of the chest tube with the drainage system.
- Immediately page the provider to insert a new chest tube.

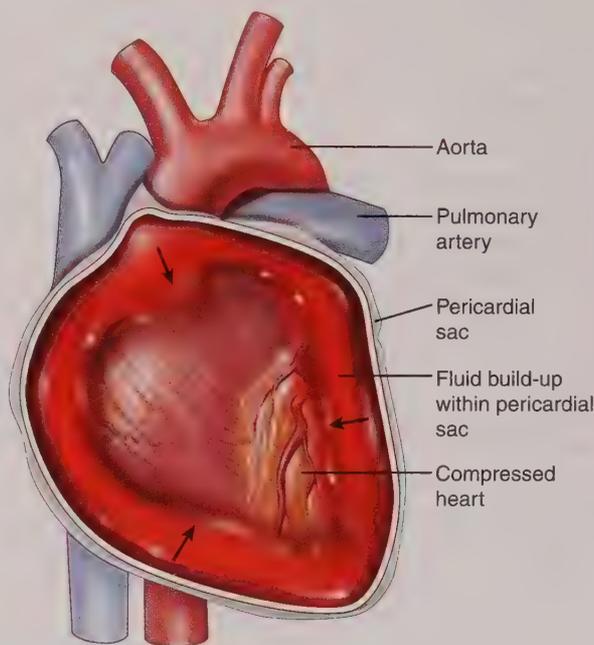

### Complications

**Tension pneumothorax** (Fig. 27.6) may occur if air or blood collects in the pleural space and is not removed. If this is left untreated, the positive pressure in the pleural cavity increases, and the affected lung collapses. As the positive pressure increases, it may cause a mediastinal shift toward the unaffected side. This can result in compression of the heart, vena cava, aorta, and contralateral (unaffected) lung. Tracheal deviation toward the unaffected side is a hallmark sign of tension pneumothorax. This is a life-threatening emergency because left ventricular heart failure and reduced cardiac output can occur. In emergent cases of tension pneumothorax, a needle decompression, performed to remove the air from the pleural space, may be required. A large-bore needle (14- or 16-gauge) is inserted between the ribs at the second intercostal space at the midclavicular line to allow for rapid evacuation of air or blood. This is immediately followed by chest tube insertion.

Cardiac tamponade is caused by excessive air, fluid, or blood collecting in the pericardial sac (Fig. 27.7). When this occurs, the heart cannot adequately fill or contract because of the compression of the ventricles. It can manifest as hypotension, muffled heart sounds, and distended neck veins, which are known collectively as Beck's triad. Cardiac tamponade due to fluid accumulation in the pericardial sac is treated with a pericardiocentesis, the insertion of a large-bore needle into the pericardial space to drain the fluid. A small pericardial catheter (similar to a small chest

**FIGURE 27.6** Tension pneumothorax. Accumulation of air or blood in the pleural space may result in a mediastinal shift and tracheal deviation toward the unaffected side, causing compression of the heart, vena cava, aorta, and unaffected lung.

**FIGURE 27.7** Cardiac tamponade.

tube but more flexible) may be placed to allow for continued drainage of the fluid until the cause can be determined and managed. A tension pneumothorax can create the same set of symptoms: compression of the heart due to the mediastinal shift, resulting in inadequate filling and contraction of the ventricles. Cardiac tamponade due to tension pneumothorax from excessive pleural effusion fluid collection is treated with an emergent thoracentesis; a needle insertion between the ribs for fluid removal.

### Surgical Management

Surgical management may be indicated for patients with an unstable chest wall. In severe cases of flail chest, operative stabilization may be required. Thoracotomy, a surgical excision to the chest wall, is an option if the chest trauma

has resulted in damaged organs or major vessels. In some cases, it may be necessary to evacuate clots or foreign material from the pleural space.

### Connection Check 27.6

You are caring for a client who sustained a chest injury following a motor vehicle collision, requiring a chest tube, and is receiving morphine via patient-controlled analgesia (PCA) for pain. Which of the following would alarm you and initiate a call to the primary care provider?

- A. Somnolence
- B. Restlessness and anxiety
- C. Itching at the IV site
- D. Minimal amounts of bloody chest tube drainage

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of chest trauma are caused by damage to the chest wall and/or lungs causing problems with ventilation and oxygenation. They include all of the following:

- Tachypnea/hyperventilation
- Tachycardia
- Shortness of breath
- Decreased oxygenation
- Decreased level of consciousness
- Decreased or absent lung sounds
- Asymmetrical chest excursion (in the case of a flail chest)
- Subcutaneous emphysema (air under a layer of the skin)

#### Nursing Diagnoses

- **Impaired gas exchange** related to hypoventilation and pain
- **Acute pain** related to structural damage secondary to fractured ribs; presence of chest tube
- **Decreased cardiac output** related to hemorrhage and decreased circulating volume (hemothorax)

#### Nursing Interventions

##### Assessments

- **Respiratory effort**  
*Increased work of breathing such as shortness of breath, accessory muscle use, or nasal flaring may indicate a need for further evaluation and treatment of chest trauma or pneumothorax and/or a need for an advanced airway*
- **Vital signs and pulse oximetry (SpO<sub>2</sub>)**  
*Tachypnea and tachycardia may occur in response to decreased oxygen levels and increased oxygen demands and/or pain. Hypotension can indicate tension pneumothorax or cardiac tamponade due to compression of the heart, vena cava, and aorta. Hypotension can also indicate excessive blood loss with a hemothorax. Decreased SpO<sub>2</sub> may be present if there is ineffective respiration due to pain or*

*injury. Continuous readings help evaluate the response to treatment.*

- **Pain**  
*Severe pain due to fractures may limit the patient's ability to breathe deeply, which may result in decreased gas exchange.*
- **Level of consciousness**  
*Agitation, anxiety, and eventually, a decreased LOC may result from hypoxemia.*
- **ABGs**  
*Initial ABGs note a respiratory alkalosis due to tachypnea and hyperventilation. A decreased PaO<sub>2</sub> may be present because of the impaired ventilatory effort and decreased surface area available for gas exchange in a collapsed lung.*
- **Chest tube**
  - **Amount and color of drainage**  
*Red, free-flowing drainage in excess of 70 mL per hour (or the amount indicated by the provider) indicates hemorrhage; cloudiness may indicate an infection.*
  - **Water-seal chamber**  
*Initially, there is bubbling on expiration, indicating air removal from the pleural space. Later, after the air has escaped from the pleural space, the water level fluctuates with respiratory effort. When the pleural-wall disruption is healed, the water fluctuation may no longer be present. At that point, the patient should be evaluated for chest-tube removal. Continuous bubbling in the water-seal chamber is an indication of an air leak.*
- **Subcutaneous emphysema**  
*Subcutaneous emphysema produces a crackling feeling under the skin. It is not painful to the patient but may become uncomfortable if excessive. It is indicative of air from a chest injury escaping into the subcutaneous space, indicating potential chest trauma. Subcutaneous emphysema of the head and neck could be life threatening because the airway could be compromised.*

##### Actions

- **Apply oxygen as ordered.**  
*The patient with a chest injury is at risk for ineffective oxygenation and ventilation. Supplemental oxygen may be necessary.*
- **Anticipate and prepare for intubation.**  
*The patient with a severe chest injury may require an advanced airway to optimize ventilation and perfusion.*
- **Elevate the head of the bed.**  
*Allows for greater lung expansion; assists with work of breathing*
- **Encourage deep breathing and coughing, every 1 to 2 hours.**  
*Prevents atelectasis and assists in keeping airways clear*
- **Encourage ambulation as soon as possible.**  
*Prevents hazards of immobility; assists in returning respiratory function to normal*
- **Chest tube management**
  - **Maintain a closed system. Tape all connections, and secure the chest tube to the chest wall.**  
*These measures are important to prevent inadvertent tube removal or disruption of the system's integrity.*

- Keep the collection apparatus below the level of the chest; keep tubing free from kinks or loops.  
*Pleural fluid drains into the collection apparatus by gravity flow as well as low-level suction. Kinks or loops can interfere with drainage.*
- **NEVER CLAMP THE CHEST TUBE!**  
*Clamping the chest tube may result in increased air or fluid collection in the pleural space, worsening the pneumo- or hemothorax, and may result in a tension pneumothorax.*
- When the chest tube is removed, immediately apply a sterile occlusive petroleum jelly dressing.  
*An occlusive dressing prevents air from reentering the pleural space through the chest wound.*
- Administer pain medications; encourage the use of patient-controlled analgesia before ambulation and pulmonary toileting.  
*Control of the patient's pain allows for more effective pulmonary toileting and assists the patient in being able to tolerate ambulation/physical therapy.*

### Teaching

- Use of pain medications  
*Pain medications should be used to ensure that pain from breathing post-injury does not reduce respiratory effort, which may result in ineffective gas exchange and a worsening of pulmonary status.*
- Importance of:
  - Coughing and deep breathing
  - Ambulation
  - Splinting with pillow while coughing  
*These actions help prevent complications such as atelectasis and pneumonia; splinting aids in patient comfort, allowing better effort.*
- Motor vehicle safety: use seat belts; avoid distracted driving.  
*Seat belts are proven to reduce injury. Distracted driving (e.g., talking on the phone or texting) has been shown to increase the occurrence of MVCs. Never drink and drive!*

### Evaluating Care Outcomes

A well-managed patient following chest trauma has unlabored respiratory effort, and ABGs within normal ranges. Lungs sounds are clear in all fields, and pain is under control. If the patient had a chest tube, skin integrity is intact.

### Connection Check 27.7

The nurse anticipates which of the following in the initial care of a patient with ARDS?

- Inotropic agents
- Fresh frozen plasma (FFP)
- Anticoagulants
- Positive-pressure ventilation

## Making Connections

### CASE STUDY: WRAP-UP

J.T. remains in the intensive care unit (ICU), sedated on the ventilator. His is managed with conventional mechanical ventilation with low tidal volumes to protect his lungs from injury. His fluid balance is managed judiciously. He is started on enteral feeding to support his nutrition. Initially prone positioning is utilized to improve gas exchange. He has frequent position changes and ROM exercises. After 5 days of careful monitoring and meticulous care, J.T. begins to improve. His oxygenation status stabilizes, and he is able to be slowly weaned from the ventilator. By day 7 in the ICU, J.T. is extubated and out of bed to the chair.

### Case Study Questions

- The nurse is aware that J.T.'s hemothorax caused ineffective gas exchange due to which of the following mechanisms?
  - Anxiety due to the need for a chest tube
  - Blood collection in the pleural space reducing negative intrathoracic pressure
  - Pain related to chest tube placement
  - Blood collection in the pleural space increasing negative intrathoracic pressure
- The nurse expects to see what oxygenation and ABG changes for J.T. when his ARDS begins to resolve?
  - New-onset respiratory alkalosis
  - An increasing PaO<sub>2</sub>/FIO<sub>2</sub> ratio
  - Resolving metabolic alkalosis
  - A decreasing PaO<sub>2</sub>/FIO<sub>2</sub> ratio
- The nurse understands that J.T.'s initial "refractory hypoxemia" indicates what about the adequacy of his supplemental oxygen support?
  - It is sufficient, and the FIO<sub>2</sub> can be reduced.
  - It fails to maintain adequate oxygen saturation.
  - It has caused signs of oxygen toxicity.
  - It has caused alveolar collapse.
- Which of the following are priorities in J.T.'s care? (Select all that apply.)
  - Adequate nutritional supplementation
  - Positioning with the good lung down
  - Adequate hydration
  - Maintain NPO status to prevent aspiration
  - Elevate the head of the bed

5. The nurse understands that the rationale for the administration of sedative and analgesic medications to J.T. while on mechanical ventilation is which of the following? (*Select all that apply.*)
- Improve respiratory effort
  - Reduce the pain
  - Decrease oxygen consumption
  - Increase patient-ventilator synchrony
  - Increase mobilization

## CHAPTER SUMMARY

A pulmonary embolism (PE) is defined as the obstruction of the pulmonary artery (or one of its branches) by particulate matter that has an origin elsewhere in the body. When a PE travels to the lungs, it lodges in the pulmonary artery and blocks blood flow. The biggest risk factor is the presence of a deep vein thrombosis (DVT). The most common cause of DVT is prolonged immobility. Medication therapy when treating a patient with acute PE is primarily anticoagulation.

Acute respiratory failure is when one or both of the gas-exchange functions of the lungs are compromised, leading to hypoxemia and/or hypercapnia (hypercarbia). There are two types of acute respiratory failure. Type I is known as acute hypoxemic respiratory failure. Type II is known as acute hypercapnic respiratory failure. Risk factors for hypercapnic failure include disease processes that impair ventilation or cause hypoventilation. Risk factors for hypoxemic failure include disorders that produce a ventilation-perfusion mismatch or that impair diffusion at the alveolar level. Treatment begins with oxygen. The patient in acute respiratory failure

should be placed on a nonrebreather mask with 100% FIO<sub>2</sub>. If the patient's oxygenation status does not improve, non-invasive positive-pressure ventilation (NIPPV) measures may need to be implemented.

Acute respiratory distress syndrome (ARDS) has the following characteristics: acute onset, refractory hypoxemia, and bilateral infiltrates consistent with pulmonary edema. Severity is characterized by the PaO<sub>2</sub>/FIO<sub>2</sub> ratio. In the exudative phase, there is a disruption of the alveolar-capillary membrane (ACM). This disturbance allows fluid to move from the capillaries into the alveoli. In the proliferative phase, surfactant is compromised, alveolar surface tension is lost, and alveoli collapse. In the fibrotic phase, there is the development of fibrotic tissue within the ACM. As the disease progresses, lung compliance decreases, and the work of breathing increases. Mechanical ventilation is initiated for patients with ARDS because of refractory hypoxemia regardless of interventions such as NIPPV and other oxygen therapies.

Chest trauma is divided into two types: blunt force and penetrating. Blunt chest trauma is the result of a blunt object hitting the chest or the chest striking a blunt surface. Blunt-force injuries can also be classified as acceleration or deceleration injuries. Penetrating trauma is the result of sharp objects entering the chest and causing damage to internal structures or organs. In both cases, normal functioning of the respiratory system may be compromised. Examples include rib fractures and flail chest, both of which cause pain that diminishes the respiratory effort. Pneumothorax (air in the pleural space) and hemothorax (blood in the pleural space) result in a loss of the negative intrathoracic pressure necessary for inspiration. Chest tube insertion is required to restore negative pressure. Treatment is guided by the common acronym ABC: airway, breathing, circulation. Life-threatening complications include tension pneumothorax and cardiac tamponade. Both are medical emergencies and require immediate intervention.

## Promoting Health in Patients With Circulatory or Perfusion Disorders

### Chapter 28

## Assessment of Cardiovascular Function

*Nancy Sullivan*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the major anatomical components of the heart and cardiovascular system
2. Discussing the electrical and mechanical components of the cardiac cycle
3. Reviewing the components of cardiac output
4. Explaining assessment parameters incorporated into the history and physical of a cardiovascular examination
5. Describing the implications of selected diagnostic evaluations
6. Explaining nursing considerations for diagnostic studies relevant to cardiovascular function
7. Discussing changes in cardiovascular function related to aging

#### CONCEPTS

- Assessment
- Nursing Roles
- Oxygenation
- Perfusion

#### ESSENTIAL TERMS

Absolute refractory period	Coronary angiography
Afterload	Cyanosis
Arteries	Depolarization
Atria	Diastole
Atrial kick	Echocardiography
Atrioventricular (AV) node	Electrocardiogram (ECG)
Atrioventricular (AV) valves	Heart rate (HR)
Baroreceptors	Preload
Bundle branch	Purkinje fibers
Bundle of His	Relative refractory period
Capillaries	Renin-angiotensin-aldosterone system
Cardiac action potential	Repolarization
Cardiac catheterization	Semilunar valves
Cardiac output (CO)	Sinoatrial (SA) node
Cardiac stress test	Stroke volume
Chemoreceptors	Systole
Chest x-ray (CXR)	Veins
Chordae tendineae	Ventricle
Contractility	

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

John Smith, a 57-year-old Caucasian male, has an appointment for his first physical in 4 years. He is in excellent health, with no particular complaints except “aches and pains after a hard day’s work.” He has no significant past medical history (PMH), takes no medications, and has no allergies. He is about 30 pounds overweight and drinks about five evenings a week. He quit smoking 2 years ago after smoking off and on for about 10 years. He does not exercise but does do heavy-lifting work around the house. Family history includes paternal death at 60 due to myocardial infarction; his mother is still alive and well ...

## OVERVIEW OF THE CARDIOVASCULAR SYSTEM

The primary function of the cardiovascular system is to deliver oxygenated blood to the tissues and return deoxygenated blood to the heart. This is accomplished through the interaction of a muscular pump, the heart (Fig. 28.1), and a large complex of arteries and veins (Fig. 28.2). The primary job of the heart is to propel blood from its left side

into the aorta and the systemic circulation to provide oxygen and nutrients to the tissues. The amount of blood ejected from the left heart, the **cardiac output (CO)**, varies depending on the body’s metabolic demands, increasing with exercise and decreasing when at rest. After circulating throughout the body, the blood returns to the right heart through the great veins, the superior and inferior vena cavae, to be delivered to the lungs to receive oxygen and remove carbon dioxide.

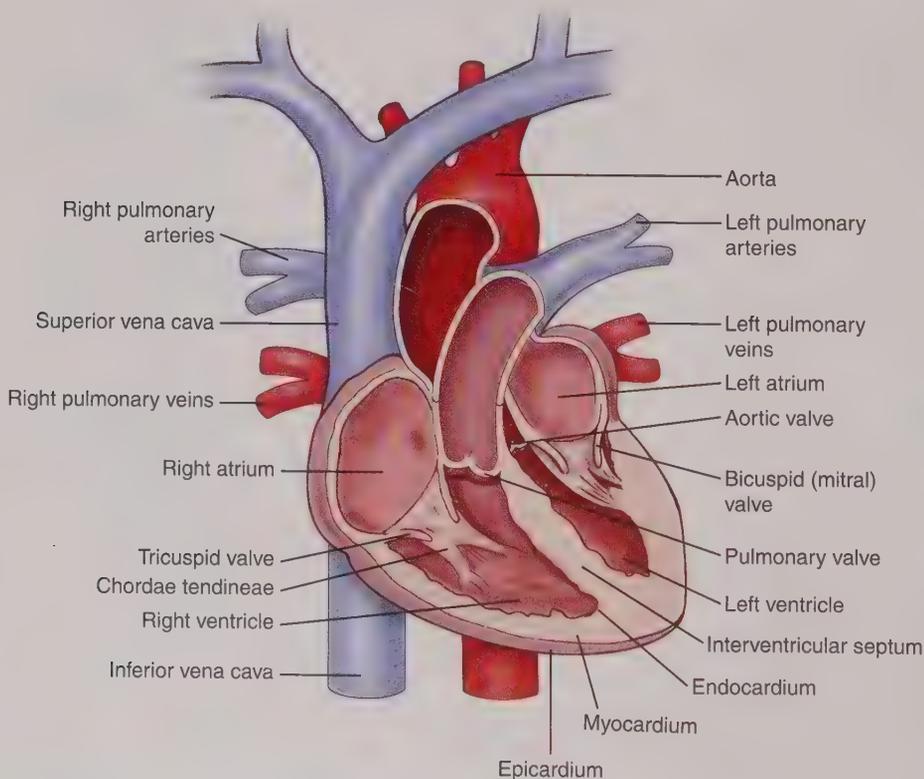

## Vascular System

The arterial and venous vascular systems consist of a combination of arteries, veins, and **capillaries**. With the exception of the pulmonary artery, arteries carry oxygenated blood. Veins convey deoxygenated blood. The vascular system provides for:

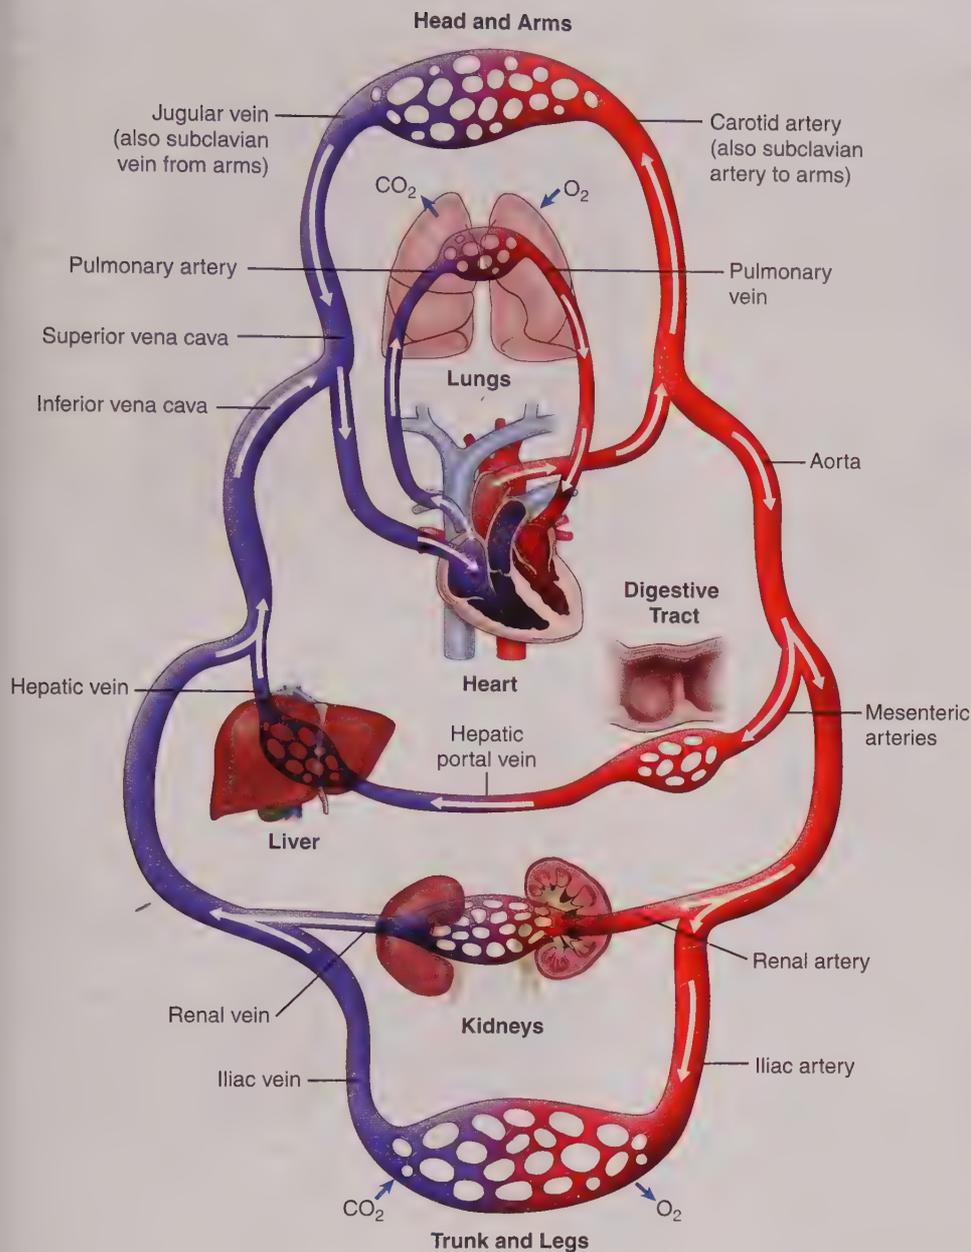

- The delivery of oxygenated blood to the tissues
- The removal and transportation of cellular waste for excretion
- The return of circulatory volume to the right heart
- The return of lymph fluid back into the general circulation

## Arterial System

The high-pressure arterial system consists of thick-walled muscular vessels whose function is to carry oxygenated blood from the heart to the tissues. This is accomplished through a series of vessels gradually decreasing in size, eventually entering the smallest vessels, the capillaries, where the actual oxygen and nutrient exchange takes place

**FIGURE 28.1** Major anatomical structures of the heart.

**FIGURE 28.2** Arterial and venous blood flow through the systemic circulation.

(Fig. 28.3). The sequence of vessels is as follows: arteries to arterioles to metarterioles to capillaries.

### Venous System

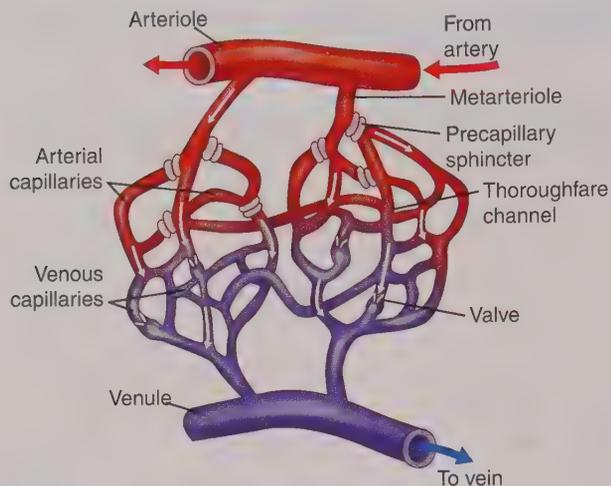

In contrast to the arterial system, the venous system is a low-pressure vascular circuit with vessels that contain valves to prevent retrograde, or backward, flow. These vessels carry blood from the capillary bed through venules, then veins, back to the right heart. Veins also have the flexibility to adapt to changes in volume without large changes in pressure. This allows for the infusion of IV fluids and blood products.

### Capillary Bed

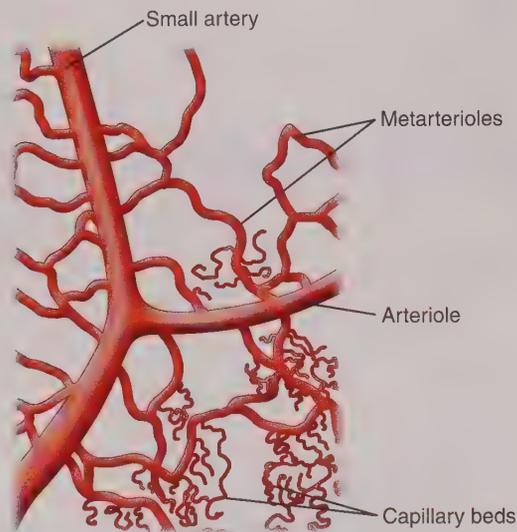

The real work of the vascular system is done at the capillary bed (Fig. 28.4). It is here where oxygen and nutrients are delivered to the tissues and cellular waste is removed.

Capillaries are tremendously abundant in the body, estimated in the billions. Their abundance makes them close to virtually every cell in the body.

The entire capillary system is never full at the same time. There are muscle cells or precapillary sphincters at the entrance of each capillary that constrict or dilate to deliver or divert blood to areas of need. When precapillary sphincters are open, capillaries are filled with blood. When a precapillary sphincter closes, that corresponding capillary shuts down, and blood travels through a thoroughfare channel, going directly from metarteriole to venule. In this way, blood is diverted to organ systems in need. For example, during exercise, there is plentiful flow through the skeletal muscle, but the skin can be bypassed.

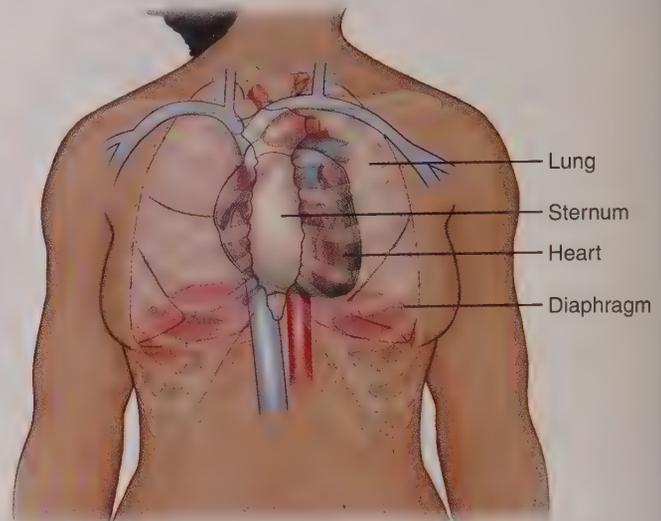

**FIGURE 28.3** Blood flow through a capillary bed: artery to arteriole to metarteriole into the capillary. Flow is controlled through the action of the precapillary sphincter diverting flow to areas of need through a thoroughfare channel.

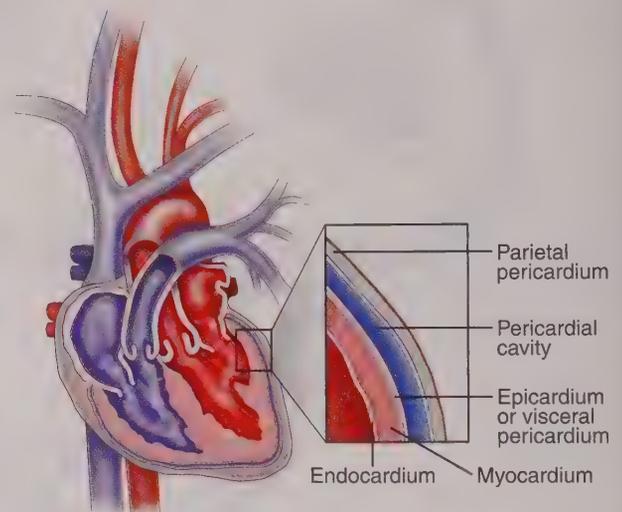

**FIGURE 28.4** The capillary bed; capillaries are abundant in the body. Capillary beds are where oxygen and nutrients are delivered to the tissues and cellular waste is removed.

## Anatomy of the Heart

The heart is a hollow, fist-sized organ located in the thoracic cavity between the lungs in a space called the *mediastinum*. It lies behind the sternum and rests on the diaphragm (Fig. 28.5). It is contained in a protective sac called the *pericardium*. The pericardium consists of two layers (Fig. 28.6). The outer layer, the pericardial sac or parietal pericardium, is a tough fibrous layer that turns inward at the base of the heart, forming the inner layer, the epicardium or visceral pericardium, which covers the heart surface. Between the two layers is a pericardial cavity containing serous fluid that provides a lubricant that allows the heart to beat without friction.

**FIGURE 28.5** The placement of the heart within the chest.

**FIGURE 28.6** Layers of the pericardium; parietal and visceral pericardium and the three layers of the heart: epicardium, myocardium, and endocardium.

## Layers

The heart muscle wall is composed of three layers (see Fig. 28.6). The thin outer layer of the heart is the epicardium, continuous with the inner layer of the pericardial sac. The thick middle layer, or myocardium, is the muscular layer responsible for the mechanical, contractile function of the heart. The thin inner layer is the endocardium. It lines the interior of the heart and the heart valves and is continuous with the inner layer, or endothelium, of the blood vessels.

## Chambers

There are four chambers within the heart, the right and left **atria** and right and left **ventricles**. The right atrium receives deoxygenated blood from the systemic circulation through the great veins, the inferior and superior vena cava. Blood flows from the right atrium to the right ventricle. It is then

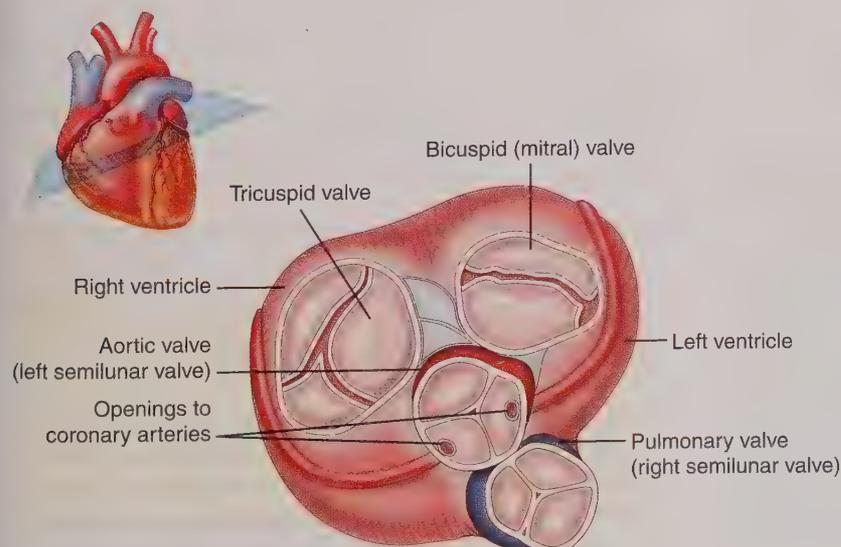

delivered to the pulmonary circuit through the pulmonary artery. Newly oxygenated blood is returned to the left atrium via the pulmonary vein. It flows to the left ventricle and is then ejected into the aorta to the systemic circulation.

### Valves

The heart needs valves (Fig. 28.7) to facilitate one-way flow. There are **atrioventricular (AV) valves** between the atria and ventricles on the right and left. The AV valve between the right atrium and ventricle is the tricuspid valve. The valve between the left atrium and ventricle is the bicuspid, or mitral, valve. When open, the valves allow flow from the atria into the ventricle. When the ventricles fill and the pressure within increases, the valves close to prevent retrograde flow back into the atria. The valves are connected to the muscle in the ventricle by fibrous cords, **chordae tendineae** (see Fig. 28.1), that prevent the valves from budging or turning inside out during ventricular contraction.

There are also **semilunar valves** between the ventricles and their respective arteries (pulmonary and aortic valves). The pulmonary valve is located between the right ventricle and pulmonary artery. The aortic valve is located between the left ventricle and aorta. Like the AV valves, they control the flow of blood between the ventricles and the pulmonary artery or aorta.

The valves in the heart open and close in response to changes in pressure. When the ventricles are relaxed during filling or **diastole**, the AV valves are open, allowing blood to flow into the ventricles. As the ventricles fill, the valves are forced upward and begin to close. The pressure increase from ventricular contraction forces the AV valves fully closed, which prevents backflow of blood into the atria. When the increase in pressure from ventricular contraction exceeds the arterial pressure in the pulmonary circuit or aorta, the semilunar valves open, allowing blood to flow into the pulmonary or systemic circulation. Figure 28.8 illustrates the pathway of blood flow through the chambers and valves.

**FIGURE 28.7** Cross-sectional view illustrating the valves of the heart. Note the openings to the coronary arteries in the aortic valve.

### Blood Supply to the Heart

In order for the heart to perform its work, it needs an adequate amount of oxygen and nutrients. The major vessels that supply blood to the heart are the left and right coronary arteries. They are the first arteries branching off of the aorta as it leaves the left ventricle, actually originating in the cusps of the aortic valve. The arteries branch off into arterioles and capillaries, then eventually merge into capillary veins that drain the blood into a coronary sinus, which eventually empties into the right atrium. Table 28.1 lists the coronaries, their primary branches, and the areas of the heart that they supply with oxygenated blood. Figure 28.9 illustrates the blood supply to the heart.

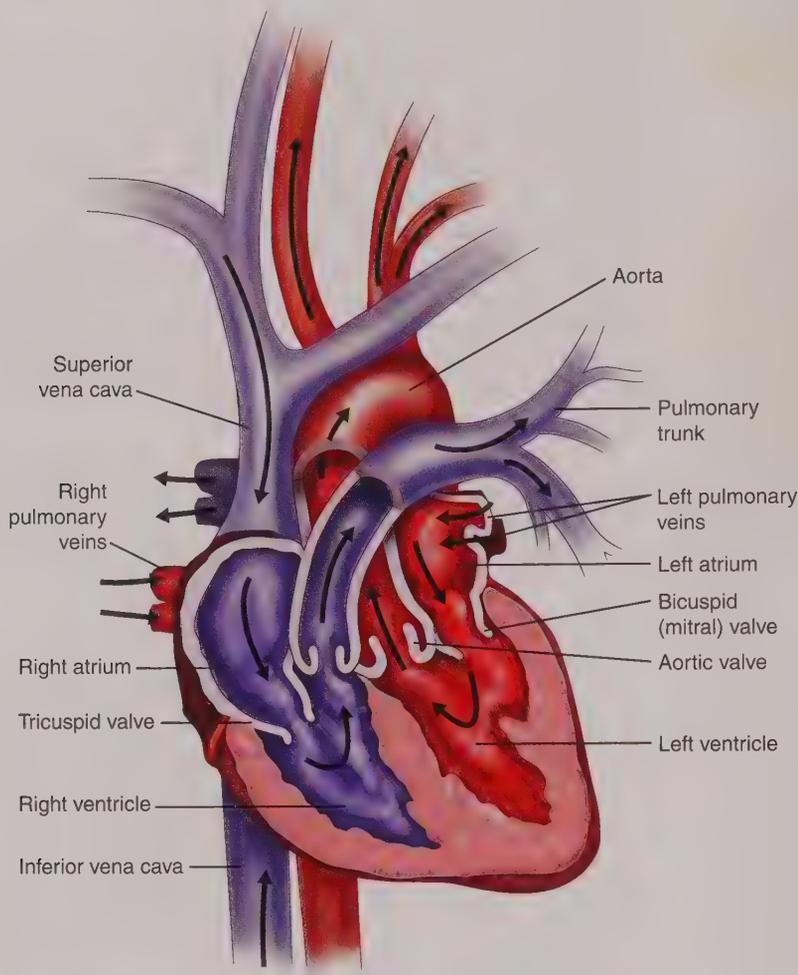

### Connection Check 28.1

What is the composition of the heart?

- Four chambers with four valves that control flow through the heart and lungs through changes in pressure
- Four chambers and four valves that control flow through the heart and lungs through changes in oxygen levels
- Two chambers on the right receiving blood from the high-pressure venous system and two chambers on the left sending blood into the low-pressure arterial system
- Two chambers on the right receiving oxygenated blood from the venous system and two chambers on the left receiving deoxygenated blood from the pulmonary circuit

### PHYSIOLOGY OF THE HEART

There needs to be both an electrical impulse conducted across the structures of the heart and a corresponding muscular contraction to facilitate the filling of the chambers of

**FIGURE 28.8** Pathway of blood flow through the heart.

**Table 28.1** Coronary Arteries, Primary Branches, and the Areas of the Heart They Supply With Blood

**Left Coronary Artery Branches**

Branches	Supplies
Left anterior descending (LAD) branch	Both ventricles Anterior interventricular septum
Circumflex branch	Anterior wall of the heart Left atrium Posterior wall of the left ventricle

**Right Coronary Artery**

Supplies the right atrium and sinoatrial node then branches off to:

Branches	Supplies
Right marginal branch	Lateral aspect of right atrium and ventricle
Posterior interventricular branch	Posterior aspect of both ventricles and interventricular septum

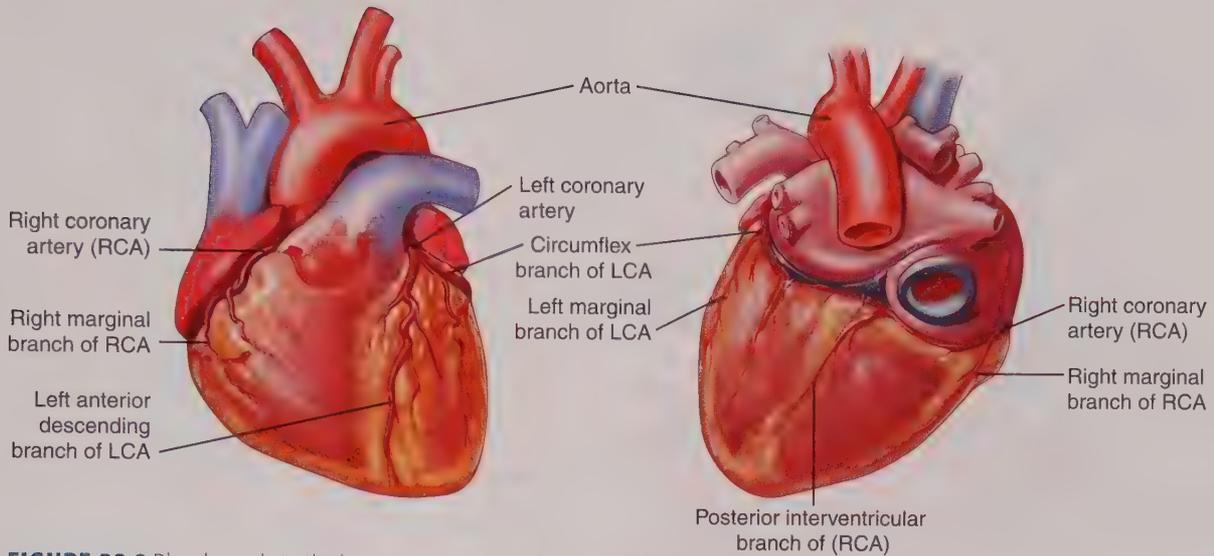

the heart and expulsion of blood into the systemic circulation. The next two sections will discuss each process and describe how they work together to produce sufficient cardiac output to deliver oxygenated blood to the tissues.

**Cardiac Conduction System**

**Properties of Cardiac Muscle Cells**

Specialized cardiac muscle cells and a cardiac electrical conduction system are necessary for the electrical conduction of the heart. The unique characteristics of the cardiac cells that facilitate cardiac electrical conduction are automaticity, excitability, and conductivity.

- Automaticity allows cardiac cells to generate impulses independently and rhythmically. The heart has several pacemaker cells that generate these impulses. The normal pacemaker, the sinoatrial (SA) node, has an inherent rate of 60 to 100 beats per minute (bpm). In the absence of an impulse from the SA node, the atrioventricular (AV) node can generate impulses at rates of 40 to 60 bpm. If the SA and AV nodes fail, ventricular cells can generate impulses at a rate of 20 to 40 bpm.
- Excitability is the ability to respond to a stimulus and generate an impulse.

**FIGURE 28.9** Blood supply to the heart.

- Conductivity allows cardiac tissue to transmit the impulses to neighboring connected cells.

Together, these properties allow cardiac tissue to act as a unit to propagate an impulse through the tissue and produce the muscular contraction necessary for the expulsion of blood during the cardiac cycle. Other properties unique to cardiac muscle cells include:

- Cardiac cells rely almost exclusively on aerobic metabolism for adenosine triphosphate production. Without the production of lactic acid that occurs with anaerobic metabolism, cardiac muscle can maintain its regular lifelong rhythm without tiring.
- Cardiac muscle relies on extracellular calcium to facilitate calcium release from the sarcoplasmic reticulum to produce its muscular contraction. This is referred to as calcium-induced calcium release. It is regulated by the slow inward flow of positively charged calcium ions during the action potential. Ion flow during the action potential is discussed in detail in this section of the chapter.
- Cardiac cells sustain a longer contraction, allowing ejection of blood from the atria and ventricles.
- Cardiac cells have a longer absolute refractory period, decreasing the possibility of repetitive, uncontrolled muscular contractions called *tetany*.

### Cells of the Electrical Conduction System

The cells of cardiac electrical conduction system that generate and conduct the action potential follow this pathway:

1. The impulse originates in the SA node. The SA node has an inherent rate of 60 to 100 bpm.
2. The impulse spreads through the atria through the *internodal pathways* to the ...
3. Atrioventricular node, where the impulse is delayed to allow for atrial contraction and complete ventricular filling.

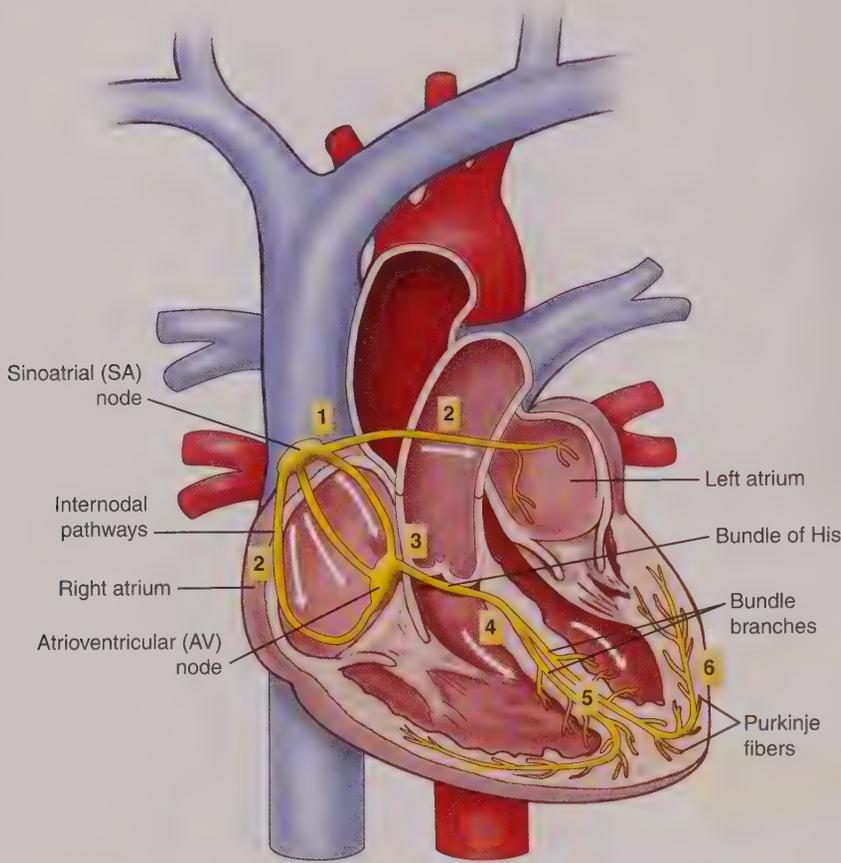

4. It leaves the AV node through the **bundle of His** and branches off into the ...
5. Right and left **bundle branches**, which travel down the interventricular septum to end in the ...
6. **Purkinje fibers**, which extend the impulse into the ventricular tissue, facilitating ventricular contraction.

See Figure 28.10 for an illustration of the electrical conduction through the heart.

### Action Potential of the Cardiac Conduction System

Electrical cardiac conduction is facilitated by the movement of ions across the cell membrane that is unique to cardiac cells. A stimulus begins the movement that produces the **cardiac action potential**, a process in which the membrane potential, the difference in charge between the interior and exterior of the cell, changes or goes up and down in a consistent pattern. **Depolarization** is the movement of ions preceding and facilitating cardiac mechanical contraction. **Repolarization** is the movement of ions back to the resting state, the cardiac resting membrane potential of  $-90$  mV, to allow for the initiation of another action potential. There are five phases of the action potential (Fig. 28.11):

- Phase 0: Rapid depolarization caused by the opening of sodium ( $\text{Na}^+$ ) channels, allowing rapid  $\text{Na}^+$  influx, moving the membrane potential to  $+30$
- Phase 1: Decrease in  $\text{Na}^+$  influx, causing a slight movement toward negative of the membrane potential, producing an initial repolarization
- Phase 2: Plateau state caused by an influx of calcium ( $\text{Ca}^{++}$ ) through the opening of  $\text{Ca}^{++}$  channels balanced by a slight outflow of potassium ( $\text{K}^+$ )
- Phase 3: Final repolarization caused by the closing of the  $\text{Ca}^{++}$  channels and the rapid outflow of  $\text{K}^+$
- Phase 4: Return to resting membrane potential

- 1 SA node fires.
- 2 Impulse spreads through atrial myocardium.
- 3 Impulse travels to the AV node.
- 4 Impulse leaves the AV node through the bundle of His.
- 5 Impulse travels through the bundle branches.
- 6 Impulse extends into the ventricular tissue through the Purkinje fibers.

**FIGURE 28.10** Electrical conduction system of the heart: sinoatrial (SA) node, atrioventricular (AV) node, bundle branches and Purkinje fibers, and the impulse pathway.

An **absolute refractory period** occurs during and immediately following depolarization. During this time, the cell is unresponsive to any stimulus. This corresponds to phase 0 through the middle of phase 3. Immediately following the absolute refractory period is the **relative refractory period**. This represents a time when a greater-than-normal stimulus may initiate an impulse. This corresponds to the end of phase 3. Medications utilized to control irregular heart rhythms or dysrhythmias typically manipulate the movement of ions in some way.

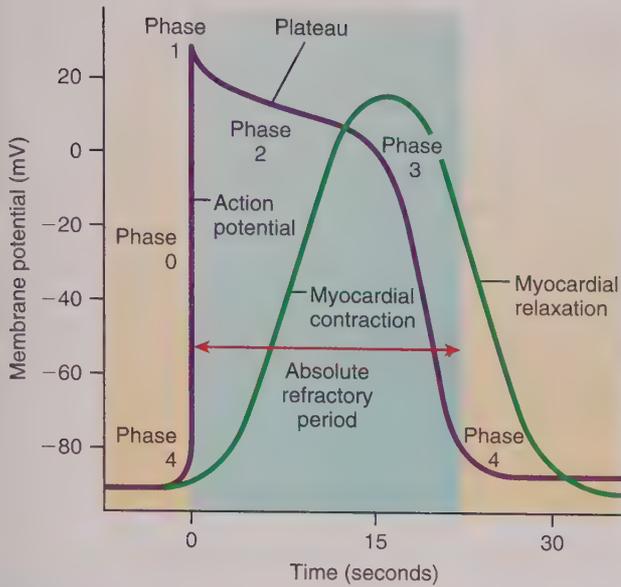

**Electrocardiogram**

The electrical activity described previously produces waveforms, which can be amplified and viewed on a paper tracing called an **electrocardiogram (ECG)**. Electrodes placed on the wrists, ankles, and six locations around the chest produce a comprehensive picture of the cardiac electrical activity. Details on obtaining an ECG are discussed later in the chapter under diagnostic imaging tests.

The principal waveforms produced are the P wave, QRS complex, and T wave. The principal segments include

the PR segment and the ST segment. The intervals include the PR interval, QRS interval, and QT interval (Fig. 28.12).

- The *P wave* corresponds to atrial depolarization produced by the propagation of the impulse from the SA node through the atria. Atrial contraction takes place milliseconds after depolarization.
- The *PR interval* from the beginning of the P wave to the beginning of the QRS complex reflects the time required for atrial depolarization and the delay of the impulse at the AV node.
- The *PR segment*—the time immediately following the P wave to the beginning of the QRS complex—reflects the delay at the AV node.
- The *QRS complex* corresponds to ventricular depolarization. Ventricular contraction occurs after the QRS complex in the *ST segment*.
- The *QRS interval* reflects the time required for ventricular depolarization.
- The *T wave* corresponds to ventricular repolarization. Atrial repolarization occurs during ventricular

**FIGURE 28.11** Phases of the cardiac action potential. Phase 0: Rapid depolarization caused by rapid  $\text{Na}^+$  influx, moving the membrane potential to +30. Phase 1: Decreases in  $\text{Na}^+$  influx, producing an initial repolarization. Phase 2: Plateau state caused by an influx of calcium ( $\text{Ca}^{++}$ ) balanced by a slight outflow of potassium ( $\text{K}^+$ ). Phase 3: Final repolarization caused by the closing of the  $\text{Ca}^{++}$  channels and the rapid outflow of  $\text{K}^+$ . Phase 4: Return to resting membrane potential. The purple curve represents the action potential. The green curve represents the changes in cardiac muscle tension.

contraction. That waveform is not visible but is buried in the QRS complex.

- The *QT interval* reflects the time required for ventricular depolarization and repolarization.

### Connection Check 28.2

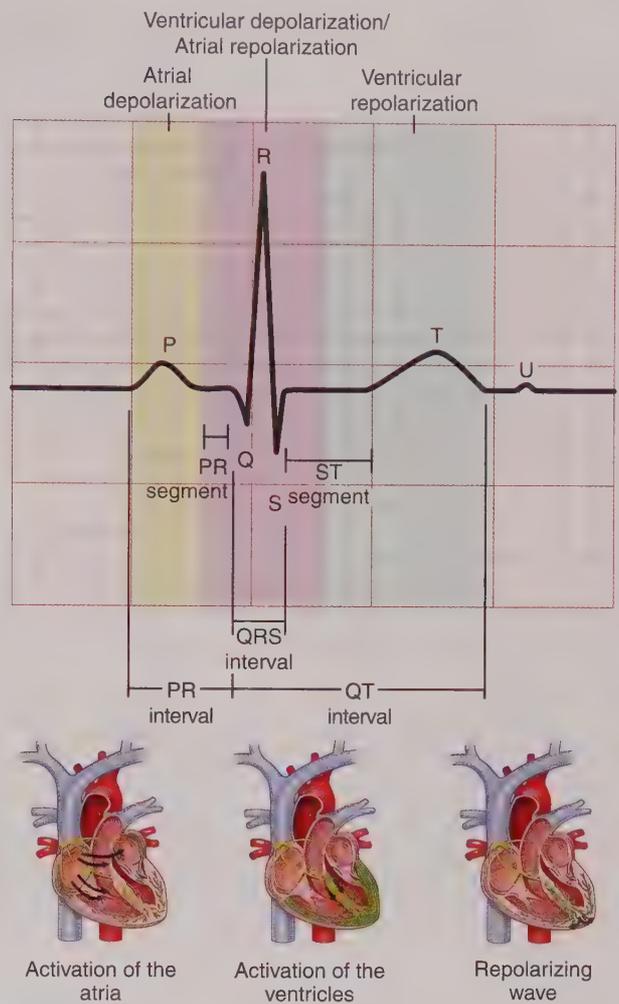

Which is true of the electrical conduction system of the heart?

- It is primarily controlled by the movement of uncharged ions.
- It has a positive resting membrane potential.
- It is reflected in the waveforms on the electrocardiogram.
- It requires cells that respond only to a stimulus from the autonomic nervous system.

### Cardiac Cycle

The cardiac cycle is defined as the circular sequence of events that produces the eventual muscular contraction that causes the ejection of blood from the right ventricle into the pulmonary circulation or from the left ventricle into the systemic circulation. This cycle works in coordination with the electrical cardiac conduction system, which is illustrated in Figure 28.13.

There are two parts to the cardiac cycle: **systole**, or contraction, and **diastole**, or relaxation. Diastole is when filling

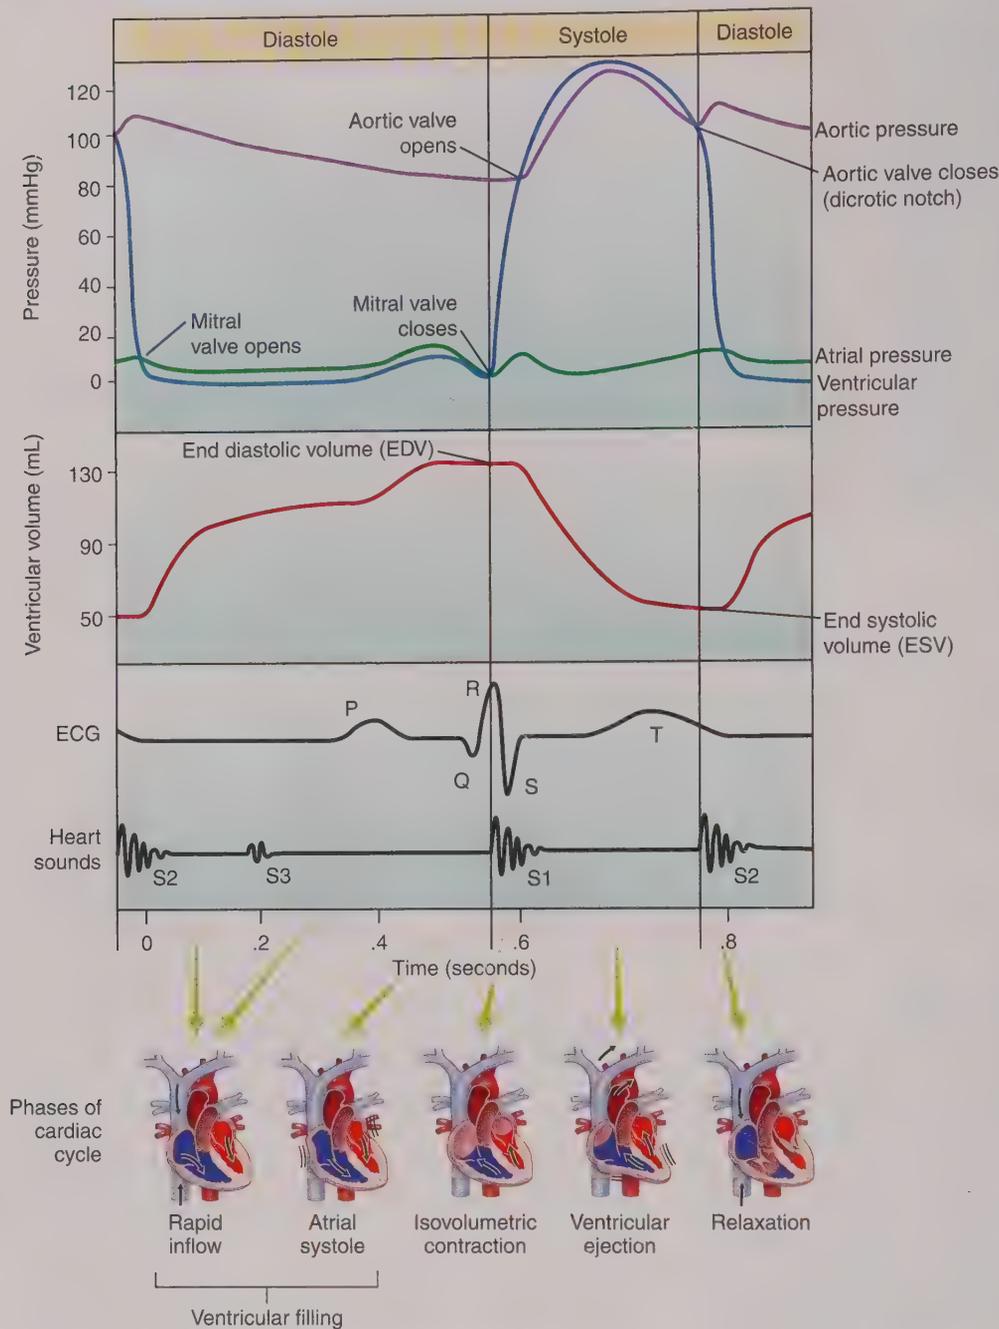

**FIGURE 28.12** Cardiac waveforms and intervals. The *P wave* corresponds to atrial depolarization; atrial contraction occurs a millisecond after depolarization. The *PR interval* reflects the time required for atrial depolarization and the delay of the impulse at the atrioventricular (AV) node. The *PR segment* is the time immediately following the P wave to the beginning of the QRS complex and reflects the delay at the AV node. The *QRS complex* corresponds to ventricular depolarization; the *QRS interval* reflects the time required for ventricular depolarization. Atrial repolarization occurs during ventricular depolarization. That waveform is not visible but is buried in the QRS complex. The *ST segment* is where ventricular contraction occurs. The *T wave* corresponds to ventricular repolarization. The *QT interval* reflects the time required for ventricular depolarization and repolarization.

of the ventricles occurs and accounts for the first two-thirds of the cycle. Myocardial tissue perfusion occurs during diastole. Systole facilitates the ejection of blood from the ventricles and occurs during the last one-third of the cycle. This cycle is occurring simultaneously on the left and right sides of the heart.

### Diastole

During diastole, the ventricles are relaxed, with a lower pressure than that of the atria, allowing the AV valves to open. Blood flows into the atria from the superior and inferior vena cava or from the pulmonary veins and then quickly flows into the ventricles. As blood flows into the ventricles,

**FIGURE 28.13** Phases of the cardiac cycle illustrated by volume and pressure changes in the left heart and corresponding electrocardiogram (ECG) changes and heart sounds. At time zero, the left ventricle (dark blue waveform) has a lower pressure than that of the left atrium (green waveform). The mitral valve opens, allowing blood to flow into the ventricle and quickly increasing the ventricular volume. The atria contract, completing ventricular filling to the end diastolic volume (red waveform). At time 0.6 seconds, pressure increases within the ventricle without any volume changes, an isovolumetric contraction, closing the mitral valve. Ventricular pressure eventually exceeds aortic pressure (purple line), opening the aortic valve and allowing a rapid ejection of blood into the systemic circulation. Note how atrial and ventricular systole occur milliseconds after depolarization, as illustrated by the P wave and QRS complex.

pressure drops in the atria and rises in the ventricles. The final phase of ventricular filling occurs when the atria contract, known as atrial systole, which accounts for the final 30% of ventricular filling. This is referred to as the **atrial kick**. The final volume in the ventricle at the end of diastole is the end diastolic volume. This is also referred to as **preload**.

**Systole**

At the completion of filling, the ventricles contract. During the initial phase of contraction, pressure increases, but there are no volume changes; thus, this is an isovolumetric contraction. The increased pressure in the ventricle causes the AV valves to close, preventing retrograde flow into the atria.

As ventricular pressure continues to increase during contraction, it eventually exceeds that of the aortic and pulmonary circuits. When this occurs, the semilunar valves are forced open, allowing a rapid ejection of blood into the pulmonary and systemic circulation.

**Blood Pressure**

Blood pressure (BP) is a reflection of the pressures generated during the cardiac cycle. It represents the force exerted against the vessel wall by blood flow. Factors that influence BP are the amount of blood ejected during systole, or CO, and the resistance to flow in the peripheral vessels, or peripheral vascular resistance.

Blood pressure is reported in two pressures, systolic and diastolic. Systolic is the peak pressure generated when blood is expelled from the left ventricle during ventricular contraction. Diastolic pressure is the minimal pressure maintained on the vessel walls during relaxation. Mean arterial pressure is the average pressure maintained throughout the cardiac cycle.

Regulation of BP is primarily controlled through changes in the factors that influence pressure: blood flow, or volume, and resistance to flow. Increases or decreases in blood volume or CO increase or decrease BP. Resistance, defined as opposition to flow, is chiefly a function of vessel diameter. Changes in flow and resistance are principally controlled by the autonomic nervous system (ANS) and hormones.

The ANS responds to messages sent by various sensory tissues in the body, **baroreceptors** and **chemoreceptors**. Baroreceptors, located in the aortic and carotid arches, are sensitive to changes in pressure. An increase in pressure stimulates the parasympathetic nervous system to dilate vessels and reduce the **heart rate (HR)** to reduce BP. The decrease in pressure stimulates the sympathetic nervous system to constrict vessels and increase the HR, which increases BP.

Chemoreceptors contained in collections of cells called *carotid bodies* and *aortic bodies* are located in the aortic arch and in the carotid arteries. They respond to changes in oxygen and CO<sub>2</sub> concentrations. Decreased levels of oxygen with increased levels of CO<sub>2</sub> produce acidosis. The chemoreceptors respond to decreased oxygen levels and acidosis by inducing vasoconstriction to increase BP and increase blood flow to the lungs, facilitating oxygen and CO<sub>2</sub> exchange. The respiratory rate (RR) is also increased.

Hormonal mechanisms that exert control over BP include angiotensin II, epinephrine and norepinephrine, aldosterone, and antidiuretic hormone. Angiotensin II, created in response to low BP, is an end product of a series of events. After a drop in BP, the kidneys respond by releasing the enzyme renin. Renin reacts with angiotensinogen to create angiotensin I. Angiotensin I is then converted in the lungs to angiotensin II via angiotensin-converting enzyme. Angiotensin II is a potent vasoconstrictor that increases BP. Angiotensin II also acts on the adrenals to release aldosterone. The release of aldosterone promotes sodium and water reabsorption in the kidneys, which increases circulating fluid volume. This is called the **renin-angiotensin-aldosterone system**. Epinephrine and norepinephrine, catecholamines released by the adrenal medulla, cause vasoconstriction, leading to increases in BP as part of the fight-or-flight mechanism in the sympathetic nervous system. Antidiuretic hormone is released by the posterior pituitary in response to the decreased blood volume. It acts on the kidney to conserve water. These concepts are discussed in more detail in Chapter 40.

Several other hormones, atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), are released from heart tissue when fluid volumes are high. They stimulate vasodilation and diuresis. This is discussed in more detail in Chapter 30.

## CARDIAC OUTPUT

Together, the electrical and muscular actions of the heart muscle fulfill the primary function of the cardiovascular system: the delivery of oxygenated blood into the systemic arterial circulation. The blood ejected from the left heart each minute to facilitate the delivery of oxygen and nutrients to the tissues is called the cardiac output (CO). Normal CO in an adult is 4 to 8 L/min. This value does not remain constant but is increased by exercise or activity and decreased in times of rest. Cardiac output is calculated by the formula  $HR \times \text{stroke volume}$  (the amount of blood ejected with each ventricular contraction). That value can be indexed by dividing by the body surface area (height  $\times$  weight) to reflect the different requirements related to body size.

### Heart Rate

Heart rate (HR) is simply the number of cardiac contractions per minute. Heart rate can be affected by many variables. Stimulus from the ANS, although not initiating the heartbeat, does adjust it up or down. The HR can be increased or decreased depending on pressure. For instance, when BP is low, the HR is increased to maintain adequate CO. Stimulus from the sympathetic nervous system initiated by information from baroreceptors in the aortic arch and the carotids that are sensitive to changes in BP increase the HR through the release of norepinephrine. This is called a *positive chronotropic effect*. The parasympathetic nervous system slows the HR through the release of acetylcholine, a negative chronotropic effect. Other chemicals that can increase HR are the hormones epinephrine and norepinephrine released from the adrenal medulla.

### Stroke Volume

Stroke volume is the amount of blood ejected with each ventricular contraction. It is influenced by three variables: preload, afterload, and contractility.

- **Preload** is the amount of blood in the ventricles at the end of diastole. It also refers to the amount of stretch of the muscle tissue at the end of filling. Increased volume produces increased stretch, which produces an increased contraction (Starling's law). This is true up to a point. Extreme overfilling decreases the effectiveness of the contraction, thus decreasing CO.
- **Afterload** refers to the resistance to flow the ventricle must overcome to open the semilunar valves and eject its contents. This is related to BP, vessel lumen diameter, and/or vessel compliance. The valves can meet resistance on both the right and left through the pulmonary artery or aorta. Hypertension on the right or left is implicated in the negative effects of increased afterload.
- **Contractility** refers to the force of the mechanical contraction. Contractile force can be increased with sympathetic stimulation or calcium release. It can be decreased in the face of hypoxia or acidosis.

Preload and afterload are reflected by measurements obtained through a centrally located IV line: preload = the central venous pressure; afterload = the systemic vascular resistance or pulmonary vascular resistance. The concept of cardiac output is discussed in more detail in Chapter 32.

### Connection Check 28.3

A patient with hypertension has which physical symptom?

- A. Decreased resistance, which may increase CO
- B. Increased resistance, which may decrease CO
- C. Increased resistance, which may increase CO
- D. Decreased resistance, which may decrease CO

### CASE STUDY: EPISODE 2

During the initial assessment, Mr. Smith offers no specific complaints. His PMH is negative for any significant disease. He does state he has aches and pains after a hard day at work; he does a lot of heavy lifting. He has no known allergies and is not taking any medication. His examination reveals:

BP—145/90 mm Hg

HR—84 bpm and regular

RR—16

His physical examination is unremarkable except for his stage 2 hypertension and excessive weight. His neurological, respiratory, and cardiovascular examinations are within normal limits ...

## ASSESSMENT

### History

Major risk factors for cardiovascular disease (CVD) include a family history of CVD, diabetes mellitus, chronic renal disease, hypertension, and dyslipidemia. A complete and thorough history that includes demographic data, family history, and personal history, including present health problems, is essential in the patient cardiovascular assessment. The patient is the primary source of information, but family members and medical records can also be very informative. Demographic data include age, sex, and ethnic background. These are all nonmodifiable risk factors. The family history can reveal significant information regarding the age, health status, and cause of death of immediate family members. Information regarding socioeconomic status is also important. Occupation, economic status, marital status, children, insurance, and support systems are important and can hint at a patient's ability to respond in times of need.

Modifiable risk factors in a patient's personal history include such things as weight, dietary habits, alcohol consumption, and smoking history. Excess consumption of fats

and sodium is a dietary habit that puts a patient at risk for heart disease. Smoking and excessive drinking are also implicated in heart disease. Activity level should be assessed. A sedentary lifestyle is a risk factor for cardiovascular disease; exercise promotes cardiovascular health.

### Current Health Problems

After the patient's past history has been established, current health problems should be identified. The existence of diabetes, hypertension, and high cholesterol indicates a risk for heart disease. Significant complaints pertinent to heart disease include the presence of chest pain, difficulty breathing (dyspnea), cough, palpitations, edema, fatigue, and/or syncope.

Chest pain should be evaluated for its location, intensity, radiation, duration, and quality. Information related to the treatment that provides relief is also significant. Dyspnea and fatigue at rest or dyspnea on exertion are important to note. Palpitations are an indication of abnormal heart rhythms: dysrhythmias. Syncope is an indication of decreased CO resulting from problems with either the mechanical or electrical properties of the heart. Weight gain associated with edema indicates a weakened heart and potentially the presence of heart failure, discussed in more detail in Chapter 30.

### Physical Assessment

#### General Assessment

The components of a cardiac physical assessment include an initial general assessment of the patient, inspection, palpation, and auscultation. The initial assessment starts with evaluating the patient's overall appearance, including color, diaphoresis, edema, and demeanor and restlessness, agitation, or confusion. The nurse's initial conversation can reveal information pertinent to the patient's orientation. Through observation, you can quickly determine weight and build, symptoms such as shortness of breath (SOB), and mobility. A patient with cardiac disease may appear pale, fatigued, or short of breath. Patients with late-stage heart failure will present with edema and appear frail and fatigued.

Other basic components of an initial cardiac assessment include an evaluation of HR and BP. The HR or pulse rate provides information on the efficiency and strength of the heart. A normal HR is 60 to 100 bpm. The HR can be determined in several ways, such as palpating the pulse over an artery close to the skin, typically the radial artery, and auscultating an apical HR. An apical rate can be auscultated by placing a stethoscope at the junction of the fifth intercostal space and the midclavicular line, the point of maximal impulse (PMI). A lower HR can indicate good physical conditioning, and thus an efficient heart, but it may also be an indicator of inadequate CO. If a low HR is associated with symptoms such as dizziness, SOB, or chest pain, further evaluation is required. Increases in HR naturally occur with exercise and exertion but are abnormal when occurring at rest. This may be due to many factors, some of which include a weak heart muscle,

pain, fever, or inadequate fluid volume, all of which require further evaluation. A pulse deficit is occurring when, if performed at the same time, the radial pulse rate is less than the apical HR. A pulse deficit can indicate arrhythmias such as atrial fibrillation or premature ectopic beats.

Blood pressure provides information on the force of the heart's contraction and volume of CO as well as the resistance offered by the arterial vascular system. High BP indicates more resistance in the vessels, requiring higher pressures to produce an adequate CO. High BP increases the risk of heart failure, myocardial infarction, and stroke. The American Heart Association guidelines for BP levels were updated in 2017 (see Evidence-Based Practice). Hypertension is discussed in detail in Chapter 31. Low BP should be assessed for clinical significance. The presence of postural hypotension, a decrease of 20 mm Hg in BP when moving from a lying or seated position to a standing position accompanied by a 10% increase in HR, dizziness, SOB, and/or syncope, could indicate inadequate CO or blood volume and requires further evaluation.

## Evidence-Based Practice

### Guidelines for the Detection and Evaluation of High Blood Pressure in Adults

Based on evidence published by the American Heart Association in 2017, blood pressure in adults is categorized as normal, elevated, or hypertension; hypertension is further classified as stage 1 or stage 2. Categorization should be based on an average of two or more readings found two or more times on examination. If the systolic blood pressure (SBP) and diastolic blood pressure (DBP) fall into two different categories, the higher category should be assigned.

BP category	SBP	and	DBP
Normal	<120 mm Hg		<80 mm Hg
Elevated	120–129 mm Hg		<80 mm Hg
Hypertension			
● Stage 1	● 130–139 mm Hg	or	● 80–89 mm Hg
● Stage 2	● >140 mm Hg	or	● >90 mm Hg

Whelton, P. K., Carey, R. M., Aronow, W. S., Casey, D. E., Collins, K. J., Himmelfarb, C. D., . . . & MacLaughlin, E. J. (2017). 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Journal of the American College of Cardiology*, 71, e127–e248.

### Inspection

Visual inspection is done to assess color, capillary refill time, edema, the presence or absence of jugular vein distention, and clubbing of the fingers or toes. Skin color and nailbed color in light-skinned people with adequate perfusion are

pink. Poor perfusion produces a pale gray or bluish color. This is called **cyanosis**. In dark-skinned people, adequate perfusion produces the same pink coloring of the nailbeds. Cyanosis appears gray.

Cyanosis can be central or peripheral. Central cyanosis appears as blue coloring in the mucous membranes, lips, and tongue. It is usually caused by impaired heart or lung function. Peripheral cyanosis, or blue discoloration of the extremities, can be caused by heart or lung failure but may also indicate peripheral vasoconstriction or obstruction.

Capillary refill time is tested by compressing a finger or toe momentarily to stop the blood flow, producing a whitening effect, then releasing pressure and timing the return to the normal pink color. A return to color within 3 seconds indicates adequate peripheral circulation. Sluggish return may indicate arterial spasm or insufficiency.

Edema may be a sign of cardiac or liver issues. Bilateral lower extremity edema, if not associated with a local injury, generally indicates venous insufficiency or heart failure. Unilateral extremity edema, again if not associated with injury, can indicate a venous or lymphatic obstruction. Edema is identified as pitting or nonpitting. Pitting edema is characterized by an indenting of the skin that remains after pressure has been applied then released.

Distention of the jugular veins may be present in a patient with a constrictive disease such as pericarditis or cardiac tamponade. It is also seen in patients with right ventricular failure, valvular disease, or hypervolemia. It is often associated with poor contractile function of the heart that is present in heart failure (discussed in more detail in Chapter 30).

Clubbing of the fingers and/or toes indicates long-term perfusion problems produced by a decrease in oxygenated blood flow to the affected extremities. This is typically caused by congenital heart defects or chronic pulmonary disease. It can also be seen in patients with lung cancer.

### Palpation

Assessment of skin temperature and pulses is done by palpation. Adequate CO produces warm skin temperatures. Cool or cold temperatures may indicate vasoconstriction, heart failure, or shock. Variations in temperature between different parts of the body may indicate vasoconstriction or vascular disease in the affected extremities.

Pulses typically palpated include the radial and dorsalis pedis pulses. A more extensive examination includes femoral, popliteal, and posterior tibial pulses. Strong, palpable pulses indicate adequate CO and good flow through the peripheral vessels.

### Auscultation

Assessment of heart and lung sounds is done through auscultation.

### Heart Sounds

The heart sounds (“lubb” and “dubb”) that are heard during auscultation are produced by the closing of the valves during the cardiac cycle (Table 28.2). The first heart sound, S<sub>1</sub>,

**Table 28.2 Summary of Heart Sounds**

Heart Sound	Cause	Description	Timing
$S_1$	Closure of AV valves	“Lubb”	
$S_2$	Closure of semilunar valves	“Dubb”	
$S_3$ : <i>Ventricular gallop</i>	Ventricular dysfunction when heard in adults	Gallop-like sounds	Early diastole
$S_4$ : <i>Atrial gallop</i>	Decreased ventricular compliance	Gallop-like sounds	Late diastole after atrial systole
<i>Systolic murmur</i>	Valvular disease such as aortic stenosis	Turbulent flow heard	Systole between $S_1$ and $S_2$
<i>Diastolic murmur</i>	Valvular disease such as aortic or pulmonic regurgitation	Turbulent flow heard	Diastole after $S_2$
<i>Click</i>	Mitral valve stenosis	High-pitched sound	Early diastole
<i>Friction rub</i>	Pericarditis	Harsh, scratching sound	Anywhere during the cardiac cycle

AV, Arterioventricular.

is the closing of the AV valves. It signifies the beginning of ventricular systole. The second heart sound,  $S_2$ , is the closing of the semilunar valves. It signifies the beginning of diastole.  $S_1$  sounds longer and louder when compared with  $S_2$ , which is short and soft. Figure 28.13 illustrates where heart sounds are heard in the cardiac cycle.

Heart sounds vary with age. A third heart sound,  $S_3$ , can be heard in children and young adults. It is caused by vibration in the ventricular walls during filling or early diastole. If heard in an adult, it may indicate decreased ventricular compliance. The combined sounds of  $S_1$ ,  $S_2$ , and  $S_3$  resemble a gallop, thus the name *ventricular gallop*. A fourth heart sound,  $S_4$ , is heard in late diastole and occurs after atrial contraction. It also can indicate decreased ventricular compliance. It is known as an atrial gallop.

Fever, inflammation, excess fluid, and narrowed or incompetent valves are a few clinical situations that produce extra sounds, such as clicks, rubs, or murmurs. A click is a high-pitched sound heard early in diastole and is typically caused by mitral valve stenosis. Murmurs are usually caused by turbulent flow through the valves. That turbulence can be caused by regurgitation of blood through an incompetent valve, flow through a narrowed valve, or an increase in flow in hypermetabolic states such as hyperthyroidism or fever. A friction rub is described as a scratching or grating sound heard during both systole and diastole. The sound is produced by inflammation of the pericardium. It is diagnostic for pericarditis and is referred to as the pericardial friction rub.

When describing heart sounds, it is important to note:

- Pitch: high, medium, or low
- Quality, such as blowing or harsh
- Intensity, such as faint, quiet, or loud
- Timing during systole or diastole
- Location where heard best on the chest wall

## Lung Sounds

Lung sounds give an indication of both lung and cardiac health. Clear breath sounds signify a healthy heart and lungs. Auscultation of rales, rhonchi, or rubs in the lung fields indicates the presence of fluid. These findings may be a result of pulmonary disease or congestive heart failure and decreased cardiac function. Heart failure is discussed in more detail in Chapter 30.

### Connection Check 28.4

A nurse is providing care for a patient newly diagnosed with heart disease. Which dietary, activity, or lifestyle modification(s) should be included in the plan of care? (*Select all that apply.*)

- Stopping smoking
- Drinking lots of water
- Limiting sedentary lifestyle
- Eating a diet rich in red meat and protein
- Limiting alcohol intake

## DIAGNOSTIC STUDIES

### Laboratory Markers as Predictors of Heart Disease

A lipid panel includes total cholesterol, low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and triglycerides. Cholesterol is a lipid necessary for the synthesis of hormones and cell walls. It is available through the ingestion of animal products (e.g., meat) and through synthesis in the liver. It is not soluble in blood, so it combines with proteins to form lipoproteins, LDLs and HDLs,

to facilitate transport through the vascular system. Low-density lipoproteins primarily transport cholesterol into the cell but can also deposit it on the walls of arterial vessels. Elevated levels, greater than 100 mg/dL, are associated with an increased risk of heart disease. High-density lipoproteins, protective lipoproteins, transport cholesterol away from the cells to the liver for excretion. Therefore, opposite of LDLs, decreased levels of HDLs, less than 40 to 60 mg/dL, are a risk factor for heart disease. A total cholesterol level includes both LDLs and HDLs. Normal levels are 200 mg/dL or less. Increased levels are a risk factor for atherosclerotic vessel disease. Triglycerides, another lipid, store unused ingested calories in fat cells, which may be later released as an energy source between meals. Elevated levels, greater than 150 mg/dL, are another risk factor for heart disease.

### Nonspecific Markers

Because diabetes and hyperglycemia are major risk factors for CVD, blood glucose levels are an essential laboratory value for evaluation. Increased homocysteine, an amino acid, is also a risk factor for heart disease. It can damage the lining of arterial walls, causing clot formation. Decreased dietary intake of folic acid and B vitamins is associated with increased levels of homocysteine. C-reactive protein is not specific for cardiac disease but is used in conjunction with other laboratory tests. Elevated levels reflect increased production of C-reactive protein in the liver secondary to systemic inflammation. Inflammation is implicated in the development of atherosclerosis. Coagulation studies such as platelets and fibrinogen levels, although not specific markers of cardiac disease, are commonly obtained for screening purposes. Increased platelets and fibrinogen levels are correlated with an increased risk of atherosclerotic heart disease. Prothrombin time, partial thromboplastin time, and international normalized ratio are measured in patients with increased risk of clot formation, such as patients with atrial fibrillation. They are also utilized to monitor anticoagulation therapy. Table 28.3 lists laboratory tests and normal values.

### Nursing Implications

The nurse's responsibilities are primarily associated with patient education. Most of the laboratory tests mentioned previously do not require any specific patient preparation, but a lipid panel requires the patient to fast for approximately 8 to 12 hours prior to the test.

### Laboratory Markers of Acute Cardiac Damage or Injury

Laboratory markers of acute cardiac damage or injury include enzymes or proteins that are elevated in response to cellular injury. Some are specific to cardiac tissue; others are more general and must be evaluated in conjunction with the specific tests.

Creatine kinase (CK) is a general marker of cellular injury. It is released from cells in the brain, skeletal muscle,

**Table 28.3 Laboratory Predictors and Markers of Heart Disease**

Laboratory Test	Normal Value*
<b>Predictors of Heart Disease</b>	
<b>Lipid panel:</b>	
Cholesterol	Less than 200 mg/dL
Low-density lipoproteins (LDLs)	Less than 100 mg/dL
High-density lipoproteins (HDLs)	Greater than 40–60 mg/dL
Triglycerides	Less than 150 mg/dL
<b>Glucose</b>	65–99 mg/dL
<b>Homocysteine</b>	4.4–10.8 mm/L
<b>C-reactive protein</b>	0 (only present when inflammation is present)
<b>Coagulation studies:</b>	
Platelets	150,000–400,000 mc/L
Fibrinogen levels	200–400 mg/dL
Prothrombin time (PT)	10–13 seconds
Partial thromboplastin time (PTT)	25–35 seconds
International normalized ratio (INR)	<2.0
<b>Markers of Heart Disease</b>	
<b>Creatine kinase myocardial bands (CK-MB)</b>	0–3 ng/mL
<b>Troponin</b>	Less than 0.4 ng/mL
<b>Myoglobin</b>	0–85 ng/mL
<b>Brain natriuretic peptide (BNP)</b>	Less than 100 pg/mL

\*Values are a reference range and may vary by institution—they are just a guide.

and cardiac tissue after muscle damage has occurred. One isoenzyme of CK, creatine kinase myocardial bands (CK-MB) is the marker specific to cardiac tissue. When myocardial damage occurs, CK-MB is released from the cells. Increased levels can be seen at 3 hours after myocardial damage and can remain elevated for up to 36 hours before returning to normal.

Troponin is another specific marker of cardiac muscle damage and is the preferred method for diagnosing cardiac injury. It is a protein released from damaged tissue and, as with CK-MB, can elevate within 4 hours of injury. It can stay elevated for up to 10 days. Because it stays elevated longer than CK-MB, it is a valuable marker when attempting to diagnosis injury in the recent past.

Myoglobin, another protein, is released and elevated in muscle damage but is not specific for cardiac tissue. It can

be used in conjunction with the other values to help rule out or rule in a myocardial infarction.

Brain natriuretic peptide (BNP) is released from overstretched ventricular tissue. Physiological responses to increased levels of BNP include venous dilation, which decreases preload; arterial dilation, which decreases afterload; and diuresis. Elevations are an indicator of heart failure. Table 28.3 lists laboratory tests and normal values.

### Nursing Implications

Nursing care related to obtaining CK, CK-MB, and troponin is primarily associated with the timing of the blood draws. When a patient is evaluated for acute injury, laboratory tests are obtained at baseline and then at regular intervals (typically 3 to 4 hours) for approximately 12 hours. It is important to obtain samples in a timely fashion and accurately note the time each blood sample is obtained.

## Diagnostic Imaging Studies

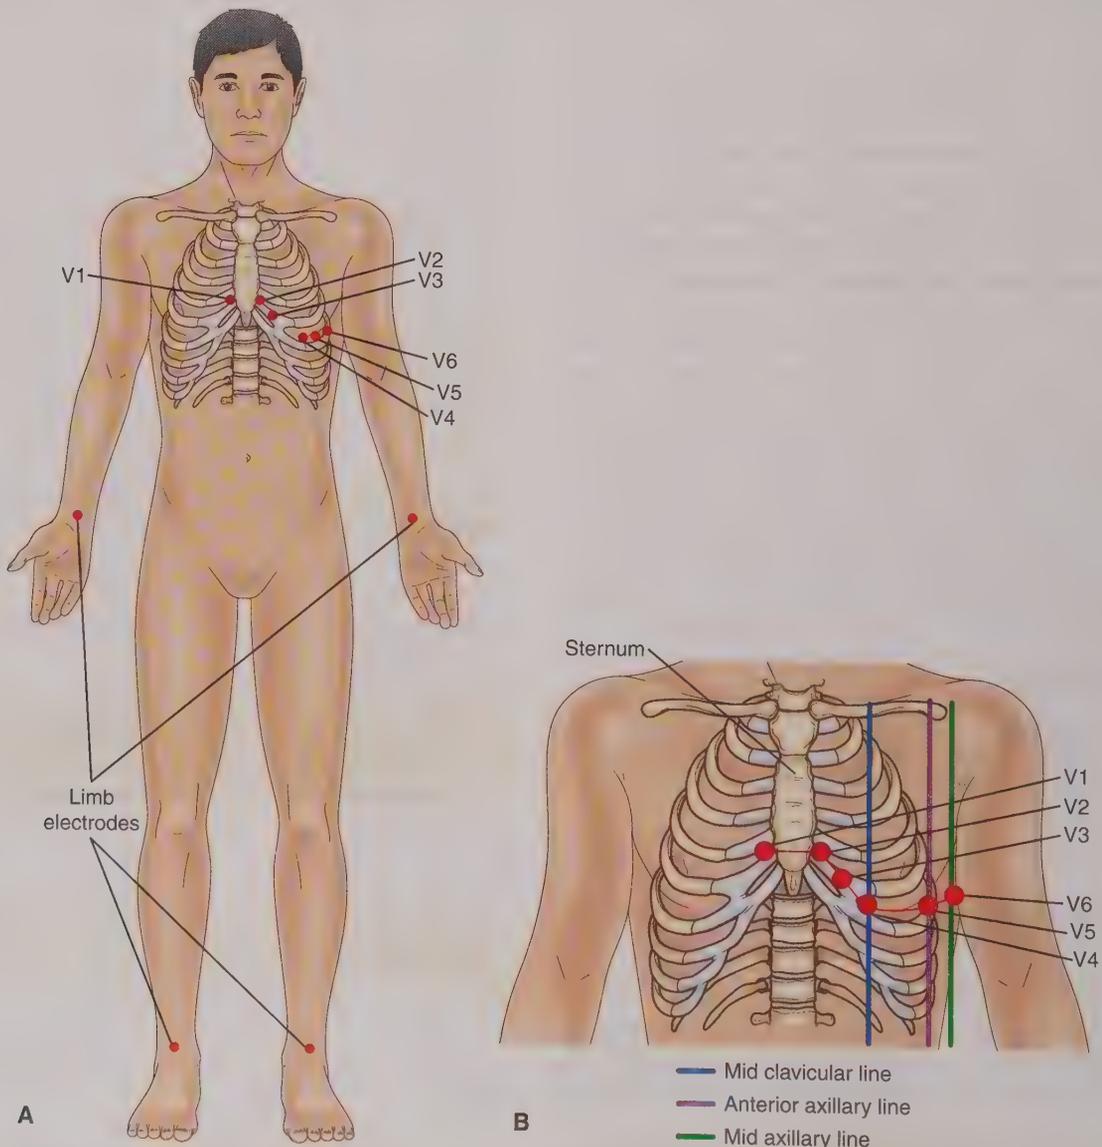

### Electrocardiography

The ECG is a basic diagnostic assessment that is completed routinely on patients to assess the electrical conduction system of the heart. It is a graphic recording of the heart's electrical activity. It can identify the presence of dysrhythmias, new or old heart muscle damage, electrolyte abnormalities, and/or cardiac hypertrophy. It is done by placing 10 electrodes on specific positions of the body (Fig. 28.14A), the bilateral upper and lower extremities (limb leads) and six positions around the left chest (chest or V leads). The chest positions are (see Fig. 28.14B):

V1: 4th intercostal space, just to the right of the sternum

V2: 4th intercostal space, just to the left of the sternum

V4: On the midclavicular line and 5th intercostal space

**FIGURE 28.14** Electrocardiogram (ECG) lead placement. A, Placement of 10 leads for ECG. B, Location of six chest leads.

V6: On the midaxillary line, horizontal with V4  
 V5: Between V6 and V4 on the anterior axillary line  
 V3: Between V4 and V2

### Nursing Implications

Electrocardiograms can be done with the patient resting or ambulatory. A resting examination is done with the patient supine and quiet. It is completed within several minutes. The skin must be clean, dry, and as free from hair as possible to ensure good electrode contact with the skin. If the patient has excessive chest hair, some hair may need to be shaved to ensure good contact.

An ambulatory examination (Holter monitoring) can be done continuously over several days while the patient maintains normal activities. In this way, symptoms such as chest pain, SOB, or syncope may be correlated with rhythm changes. The patient is instructed to keep a log of activities, especially noting the time and activity corresponding to adverse symptoms.

### Radiology

The chest x-ray (CXR) is a general screening tool that provides information about the size, shape, and position of the heart. By itself, a CXR cannot diagnose heart disease but can highlight complications such as cardiac enlargement (Fig. 28.15) or pulmonary congestion. Pneumonia, pneumothorax, and other primary lung disorders are diagnosed via CXR. It is also used to confirm the placement of central venous catheters, endotracheal tubes, and chest tubes.

### Nursing Implications

Preparation for a CXR is minimal. A hospital gown typically replaces any clothing worn on the upper body, especially a

bra. The patient is instructed to hold his or her breath for several seconds while the film is obtained, minimizing movement and improving the quality and sharpness of the x-ray.

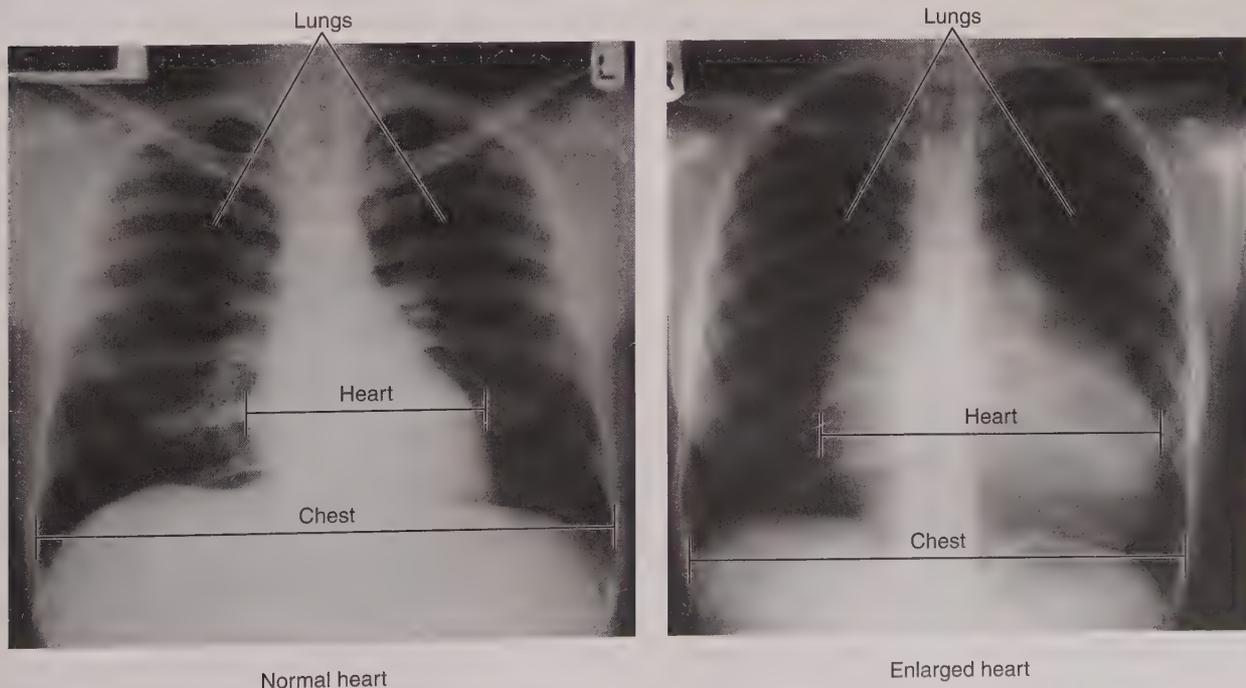

### Echocardiography

Echocardiography uses ultrasound to provide information on the size and pumping function of the heart, blood-volume status, and valve function and integrity. Two common types of echocardiography are the transthoracic echocardiogram (TTE) and the transesophageal echocardiogram (TEE). The standard TTE is performed by placing a transducer on the patient's chest. The ultrasound waves are converted to a picture, which can be evaluated.

A TEE is obtained by placing the ultrasound transducer in the patient's esophagus. This provides information from the posterior of the heart. It is used when complications such as obesity or lung disease may obscure the standard TTE by interfering with the transmission of the ultrasound sound waves anteriorly. It also provides valuable information about the posterior aspect of the heart such as the left atrium (Fig. 28.16). Additionally, information about the presence of clots in the atrium, a risk factor for stroke, is more easily viewed through TEE.

### Nursing Implications

Patients require education about the purpose and potential findings associated with echocardiography. When scheduled for a TEE, patients are instructed not to eat or drink for at least 8 hours prior to the procedure. Small sips of water with medications are the exception. Patients are given sedation for the test, so they should be

**FIGURE 28.15** Chest x-ray (CXR) of normal heart and enlarged heart.

**FIGURE 28.16** Transesophageal echocardiogram (TEE) demonstrating the chambers of the heart. LA, left atrium; LV, left ventricle; RV, right ventricle; Ao, aorta.

instructed to have someone with them who can drive them home.

### Cardiac Stress Testing

A **cardiac stress test** is done to evaluate heart functioning during times of increased workload. It is a way to evaluate the functional ability of the heart. It is also a screening tool for symptoms of cardiovascular disease that may become apparent only when the heart is stressed. In that circumstance, symptoms such as chest pain, dizziness, dysrhythmias, or SOB may occur during the test.

Regular stress testing is typically done on a treadmill or stationary bike. The patient is attached to a monitoring system. Heart rate, rhythm, and BP are monitored at regular intervals during the exercise. Chemical stress testing is done if the patient is unable to exercise because of physical limitations. Cardiac stress is induced with IV administration of a medication such as dobutamine, a medication that stimulates the heart similar to exercise. The patient is monitored in the same fashion as the treadmill test.

Isotope or nuclear stress testing is a combination of a regular stress test and a chemical stress test. In this case, the chemical is an intravenously injected nuclear isotope tracer such as thallium. The purpose of this test is to visualize areas of poor perfusion in the heart due to blocked arteries. The isotope is more readily supplied to and picked up by tissues that have adequate perfusion, creating “hot spots” when imaged. Areas of poor perfusion get a lesser supply of the isotope, thus creating “cold spots.” Imaging is done after exercise and at rest.

Another form of nuclear imaging is done with the isotope technetium. Opposite to thallium, this radioisotope becomes bound to damaged tissue, creating “hot spots.” Imaging is done several hours after injection, allowing renal clearance of the medication not accumulated in the damaged cardiac tissue.

### Nursing Implications

Patients are instructed to:

- Not eat or drink for 4 hours prior to the procedure to avoid any nausea that might be associated with heavy exercise
- Avoid smoking prior to the test
- Avoid caffeine prior to the test

During the procedure, the patient is closely monitored for the appearance of symptoms such as chest pain and/or dysrhythmias as noted previously. The nurse must be prepared to respond if patient decompensation occurs.

### Catheterization and Angiography

**Cardiac catheterization** is an invasive x-ray procedure during which a radiopaque catheter is advanced through an artery or vein to the heart under fluoroscopy in order to evaluate cardiac filling pressures, CO, and valvular function. Both right and left heart studies can be conducted. A right heart catheterization can be done through a suitable vein (femoral, brachial, subclavian). The catheter is advanced to the right heart via the inferior or superior vena cava. A left heart catheterization is done through a suitable artery (femoral, brachial, radial). The catheter is advanced up through the aorta and into the left heart.

**Coronary angiography** is the primary reason cardiac catheterization is performed. It is a left-sided cardiac catheterization with the purpose of inspecting the coronary arteries for blockage and determining the necessity of revascularization procedures such as percutaneous coronary intervention or coronary bypass surgery. It is done through a technique called cineangiography. Once the catheter is in place, contrast dye is injected that allows visualization of the vessels. Multiple consecutive images (15 frames per second) are obtained, allowing visualization of the dye flowing through the specific arteries being studied, noting any areas of stenosis or blockage (Fig. 28.17).

**FIGURE 28.17** Coronary angiography. The circle indicates an area of stenosis in the left anterior descending coronary artery.

Cardiac catheterization carries several significant risks. The threat of dysrhythmia is always present when inserting a catheter into the heart. Touching the myocardium with the catheter tip frequently causes an extrasystole, or irregular beat. There is a risk for bleeding, especially when cannulating an artery for the procedure. And as with any invasive procedure, there is a risk for infection. Other very serious risks include myocardial infarction, perforation of the heart or great vessels, and stroke.

### Connection Check 28.5

What is the most likely procedure to determine the cause of severe chest pain in the patient newly admitted to the hospital?

- A. Coronary angiography
- B. Nuclear stress testing
- C. Right heart catheterization
- D. TEE

### Nursing Implications

Patient teaching includes:

- Fasting 6 to 8 hours prior to procedure
- Expected duration and activities to expect (IV insertion, sedation) during procedure
- Information regarding potential sensations that may be experienced during the procedure, such as a “hot flash” as the dye is injected or palpitations if dysrhythmias occur
- Maintaining adequate fluid intake after the procedure
- Avoiding strenuous activity until your provider gives the OK to resume normal activities
- Monitoring cannula insertion site for bleeding

Pre-procedure care includes:

- Establish baseline vital signs
- Review blood work focusing on renal studies
- Complete pre-procedure checklist that includes obtaining height and weight and ensuring patient has been NPO
- Administer pre-procedure hydration
- Check glucose levels while NPO
- Anticipate holding diabetic medications

Intraprocedure nursing interventions for cardiac catheterization include:

- Psychological support of the patient during the procedure to help ease fears
- Vigilant cardiac monitoring during the procedure to observe for dysrhythmias
- Readiness and ability to respond with advanced cardiac life-support interventions should a lethal dysrhythmia occur

 **Safety Alert** There is a significant risk of complications after cardiac catheterization. Postprocedure nursing interventions include:

- Maintaining the patient on flat bedrest for 2 to 6 hours to prevent stress on the insertion site, which may cause bleeding
- Observation of the catheter insertion site for bleeding or hematoma formation
- Cardiac monitoring and frequent vital signs
- Monitoring the patient for chest pain
- Assessing for signs of stroke, such as confusion, weakness, or slurred speech
- Monitoring peripheral pulses, color, and temperature in the affected extremity
- Monitoring urine output secondary to the osmotic diuresis caused by the contrast dye
- Maintaining sufficient oral and/or IV fluid intake to ensure renal clearance of the dye and to maintain adequate hydration status
- Obtain blood work to assess renal function, hemoglobin/hematocrit, and coagulation studies

### Connection Check 28.6

What is an important nursing action following a cardiac catheterization intervention?

- A. Early mobilization to prevent clot formation
- B. Fluid restriction to avoid fluid overload
- C. Bedrest to avoid stress on cannula insertion site
- D. Head of bed at 30 degrees for respiratory support

### AGE-RELATED CHANGES

Aging produces a number of physiological changes in the anatomy and physiology of the cardiovascular system. Physical deconditioning can result in atrophy of the left ventricle, decreased elasticity of the aorta, and rigidity of the valves. These changes, although not apparent in ordinary circumstances, can affect the older adult's ability to respond sufficiently in times of need. Other changes related to age include:

- Stenosis of the heart valves, stiffening of the arterial walls, and increased fibrosis of the heart chambers, leading to hypertension
- Formation of atherosclerotic plaques and narrowing of the arterial walls, leading to increased risk of thrombosis and stroke

Heart disease is the number one cause of death in the older adults. Common cardiovascular health issues related to aging include hypertension, coronary artery disease, congestive heart failure, and atrial fibrillation. Age-related changes are discussed in more detail in Chapter 5.

### Connection Check 28.7

What information should be included in the teaching plan for a 76-year-old patient after a physical?

- Initiating a new strenuous exercise regimen is recommended.
- Limit physical activity and exercise.
- Report any new or excessive fatigue.
- Excessive fatigue is not unusual as you age.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Smith is scheduled for an ECG and laboratory analyses to include electrolyte, glucose, cardiac, renal, and liver parameters. He is also scheduled for a cardiac exercise stress test.

Test results include:

- Laboratory findings: cholesterol: 220 mg/dL; LDLs: 180 mg/dL; HDLs: 20 mg/dL; all else within normal limits.
- Exercise stress testing reveals SOB and fatigue on exertion.
- ECG reveals normal sinus rhythm with a rate of 85 bpm.

In general, Mr. Smith's examination reveals:

- Overweight by ~30 lb
- Cholesterol and LDLs are slightly elevated, HDLs slightly decreased.
- Stage 2 hypertension

Otherwise appears well

### Case Study Questions

- What are Mr. Smith's modifiable risk factors? (*Select all that apply.*)
  - Weight
  - Family history of heart disease
  - Dietary patterns
  - Drinking history
  - Homocysteine levels
- What statement indicates further teaching is necessary?
  - "My family history makes me worry."
  - "Changing my eating habits is hard."
  - "I will talk with my doctor before starting an exercise program."
  - "My blood pressure is not so high."
- Mr. Smith's BP increases his risk of heart disease through what action(s)? (*Select all that apply.*)
  - Prolonged increased afterload
  - Prolonged increased stress on vasculature
  - Increased cardiac workload
  - Increased automaticity
  - Decreased contractility

- Which instructions are appropriate for Mr. Smith?
  - Lose weight, exercise, and limit alcohol intake.
  - Prepare for coronary angiography.
  - Schedule an ambulatory ECG.
  - Plan for a TEE.
- What information should be included in the teaching plan for Mr. Smith? (*Select all that apply.*)
  - Check your BP frequently.
  - Start running as an exercise program immediately.
  - A diet limiting carbohydrates in favor of fats and proteins is advisable.
  - If you must drink, limit it to one drink per day.
  - If you must drink, beer is better than wine.

## CHAPTER SUMMARY

The cardiovascular system consists of the four-chambered heart, a series of high-pressure arteries that provide oxygenated blood to the tissues via the capillaries, and a series of low-pressure veins that return the blood back to the heart. Blood flow through the heart is facilitated by pressure changes that open and close valves. As the ventricles fill, the pressure within rises, closing the AV valves. The eventual ejection of blood from the left heart occurs when the pressure inside the left ventricle exceeds that of the aorta, opening the aortic valve.

Providing adequate cardiac output to meet the body's need requires both an electrical impulse conducted across the structures of the heart and a corresponding muscular contraction to facilitate the filling of the chambers and ejection of blood into the pulmonary and systemic circuits. The cycle of relaxation and contraction that produces cardiac output is called the *cardiac cycle*. It consists of diastole (relaxation) when filling occurs and systole (contraction). The muscular contraction of the cardiac cycle is controlled by the movement of charged ions across the cardiac cellular membrane, also called the cardiac action potential. The resting membrane potential is  $-90$  mV. In response to a stimulus, an action potential is propagated. Depolarization occurs, and the membrane potential becomes slightly positive because of the movement of potassium, sodium, and calcium ions in and outside the cell. At the end of the action potential, repolarization occurs. The cell returns to  $-90$  mV and is ready for another stimulus.

Cardiac cells act together as a unit to propagate an impulse across the cardiac tissue to produce the eventual contraction. The specialized cells of the cardiac conduction system consist of the SA node, the AV node, the bundle of His, the bundle branches, and the Purkinje fibers. This electrical activity produces a waveform on a paper tracing called an electrocardiogram (ECG). The P wave represents atrial depolarization, the QRS interval represents ventricular

depolarization, and the T wave represents ventricular repolarization.

The blood ejected from the left heart is referred to as the *cardiac output (CO)*. The CO is calculated by the formula heart rate (HR)  $\times$  stroke volume. Stroke volume is controlled by three variables: preload, afterload, and contractility. Cardiac output does not remain constant but is increased by exercise or activity as a result of an increase in the HR; it is decreased at times of rest.

The overall assessment of cardiovascular health includes the evaluation of many variables. The patient's history reveals modifiable and nonmodifiable risk factors, personal health history, and family history. Family history is an example of a nonmodifiable risk factor. When the patient is interviewed, current health problems are discussed as well as future goals. The physical examination of the patient will include a head-to-toe assessment and a laboratory assessment,

which includes cardiac risk factors as well as a general laboratory evaluation. Laboratory tests specific for acute events such as a myocardial infarction (CK-MB and troponin) are performed as necessary. An ECG is performed routinely at a physical examination. Other radiographical examinations, such as cardiac stress testing and echocardiograms, are performed as indicated by patient presentation. Cardiac angiography is indicated if coronary artery disease is suspected. Patient preparation prior to any examination includes patient teaching regarding the procedure, dietary restrictions and activity restrictions before and after procedures, and information about medications. During procedures that stress the heart, the nurse must be alert and ready to respond to any patient decompensation. Meticulous nursing care is necessary after cardiac catheterization to reduce strain and prevent bleeding from the cannula insertion site.

## Coordinating Care for Patients With Cardiac Dysrhythmia

*Marida Twilley*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Defining the pathophysiology of rhythm disorders
2. Identifying a method to interpret electrocardiograms (ECGs)
3. Recognizing sinus, atrial, junctional, and ventricular dysrhythmias
4. Classifying first-, second-, and third-degree blocks
5. Explaining the types of pacing used in the treatment of certain dysrhythmias
6. Employing the appropriate intervention for each dysrhythmia reviewed
7. Differentiating the use of cardioversion from defibrillation
8. Analyzing the appropriate nursing interventions for patients with cardiac dysrhythmias
9. Designing an effective patient teaching plan for a patient experiencing atrial fibrillation

### CONCEPTS

- Assessment
- Clotting
- Medication
- Perfusion

### ESSENTIAL TERMS

Accelerated idioventricular rhythm (AIVR)  
Agonal  
Asystole  
Atrial fibrillation (AF)  
Atrial flutter (AFL)  
Atrial tachycardia (AT)  
Atrioventricular (AV) node  
Complete heart block (CHB)  
Dysrhythmia  
First-degree AV block  
Idioventricular rhythm (IVR)  
Mobitz I  
Mobitz II  
Normal sinus rhythm (NSR)  
Premature atrial contraction (PAC)  
Premature junctional contraction (PJC)  
Premature ventricular contraction (PVC)  
Pulseless electrical activity (PEA)  
Second-degree AV block type I  
Second-degree AV block type II  
Sinoatrial (SA) node  
Sinus bradycardia (SB)  
Sinus tachycardia (ST)  
Supraventricular tachycardia (SVT)  
Third-degree AV block  
Ventricular fibrillation (VF)  
Ventricular tachycardia (VT)  
Wenckebach

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Ms. Danielle Fletcher is a 68-year-old female who presents to the emergency department (ED) with complaints of acute lightheadedness and palpitations. She reports that she is becoming progressively more dyspneic (short of breath). Her medical history includes hypertension (HTN) and type 2 diabetes that is diet controlled. Ms. Fletcher is currently taking hydrochlorothiazide 12.5 mg daily and lisinopril 20 mg daily. On admission to the ED, Ms. Fletcher is triaged quickly to obtain baseline vital signs, such as blood pressure, heart rate (HR), respirations, and temperature, and a 12-lead electrocardiogram (ECG). A thorough history is obtained to determine onset and triggers of symptoms for this event. Ms. Fletcher's ECG reveals atrial fibrillation (AF)...

## INTRODUCTION

An electrical conduction system with specialized muscle cells is necessary for the cardiac action potential that generates a heartbeat and thus cardiac output (CO). There is a designated pathway that the heart's normal electrical conduction travels. This pathway begins with the **sinoatrial (SA) node**, the heart's primary pacemaker, which can generate impulses at a rate of 60 to 100 beats per minute (bpm). The SA node is located in the upper wall of the right atrium near the superior vena cava. Once the SA node fires, the impulse travels through the atrial pathways and heads toward the **atrioventricular (AV) node**. This node can also be considered the gatekeeper of the heart's electrical conduction system. The AV node is responsible for allowing impulses to travel between the atria and the ventricles. Also, if for some reason the SA node fails to fire, the AV node can generate impulses at a rate of 40 to 60 bpm. Once the impulse has passed through the AV node into the ventricles, the impulse travels quickly through the ventricular pathways; the bundle branches and Purkinje fibers. Again, if the SA and AV nodes fail to

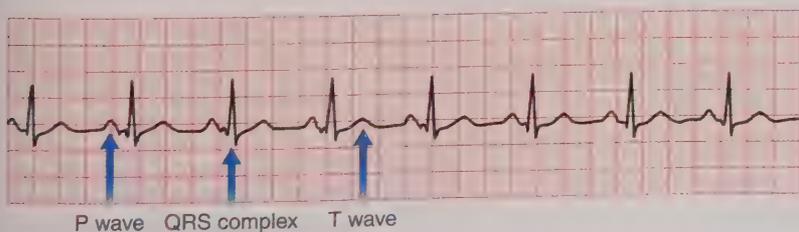

generate an impulse to stimulate the ventricles, then the ventricular pacer cells can generate impulses at a rate of 40 bpm or less. In a worst-case scenario, the Purkinje fibers can generate a ventricular rate of 20 bpm or less. The electrical conduction system is one of two components of the generation of heartbeat and cardiac output. The other component is the actual muscular contraction (squeeze). The electrical conduction system will stimulate the heart's muscle so that the chambers can contract/squeeze to force blood out of the heart. A fully functioning heart requires electrical conduction and mechanical contraction to produce CO.

When the impulse travels along the normal conduction pathway generated by the SA, it is called **normal sinus rhythm (NSR)**. It generates waveforms that indicate the firing of the SA node, the *P wave*, followed by a *QRS complex* indicating ventricular depolarization, and a *T wave*, indicating ventricular repolarization, all within the correct timing intervals (Fig. 29.1). These waveforms and intervals are discussed in detail later.

### Safety Pulseless Electrical Activity Alert

There are occasions when the electrical conduction system is functional, but the heart muscle is not responding with a contraction. This is called **pulseless electrical activity (PEA)**. If not treated quickly, the electrical conduction system will eventually stop working because of the lack of oxygen to the heart's pacemaker cells. Causes of this in patients include hypoxia (lack of oxygen), hypovolemia (low blood/fluid volume in the circulatory system), hyper- or hypokalemia (high or low blood potassium levels), acidosis (excessive acid in the body), hypoglycemia (low blood glucose level), hypothermia (low body temperature), medication toxicities (overdose), pericardial tamponade (excessive blood/fluid around the heart), pneumothorax (collapsed lung), myocardial infarction, and pulmonary embolism (blood clot in the lung), to name just a few. The treatment for PEA is chest compressions, epinephrine, and treating the possible causes. With this in mind, it should not be assumed that a patient will have a pulse because you see a rhythm on a cardiac/heart monitor; make sure that you palpate for a pulse to confirm that the heart is pumping and circulating blood.

**FIGURE 29.1** Normal sinus rhythm (NSR) with a P wave, QRS complex, and T wave.

## EPIDEMIOLOGY

When there is a disruption in the electrical conduction system, an irregular rhythm or dysrhythmias can occur. Age is a primary risk factor for dysrhythmias. Older adults have fewer pacemaker cells in the SA node, and there may be fat deposits around SA node, causing a delay in the propagation of the action potential. Also, slowed impulse transmission may be related to calcification around the AV node and valves. Other risk factors that can put a patient at higher risk for developing a dysrhythmia include:

- Myocardial infarction (MI)
- Hypertension (HTN)
- Heart valve disease
- Heart failure (HF)
- Cardiomyopathy (CM)
- Infections
- Diabetes mellitus
- Sleep apnea
- Heart surgery (and procedures)
- Electrolyte disturbances
- Recreational drug use such as cocaine, alcohol, or tobacco
- Medication toxicities such as digoxin toxicity

## PATHOPHYSIOLOGY

**Dysrhythmias** are disruptions in the cardiac conduction pathway or disorders of the electrical impulse conduction within the heart. They can result in deviations from a normal HR and/or rhythm, causing decreases in cardiac output (CO). Some dysrhythmias are lethal, causing a complete loss of CO, which results in cardiopulmonary arrest. Other dysrhythmias are apparent on ECGs but are symptomless. In between are symptomatic dysrhythmias that may require treatment. Symptoms of cardiac instability include:

- Palpitations (fast fluttering or beating in the chest or skipping beats)
- Hypotension
- Diaphoresis (sweating)
- Shortness of breath (SOB)
- Syncope (fainting)

- Lightheadedness
- Weakness and fatigue
- Dizziness
- Anxiety

## Connection Check 29.1

As the nurse, you know that the following can cause rhythm disorders: (Select all that apply.)

- Exercise
- Electrolyte imbalances
- Myocardial hypertrophy
- Myocardial damage
- Eating red meat

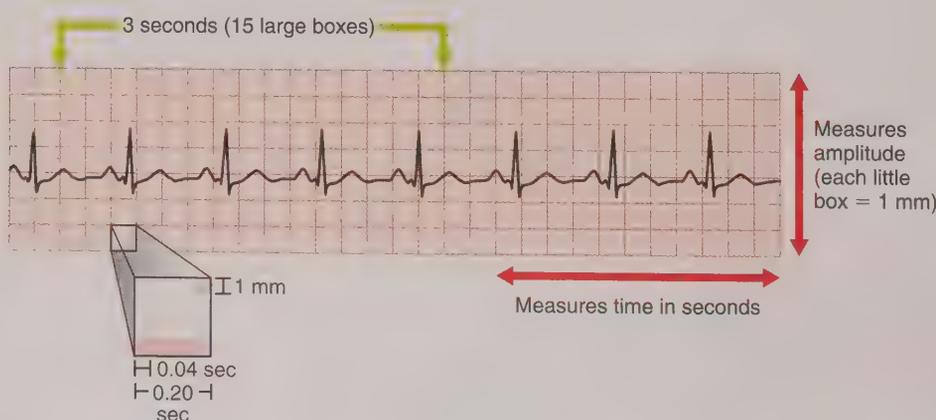

## ECG REVIEW

### Electrocardiogram

An ECG provides a graphic representation of the heart's electrical activity. When electrodes are placed on the patient's skin, they can monitor the flow of the electrical charges and transmit the corresponding waveforms to an ECG machine or cardiac monitor. The standard ECG has 12 leads or views of the electrical activity in the heart. Each lead has a negative and positive electrode or pole. The electrical impulse is measured as it moves between two poles or points. When the electrical impulse is moving toward a positive pole, the waveforms will be upright on the ECG. If the electrical impulse is moving away from the positive pole, it will produce a downward or negative deflection on the ECG. Waveforms vary in shape and size depending on which lead the monitor is set to read. The best lead to identify or interpret the heart's rhythm is lead II. Lead II mimics the heart's natural electrical direction in a healthy, normally positioned heart.

### ECG Paper

When a patient receives an ECG or is placed on a cardiac monitor, the heart's electrical activity will be printed on specialized graph paper for interpretation. The ECG graph paper can measure both amplitude and time (Fig. 29.2).

**FIGURE 29.2** Electrocardiogram graph paper measures both amplitude and time.

The amplitude is measured on the vertical axis in millimeters (mm), whereas time is measured in seconds (sec) along the horizontal axis. The standard paper speed for ECGs is 25 mm per second. The graph paper is segmented into small and large boxes. Each small box is 1 mm in height (amplitude) and 0.04 sec in length. When looking at the graph paper, you will notice that there are darker lines that create a larger box. The larger boxes are divided into areas five small boxes high and five small boxes long. One large box equals 0.20 sec long (0.04 sec  $\times$  five small boxes = 0.20 sec). This creates a quick reference when measuring the time intervals of the various waveforms discussed next.

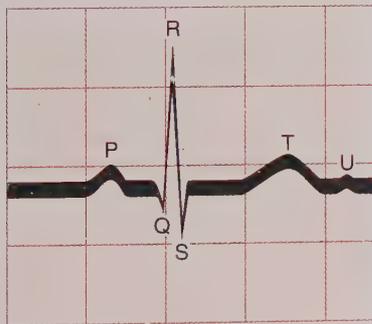

### Waveforms

The normal conduction pathway produces waveforms on an ECG that show the current as it travels across the heart tissue (Fig. 29.3). They are listed as follows in the order they normally appear on the ECG:

1. P wave
2. QRS complex
3. T wave
4. U wave

The *P wave* is the first waveform that is normally seen (Fig. 29.4). The P wave represents the SA node sending out an electrical impulse and represents atrial depolarization. This wave should be upright (positive deflection) with a rounded top in lead II. The P wave itself should not be longer than 0.10 sec in length and no higher than 2.5 mm.

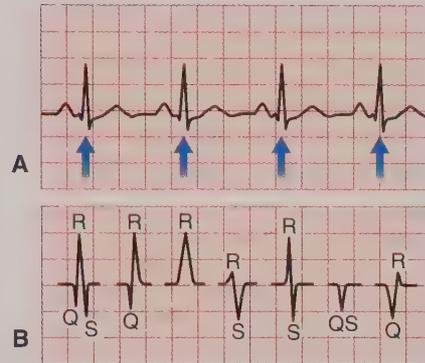

The *QRS wave* (or *QRS complex*) is the next waveform that is normally seen (Fig. 29.5A). This complex represents ventricular depolarization. The ventricles depolarize from the endocardial layer (inside of the heart) to the epicardial layer (outermost layer of the heart). The QRS complex can take on many different forms (Fig. 29.5B). Normal QRS

**FIGURE 29.3** Waveforms seen on an electrocardiogram (ECG) that show the heart's electrical current as it travels.

**FIGURE 29.4** The P wave: atrial depolarization.

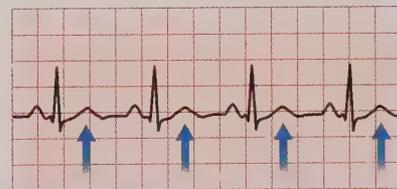

**FIGURE 29.5** A, The QRS wave (or QRS complex): ventricular depolarization. B, The QRS complex can take many different forms.

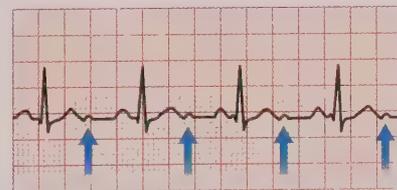

complexes are usually pointy and skinny in width. As a rule of thumb, a wide QRS (greater than 0.10 sec or two and a half small boxes wide) means that there is something occurring in the ventricles causing the QRS to widen. For example, it may indicate that the impulse originated in the ventricles or that there is a block in the ventricles delaying the impulse from traveling through the ventricles to allow for a normal depolarization.

The *T wave* occurs after the QRS and represents ventricular repolarization (Fig. 29.6). This wave should be upright and rounded in lead II. Even though the T wave is not used for rhythm interpretation, it can be helpful in monitoring extreme electrolyte imbalances such as hypokalemia or hyperkalemia, disturbances with the myocardial oxygen supply, or other cardiac disorders such as pericarditis or ventricular aneurysm. There is no visible waveform that represents atrial repolarization. That is typically “buried” in the QRS complex.

The *U wave* represents Purkinje fiber repolarization and is rarely seen (Fig. 29.7). However, this waveform can be seen in patients with certain medication toxicities (e.g., digoxin toxicity) and electrolyte imbalances (e.g., hypokalemia). When a U wave is seen, it should be a small rounded wave in lead II. Be careful not to confuse it with the P wave.

**FIGURE 29.6** The T wave: ventricular repolarization.

**FIGURE 29.7** The U wave: Purkinje fiber repolarization.

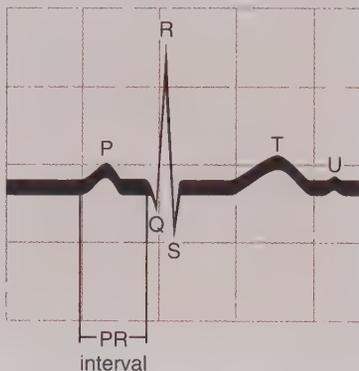

## Intervals

The intervals measure the amount of time it takes for the impulse to travel from one waveform to the next. They are the:

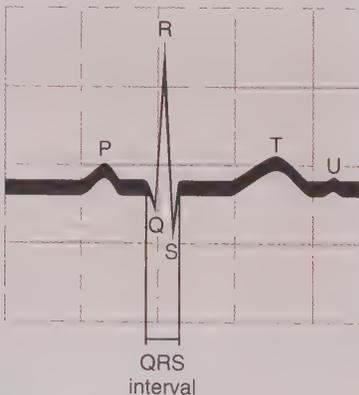

- PR interval
- QRS interval
- QT interval

The *PR interval* is the measure of time that it takes an electrical impulse to depolarize the atria and travel to the ventricles. To measure this interval, start from the beginning of the P wave (where it starts to leave the baseline) and count the number of small boxes to the beginning of the QRS complex (not the R wave; Fig. 29.8). The normal PR interval is from 0.12 sec (three small boxes) to 0.20 sec (five small boxes) in length.

The *QRS interval* is the measure of time to depolarize the ventricles. It is measured from where the QRS waveform leaves the baseline to where the QRS returns to the baseline (Fig. 29.9). The normal interval is 0.06 to 0.10 sec in length. As discussed previously, if the QRS is prolonged (more than 0.10 sec; equal to or more than three small boxes), it may be a sign of a disturbance within the ventricle itself (i.e., that the impulse originated in the ventricles or that there is a block in the ventricles delaying impulse travel time through the ventricles).

**FIGURE 29.8** The PR interval: measure of time to depolarize the atria and travel to the ventricles.

**FIGURE 29.9** The QRS interval: the measure of time to depolarize the ventricles.

The *QT interval* is the measure of time that it takes the ventricle to depolarize and then repolarize. To measure a QT interval, start where the QRS leaves baseline and measure to where the T wave returns to baseline (Fig. 29.10). This interval is heart-rate dependent and should never be more than half the distance from one QRS to the next. A normal QT is usually less than or equal to 0.52 sec in length.

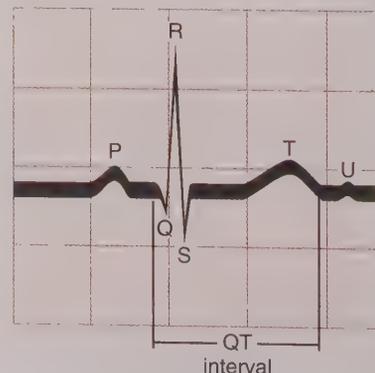

## Steps in ECG Interpretation

When evaluating a cardiac rhythm, ask the following questions to help identify the rhythm seen on the ECG:

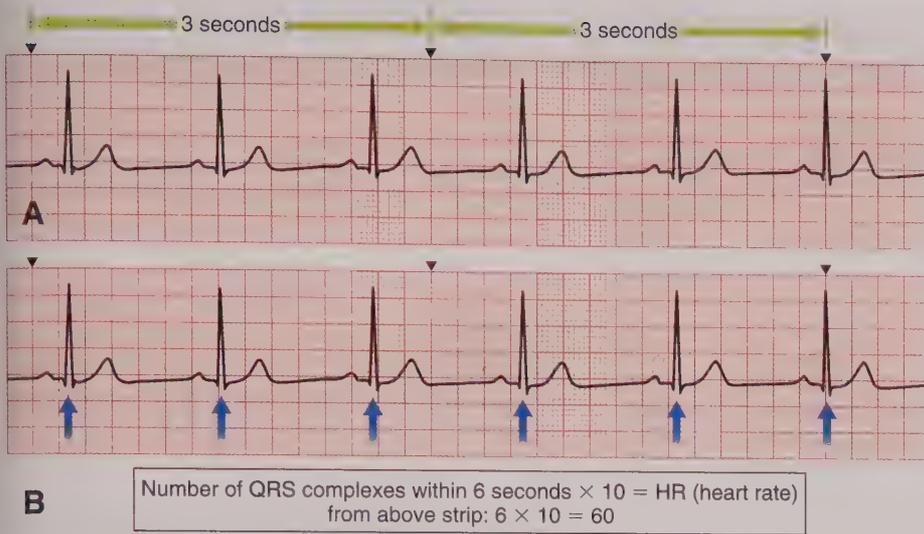

- Is the rate fast, slow, or normal?
- Is the rhythm regular; are complexes an equal distance from one to the next?
  - Are the distances from P wave to P wave equal throughout the strip? This is referred to as the *P-P interval*.
  - Are the distances from QRS wave to QRS wave equal throughout the strip? This is referred to as the *R-R interval*.
- Are there P waves present?
- Are there QRS complexes present?
- Are there T waves present?
- Are the intervals within normal limits (e.g., PR interval, QRS interval)?
- Is there a P wave before every QRS?
- Is there a QRS after every P wave?

## Calculating Heart Rate

Establishing the heart rate (HR) is the first step in ECG evaluation. A *6-second strip* is a quick way to calculate an average HR, but it is not completely reliable if the rhythm is irregular. Electrocardiograph or monitor paper will print time markers, which may be vertical lines or arrows on the top or bottom of the strip (Fig. 29.11A). Most ECG/monitor paper time markers represent 3 seconds, which is 15 large boxes long; six seconds equals 30 large boxes. In order to use this method, count the number of QRS complexes that fall within a 6-second period of time or 30 large boxes and multiply by 10. For example, if you see six QRS complexes, multiply six by 10, which equals 60 bpm (Fig. 29.11B).

**FIGURE 29.10** The QT interval: the measure of time that it takes the ventricle to depolarize and then repolarize.

**FIGURE 29.11** A, A 6-second strip. B, Calculating a heart rate using a 6-second strip.

Another method to calculate HR is to count the number of **small** boxes between two R waves and divide that number into 1,500. As an example, if there are 19 small boxes between two R waves, the calculation is  $1,500/19 = \text{HR of } 79$ . One last method is to count the number of **large** boxes between two R waves and divide that number into 300; for example, for five large boxes, the calculation is  $300/5 = \text{HR of } 60$ .

### Calculating Regularity

An important step in evaluating an ECG is determining regularity. Regularity can be determined by counting the boxes between the waveforms being measured, such as P wave to P wave (P to P) or QRS complex to QRS complex (R to R). A regular rhythm will have the same number of boxes or equal space between waveforms or complexes (Fig. 29.12A). This is also called *marching out* the rhythm. *Marching out* the waveforms can help demonstrate if waves are falling early or late or are even hiding within another waveform. If the spaces are not equal, then it is considered irregular (Fig. 29.12B).

### Connection Check 29.2

As the nurse caring for a patient on a cardiac monitor, you understand that which of the following steps are necessary to correctly identify the rhythm? (*Select all that apply.*)

- A. Determine the rate
- B. Determine the regularity
- C. Determine if there is a QRS for every P wave
- D. Determine if there is a P wave for every QRS
- E. Determine if there is a U wave for every QRS

## CARDIAC DYSRHYTHMIAS

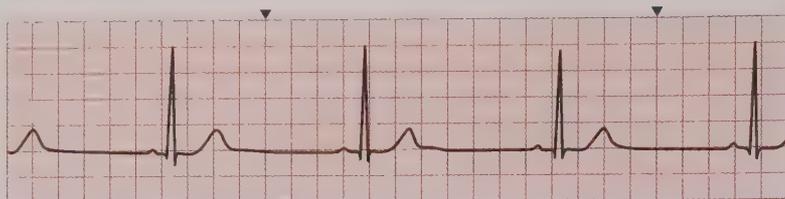

### Sinus Dysrhythmias

#### Sinus Bradycardia

**Sinus bradycardia (SB)** is a regular rhythm that has the same characteristics as NSR except the HR is less than 60 bpm (Fig. 29.13).

**FIGURE 29.12** Marching out the waveforms. A, Example of a regular rhythm; equal distance R to R. B, Example of an irregular rhythm. Notice the difference in distance between R waves.

**FIGURE 29.13** Sinus bradycardia (SB): sinus rhythm with a rate less than 60; in this strip, the rate is 40.

**Causes**

Causes of SB include but are not limited to hypoxia and/or hypothermia. It can occur during sleep, or it may be the normal rate in well-trained athletes. It is important to determine if the patient is symptomatic or experiencing symptoms such as syncope, chest pain, hypotension, shortness of breath (SOB), or diaphoresis while bradycardic. A symptomatic patient will require treatment. It may be normal in a nonsymptomatic patient, or that patient may just require observation.

**Treatment**

Treatment of symptomatic SB is atropine 0.5 mg IV push (IVP) (see Table 29.1).

**Sinus Tachycardia**

**Sinus tachycardia (ST)** is a regular rhythm that has the same characteristics as NSR except the HR is greater than 100 bpm (Fig. 29.14).

**Causes**

Causes of ST include but are not limited to fever, anemia, hypovolemia, hypotension, pulmonary embolism (PE), and myocardial infarction (MI).

**Treatment**

The treatment for ST is based on patient symptoms and possible causes. For example, if the patient is anemic and volume depleted, the treatment may be as simple as

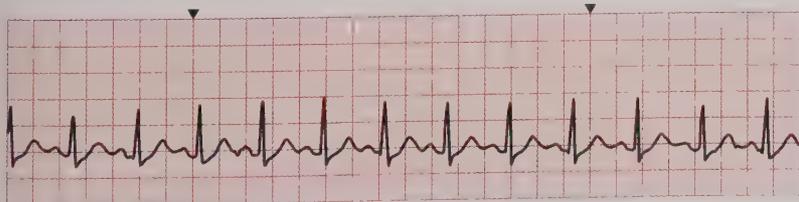

**Table 29.1 Overview of Medications for Cardiac Dysrhythmias**

Medication Class	Medication Name(s)	Action	Indicated Rhythm	Special Considerations
<b>Diagnostic/ Antiarrhythmic</b>	Adenosine (Adenocard)	Slows down the heart rate temporarily to allow for better visualization of the rhythm	SVT	Dosing is rapid IV push of 6 mg followed by a 20-mL normal saline bolus; may repeat in 1–2 min with a dose of 12 mg followed by the normal saline bolus.  If the patient has central venous access, the dose can be halved (e.g., 3 mg followed by 6 mg).  Maximum dose: no more than two doses  May result in asystole—The patient should be monitored, and a transcutaneous pacemaker should be readily available if the patient remains in prolonged asystole.
	Amiodarone (Cordarone, Pacerone)  Dronedarone (Multaq)  Dofetilide (Tikosyn)	Slows the cardiac action potential, thus slowing the heart rate	VT VF AF	Amiodarone (Cordarone, Pacerone):  ● IV preparation for continuous infusion must be in a glass bottle.  Monitor:  ● Pulmonary function test ● Thyroid function ● Liver function

**Table 29.1 Overview of Medications for Cardiac Dysrhythmias—cont'd**

Medication Class	Medication Name(s)	Action	Indicated Rhythm	Special Considerations
<b>Anticholinergic</b>	Atropine sulfate	Increases SA node stimulus and increases conduction through the AV node	Sinus bradycardia	Use cautiously with MI patients
<b>Anticoagulant</b>	Warfarin (Coumadin), Dabigatran (Pradaxa) Rivaroxaban (Xarelto) Apixaban (Eliquis) Edoxaban (Savaysa) Heparin	Inhibits clot formation	AF AFL	Monitor signs and symptoms of bleeding. Warfarin: ● Monitor INR or PT. Dabigatran, rivaroxaban, apixaban, and edoxaban: ● Monitor renal function. Heparin ● Monitor aPTT. ● Monitor platelets.
<b>Beta blocker</b>	Atenolol (Tenormin) Metoprolol (Lopressor) Carvedilol (Coreg) Sotalol (Betapace)	Negative chronotropic effects to help slow down the heart rate; decreases cardiac workload and oxygen demand	ST AF with RVR	Use cautiously in patients with: ● Heart failure ● Asthma Carvedilol is used in patients with heart failure for rate and rhythm control. Sotalol is used in AF rate and rhythm control.
<b>Calcium channel blocker</b>	Diltiazem (Cardizem)	Slows conduction through the AV node	AF AFL	Use cautiously in patients with heart failure.
<b>Cardiac glycoside</b>	Digoxin (Lanoxin)	Slows conduction through the AV node; improves cardiac contractility	ST AF AFL	Monitor: ● Digoxin levels ● Renal function Use cautiously in combination with amiodarone (Cordarone, Pacerone).
<b>Vasopressor</b>	Epinephrine	Produces vasoconstriction	VT VF	Ensure free-flowing IV. Use in combination with CPR.

AF, Atrial fibrillation; AFL, atrial flutter; AV, atrioventricular; CPR, cardiopulmonary resuscitation; IV, intravenous; RVR, rapid ventricular response; SA, sinoatrial node; ST, sinus tachycardia; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

**FIGURE 29.14** Sinus tachycardia (ST): sinus rhythm with a rate greater than 100; in this strip, the rate is 130.

administering red blood cells and IV fluids. Medications such as beta blockers or calcium channel blockers may be used to control or reduce the HR.

See Table 29.2 for a summary of sinus dysrhythmias.

### Atrial Dysrhythmias

Atrial dysrhythmias are caused by pacemaker cells firing not from the SA node but from somewhere else within the atria. They include premature atrial contractions (PACs), atrial fibrillation (AF), and atrial flutter (AFL). Supraventricular dysrhythmias also arise from the atria with the exception of junctional tachycardias.

### Premature Atrial Contractions

**Premature atrial contractions (PACs)** are non-life-threatening dysrhythmias that can be seen in NSR. In this dysrhythmia, a pacemaker cell close to the SA node fires earlier than expected (Fig. 29.15). This is an irregular rhythm due to the early impulse or beat. The PAC has a pause at the end of the complex called a *compensatory pause* allowing the conduction system to reset and resume the regular rhythm.

#### Causes

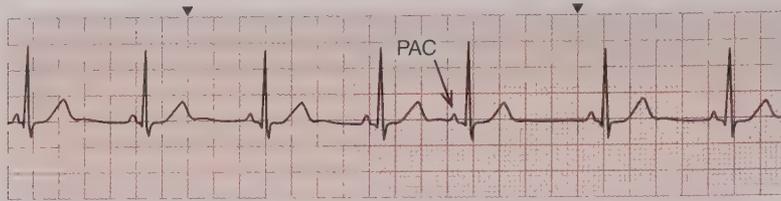

Causes of PAC include hypoxia, excessive stimulant ingestion (e.g., caffeine), infections, digoxin toxicity, and coronary artery disease.

**Table 29.2 Summary of Sinus Dysrhythmias**

Dysrhythmia	Signs and Symptoms	Medical Interventions	Nursing Interventions	Patient Teaching
<b>Sinus bradycardia, asymptomatic</b>	None	Assess and treat the causes as necessary: <ul style="list-style-type: none"> <li>● Hypoxia</li> <li>● Ischemia</li> <li>● Electrolyte imbalance</li> <li>● Medication toxicities such as digoxin or calcium-channel-blocker overdose</li> </ul>	All asymptomatic sinus dysrhythmias: Notify provider. Assess the patient for: <ul style="list-style-type: none"> <li>● LOC</li> <li>● Palpable pulses</li> <li>● BP</li> </ul> Obtain a 12-lead ECG.	All asymptomatic sinus dysrhythmias: Educate patient/family about signs and symptoms that can occur. Discuss signs and symptoms that warrant the patient or family contacting the primary care provider or healthcare provider or calling 911 for emergency help.
<b>Sinus tachycardia, asymptomatic</b>	None	Depends on the rate and cause of ST HR less than 150 bpm: Observe patient for possible signs of decompensation. Treat the causes: <ul style="list-style-type: none"> <li>● Infection</li> <li>● Fever</li> <li>● Hypovolemia</li> <li>● Hypoxia</li> <li>● Ischemia</li> <li>● Electrolyte imbalance</li> <li>● Stimulants</li> </ul> HR greater than 150 bpm (the patient can decompensate quickly): consider beta blockers to slow down the HR.

**FIGURE 29.15** Premature atrial contractions (PACs); notice how the PAC occurs early or prematurely compared with the four previous complexes.

### Treatment

The treatment for PACs is to monitor the frequency and eliminate the cause. This is especially important if the patient is symptomatic. If the patient gets PACs after drinking a pot of coffee in the morning, the “treatment” will be to eliminate or limit the coffee intake. This will help decrease the stimulus to the SA node and hopefully resolve the PACs.

### Atrial Fibrillation

**Atrial fibrillation (AF)** is one of the most commonly seen dysrhythmias in the United States. The National Institutes of Health estimates that 2.2 million Americans are diagnosed with this dysrhythmia, and the American Heart Association (AHA) estimates that upward of 6.1 million Americans have been affected by AF, which often leads to other heart-related complications as well as increased risk of stroke. It accounts for roughly one-third of all hospital admissions due to dysrhythmias. The general classifications of AF are as follows: paroxysmal or spontaneously self-limiting, persistent or continuing beyond 7 days, long-standing or lasting more than 12 months, and permanent or persistent AF that is resistant to rhythm control therapies.

Atrial fibrillation has no *P waves*. It is best described as multiple pacemaker cells generating independent electrical impulses and causing chaos within the atria (see Figs. 29.16A, B, and C). It is characterized as irregularly irregular. The QRS complexes are usually narrow with irregular R–R intervals. Although the naked eye cannot measure an atrial rate in this rhythm, it can range from 300 to 600 bpm. The HR or ventricular response is determined by the AV node’s

ability to accept and transmit the impulses to the ventricle. When the AV node maintains the HR at less than 100 bpm, the AF is considered controlled (Fig. 29.16A). If the HR is greater than 100, the AF is considered uncontrolled and is called AF with rapid ventricular response (RVR; Fig. 29.16B).

### Causes

The risk for AF increases with age. Causes include but are not limited to cardiomyopathy, pericarditis, hyperthyroidism, HTN, valvular disease, obesity, diabetes, chronic kidney disease, patients undergoing cardiac procedures or surgery, and coronary artery disease.

### Complications

#### Loss of Cardiac Output

Because the atrial pacemaker cells are firing and competing against one another at such a rapid rate, the atria can only quiver instead of beating or contracting/squeezing normally. Without a normal atrial contraction, the heart can lose approximately 30% of its CO. This is referred to as *loss of atrial kick*, the filling force contributed by atrial contraction immediately before ventricular systole to maximize ventricular preload. This decrease in CO can cause significant symptoms for some patients, such as syncope, palpitations, and SOB.

#### Clots

Because the atria are not squeezing or contracting efficiently, blood pools in the atria, which can predispose the patient to clot formation. Blood clots moving through the circulation put the patient at risk for embolic events such as strokes. Care

**FIGURE 29.16** Atrial fibrillation (AF). A, Controlled AF with a ventricular rate of 50. B, Uncontrolled AF with rapid ventricular response (RVR).

should be taken when administering any treatments that could convert AF to NSR because of the increased risk of an embolus (blood clot) being forced out into the circulatory system.

### Treatment

The treatment plan for AF is, in general, based on whether it is new onset or an established diagnosis in a patient. Other factors include ventricular response or HR and patient clinical manifestations. Anticoagulation should be considered in all patients with AF to prevent clot formation (see Table 29.1). Initial rate control is typically necessary in new-onset AF. Medications to control the HR, such as digoxin, beta blockers, and calcium channel blockers, are considered. Once the heart rate is managed, rhythm control is considered either through antiarrhythmic medications, cardiac ablation (scarring/destroying the tissue in the heart responsible for the irregular rhythm), or cardioversion. Typically, cardioversion (Table 29.3) is considered for AF after adequate anticoagulation is attained. Sometimes the atrium is evaluated for the presence of clots by transesophageal echocardiogram (TEE) prior to the procedure because it is not recommended if clots are present due to the risk of embolic events. If the patient is symptomatic (e.g., hypotensive, short of breath, having pain), urgent cardioversion may be required before adequate anticoagulation is attained. In that case, the patient should receive intravenous heparin as soon as possible with a loading dose before the procedure. Once initial stabilization has been attained or with established AF care, further treatment considerations include deciding on long-term rhythm or rate control, again with digoxin, beta blockers, and calcium channel blockers or antiarrhythmic medications (see Evidence-Based Practice).

### Evidence-Based Practice

#### Follow Up From the AFFIRM Trial

In 2011, the AFFIRM trial, which investigated the mortality and morbidity of patients with AF and the relationship to rate and rhythm control, was published. The trial enrolled 4,060 patients with AF, with ages ranging from 46 to 80 years (mean age, 65 years).

The results showed the following:

- Increased mortality rates were associated with myocardial infarctions, coronary artery bypass graft, and digoxin therapy.
- Amiodarone was associated with increased intensive care unit stays and death.
- Rhythm control (converting the AF to sinus rhythm) and rate control in conjunction with anticoagulation therapy were equally effective in preventing strokes.

A follow-up study published in 2017 found that many patients turned to “crossover” treatment strategies to manage their symptoms. Of the study participants, 29% switched to rate from rhythm control, largely due to a failure to maintain rhythm control (45%) or intolerable side effects (20%). In addition, 12% switched to rhythm from rate control for similar reasons—failure to control the symptoms of AF (64%) and, again, intolerable side effects (3.6%). An interesting finding is that there was a significant difference in mortality in the subgroup of patients who switched to rate control compared with those who did not switch and maintained rhythm control. There was not a significant difference in the other subgroup, switch from rate to rhythm control, compared with the group that maintained rate control.

Maan, A., Zhang, Z., Qin, Z., Wang, Y., Dudley, S., Dabhadkar, K., ... Heist, E. K. (2017). Impact of treatment crossovers on clinical outcomes in the rate and rhythm control strategies for atrial fibrillation: Insights from the AFFIRM (Atrial Fibrillation Follow-Up Investigation of Rhythm Management) trial. *Pacing and Clinical Electrophysiology*, 40(7), 770-778.

### CASE STUDY: EPISODE 2

The patient history reveals that Ms. Fletcher has not been feeling well for several days. Her symptoms are related to a decrease in CO resulting from AF. She is seeking treatment in the ED because she became more short of breath and dizzy this morning. Anticoagulation therapy is indicated initially to prevent thrombus formation. She is placed on a heparin drip. Laboratory clotting studies are performed to evaluate the effectiveness of the heparin drip. She is placed on bleeding and fall precautions. Ms. Fletcher is given patient education on the risk of increased bleeding caused by the anticoagulation medication...

#### Atrial Flutter

**Atrial flutter (AFL)** is a dysrhythmia produced by a pacemaker cell other than the SA node. Because the SA node is not the primary pacemaker in this rhythm, there are no P waves. Flutter waves (*F waves*), however, are present. F waves resemble a sawtooth pattern between narrow QRS complexes (Fig. 29.17). The atrial rate can range from 250 to 350 bpm. The number of F waves to a QRS complex can vary depending on the AV node's ability to accept and transmit impulses through to the ventricles which could produce a normal HR (60–100 bpm) or have an RVR response

**Table 29.3 Summary of Cardioversion and Defibrillation**

	<b>Cardioversion</b>	<b>Defibrillation</b>
<b>Definition</b>	Controlled electrical discharge of energy at the peak of the R wave	Uncontrolled electrical discharge of energy anywhere during the cardiac cycle
<b>Indications</b>	Symptomatic tachy dysrhythmias <i>with a pulse</i> : <ul style="list-style-type: none"> <li>● Supraventricular (SVT) rhythms</li> <li>● AF with RVR (with caution)</li> <li>● AFL with RVR</li> <li>● VT with a pulse</li> </ul>	Tachy dysrhythmias <i>without a pulse</i> : <ul style="list-style-type: none"> <li>● VT</li> <li>● VF</li> </ul>
<b>Pad placement</b>	Anterior/posterior (sometimes called <i>sandwiching the patient</i> ; see Fig. 29.30B)	Anterior position (apex/sternum) used most often because of ease of application, but anterior/posterior approved (see Fig. 29.30A)
<b>Energy level (joules; J)</b>	SVT and AFL start between 50 and 100 J, then slowly increase to 200 J.  AF starts between 120 and 200 J, then increases until maximum energy of 200 J.  VT with a pulse starts at 120–200 J.	VT/VF = 200 J

AF, Atrial fibrillation; AFL, atrial flutter; RVR, rapid ventricular response; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

Based on American Heart Association (AHA) Advanced Cardiac Life Support (ACLS) guidelines: ACLS 2015 guidelines using biphasic defibrillator.

**FIGURE 29.17** F waves. A, Atrial flutter (AFL; 2-to-1 conduction rate). B, AFL with a variable conduction rate.

(HR >150 bpm). Like AF, AFL can be a chronic or short-term dysrhythmia.

### Causes

Causes of AFL in adult patients include acute MI, severe mitral valve disease, thyrotoxicosis (high thyroid hormone levels), and chronic obstructive pulmonary disease. Patients who have had surgical procedures within the chest, such as coronary artery bypass graft or pneumonectomy (removal of a portion of the lung), are prone to AFL. Atrial flutter can also be seen with digoxin toxicity.

### Treatment

Treatment options for AFL are similar to those for AF. The goal of treatment is to control the ventricular rate

until the SA node takes over again, producing a normal rhythm. Beta blockers, calcium channel blockers, and digoxin can be used to control the ventricular rate (see Table 29.1). Some of these agents should be used cautiously because they can exacerbate HF symptoms and cause bradycardia. If a patient is still in AFL after the rate is controlled or is less than 100 bpm, then an antiarrhythmic may be ordered to chemically convert the rhythm back to an NSR.

Cardioversion (see Table 29.3) can be used to terminate the AFL but is not the first-line treatment unless the patient is severely symptomatic, and it may not be successful. Some of the symptoms that could warrant cardioversion include but are not limited to chest pain, hypotension, and SOB.

## Supraventricular Tachycardia

**Supraventricular tachycardia (SVT)** is a rapid heart rhythm that originates above the ventricles. It most commonly appears as a regular, narrow QRS complex tachycardia. By definition, SVT is any narrow complex rhythm greater than 100 bpm, but can have HRs from 150 to 250 bpm (Fig. 29.18A). The rate may be slower depending on the patient's condition and the underlying cause of SVT. Another presentation is paroxysmal supraventricular tachycardia (PSVT), which is intermittent, coming on quickly and ending quickly (Fig. 29.18B).

Supraventricular tachycardia can be considered an umbrella term to capture one of five narrow complex tachycardia rhythms:

- Sinus tachycardia (ST; see Fig. 29.14), previously discussed in the sinus dysrhythmia section
- **Atrial tachycardia (AT)**, which is similar to ST except the electrical impulse is not generated from the sinus node. The electrical impulse is generated somewhere in the atria and can have unifocal (uniform appearance—originating from a single source; Fig. 29.19A) or multifocal (nonuniform appearance—originating from multiple sources; Fig. 29.19B) presentation.

- Atrial fibrillation with RVR (see Fig. 29.16C)
- Atrial flutter with RVR (see Fig. 29.17)
- Junctional tachycardia (JT), which is discussed in the junctional section later in the chapter (see Fig. 29.20C)

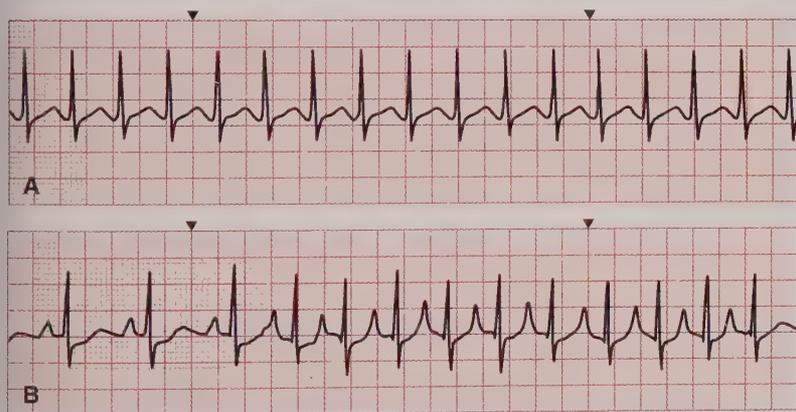

### Treatment

The treatment for SVT is based on the symptoms and underlying rhythm. The key for treating SVT is to figure out the underlying rhythm while slowing down the HR. If the patient is symptomatic, medications (see Table 29.1) can be used, and electrical cardioversion can be considered; however, careful consideration should be taken if the underlying rhythm is not known.

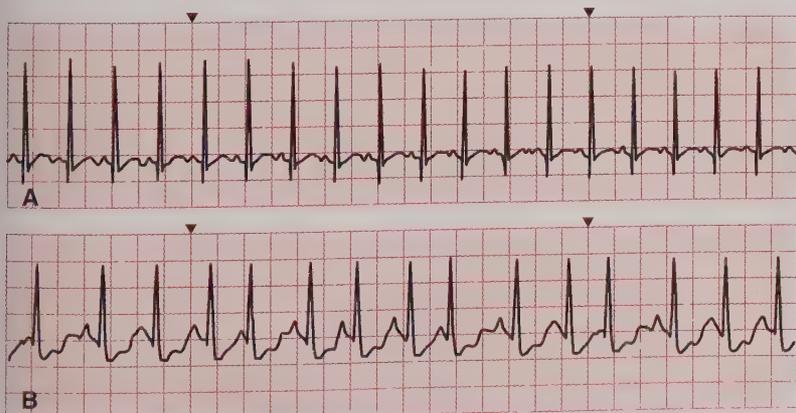

See Table 29.4 for a summary of atrial dysrhythmias.

**Safety Alert** Patients receiving adenosine (Adenocard) may experience prolonged periods of asystole after administration. Prior to administration of the medication, the patient should be on a monitor, and a transcutaneous pacemaker should be readily available should pacing of the patient be necessary.

**FIGURE 29.18** Supraventricular tachycardia (SVT). *A*, Continuous SVT with a heart rate of 170. *B*, Paroxysmal supraventricular tachycardia (PSVT).

**FIGURE 29.19** Atrial tachycardia (AT). *A*, Unifocal AT originating from the one pacemaker in the atria. *B*, Multifocal AT originating from many pacemakers in the atria.

AT, Atrial tachycardia; BP, blood pressure; CAD, coronary artery disease; COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; HR, heart rate; HTN, hypertension; JT, junctional tachycardia; LOC, level of consciousness; MI, myocardial infarction; RVR, rapid ventricular response; SOB, shortness of breath; ST, sinus tachycardia.

### Connection Check 29.3

Key patient teaching points for AF include which of the following? (Select all that apply.)

- A. Medications for HR control
- B. Bleeding precautions
- C. Signs and symptoms of AF with RVR
- D. Cardioversion
- E. Defibrillation

### Junctional Rhythms

Junctional rhythms begin within the AV node. The AV node is a cluster of pacemaker cells positioned between the atria and the ventricles. The AV node generates impulses at a rate between 40 and 60 bpm (Fig. 29.20A). If the rate increases to 61 to 100 bpm, it is identified as an accelerated junctional rhythm (Fig. 29.20B). If the HR is greater than 100 bpm, it is identified as a junctional tachycardia (Fig. 29.20C). In order for both the atria and the ventricles to depolarize during a junctional rhythm, the electrical

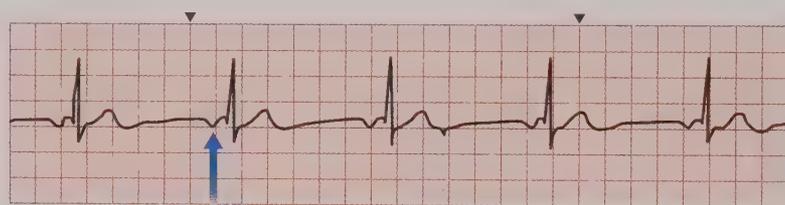

impulse from the AV node must split and travel in different directions. The ventricular conduction pathway will accept the electrical impulse as usual. However, in order for the atria to depolarize, the electrical impulse must travel backward (the opposite direction of the normal conduction), producing a retrograde P wave. This will display as an inverted or upside-down P wave, an absent P wave, or a retrograde P wave at the end of the QRS wave.

### Premature Junctional Contractions

**Premature junctional contractions (PJC)s** are junctional impulses generated early by the AV node (Fig. 29.21). As with PACs, PJC)s are not life threatening. They can present with an inverted P wave prior to, buried in, or after the QRS wave and will have a compensatory pause immediately following the PJC. Patients with PJC)s are rarely symptomatic and typically do not require treatment.

### Causes

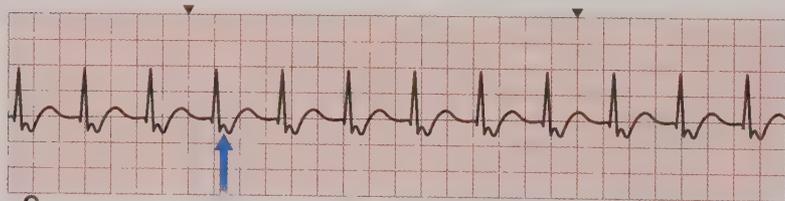

Causes of junctional dysrhythmias include digoxin toxicity, acute MI, and heart surgery.

A Retrograde inverted P wave

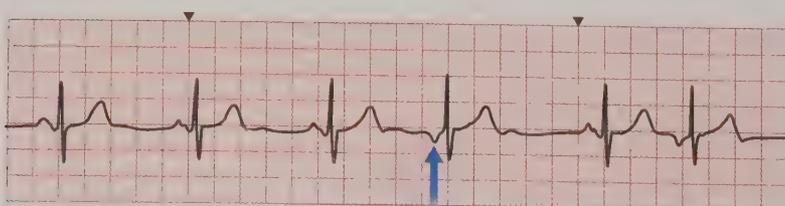

B Absent P wave

C P wave

**FIGURE 29.20** Junctional rhythms. A, Junctional rhythm with a ventricular rate of 50. B, Accelerated junctional rhythm with a ventricular rate of 70. C, Junctional tachycardia with a ventricular rate of 120.

Premature junctional contraction with inverted P wave

**FIGURE 29.21** Premature junctional contractions (PJC)s; notice the inverted P wave.

## Treatment

Treatment of junctional dysrhythmias is based solely on the patient's symptoms and possible causes. For example, if medication toxicity is the cause, then the medication should be stopped and reversed using an antidote if needed and if available.

See Table 29.5 for a summary of junctional dysrhythmias.

### Connection Check 29.4

Which of the following is *not* an appropriate intervention for all atrial dysrhythmias?

- An ECG
- A pulse check
- Blood pressure
- Cardioversion

## Ventricular Rhythms

Ventricular rhythms are those rhythms that originate somewhere within the ventricles. When an impulse starts in the ventricle, there is no P wave, and the QRS is usually wide ( $\geq 0.12$  sec or three small boxes). The normal rate for pacemaker cells within the ventricles is 40 bpm or less. Types of ventricular rhythms include premature ventricular contractions (PVCs), ventricular tachycardia (VT), ventricular fibrillation (VF), and idioventricular rhythms (IVRs).

### Premature Ventricular Contractions

**Premature ventricular contractions (PVCs)** are wide and atypical (or bizarre-looking) QRS complexes that fire earlier than expected from within the ventricles (Fig. 29.22). As with other premature contractions, there is a compensatory pause at the end to allow the heart's conduction system to

**Table 29.5 Summary of Junctional Dysrhythmias**

BP, Blood pressure; ECG, electrocardiogram; HR, heart rate; IVP, intravenous push; LOC, level of consciousness; SOB, shortness of breath; TCP, transcutaneous pacing.

reset. There are no P waves visible prior to the QRS because the impulse originated in the ventricle. Premature ventricular contractions coming from one ventricular pacemaker cell are called *unifocal PVCs* (Fig. 29.22A). If they come from multiple ventricular pacemaker cells, they are called *multifocal PVCs* (Fig. 29.22B). Two PVCs in a row is called a *couplet* (Fig. 29.22C). Three PVCs in a row is called a *triplet* or a *three-beat run of VT* (Fig. 29.22D). A PVC that occurs every other beat is called *bigeminy* (Fig. 29.22E). A PVC falling every third beat is called *trigeminy* (Fig. 29.22F).

### Causes

Causes of PVCs include hypoxia, MI, CM, electrolyte imbalance, excessive stimulant ingestion (such as caffeine), hypertension, and recreational drug use.

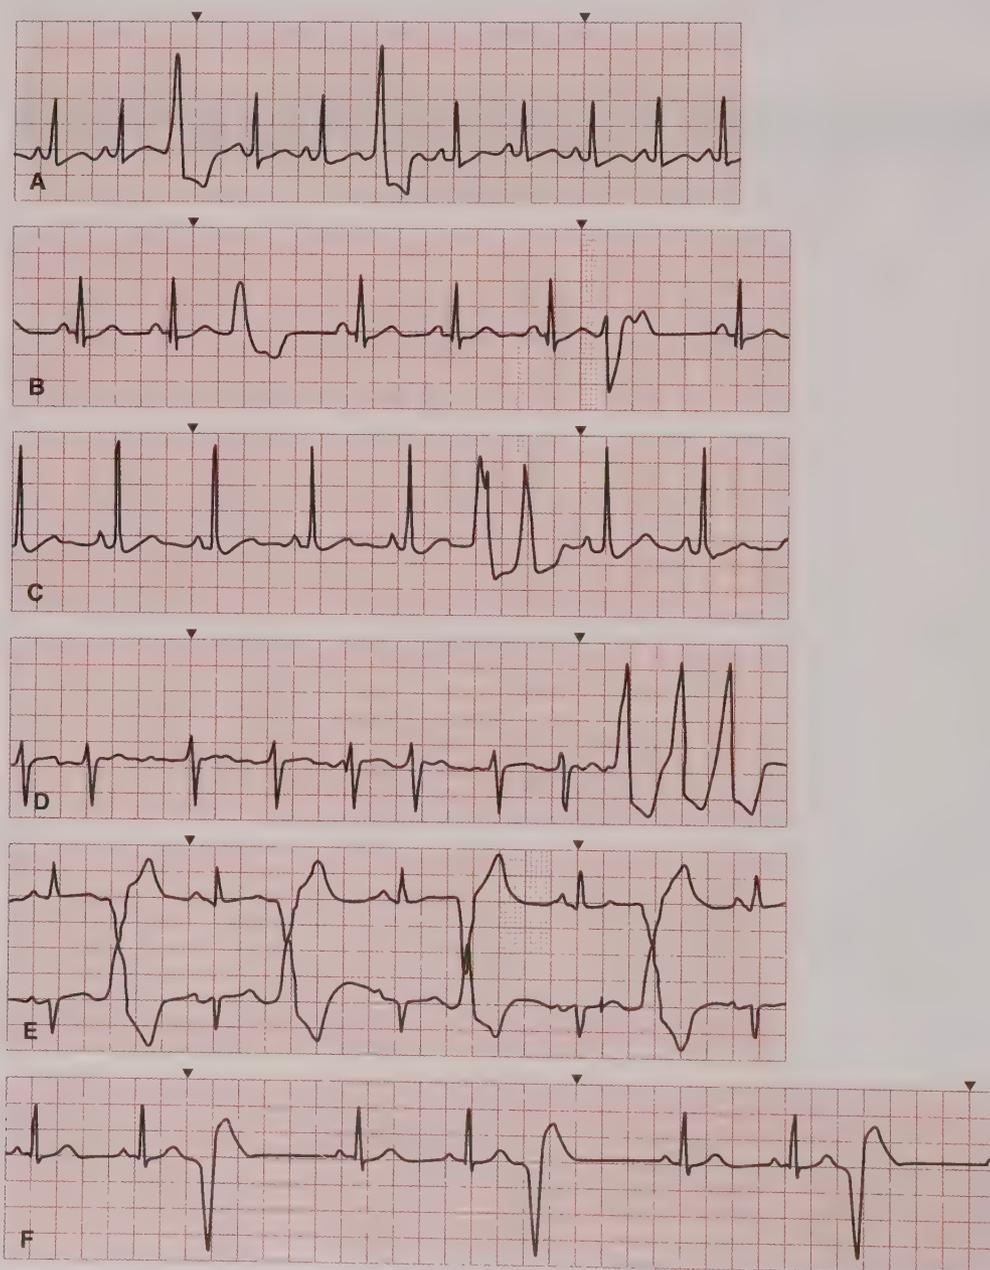

### Treatment

Treatment of PVCs is based on the patient's symptoms. If the patient is symptomatic, treatment includes correcting the cause and, rarely, antiarrhythmic therapy.

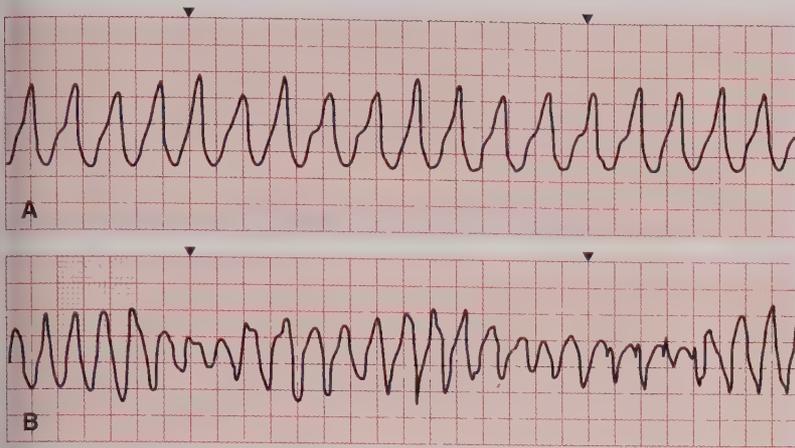

### Ventricular Tachycardia

**Ventricular tachycardia (VT)** is defined as three or more PVCs (wide and fast impulses originating from the ventricles) in a row. The ventricular rate is usually greater than 150 bpm. It can be monomorphic (originating from one pacemaker cell; Fig. 29.23A) or polymorphic (originating from multiple pacemaker cells; Fig. 29.23B).

VT can be a life-threatening dysrhythmia as a result of the significant reduction in CO that can occur. A patient in VT might be able to maintain a pulse and a blood pressure

**FIGURE 29.22** Premature ventricular contractions. *A*, Unifocal PVCs: notice how the PVCs present the same. *B*, Multifocal PVCs: notice how the PVCs present differently. *C*, Couplet. *D*, Triplet or a three-beat run of ventricular tachycardia (VT). *E*, Bigeminy. *F*, Trigeminy.

**FIGURE 29.23** Ventricular tachycardia (VT).

A, Monomorphic: originating from one pacemaker cell.

B, Polymorphic: originating from multiple pacemaker cells.

for a limited time, but VT will cause death if prolonged or untreated.

### Causes

Causes of VT include:

- Hypovolemia
- Hypoxia
- Acidosis
- Hypokalemia
- Hyperkalemia
- Hypoglycemia
- Hypothermia
- Toxins
- Cardiac tamponade
- MI
- PE

### Treatment

Treatment for VT is based on the patient's presentation, which is either:

- VT with a pulse
- Pulseless VT

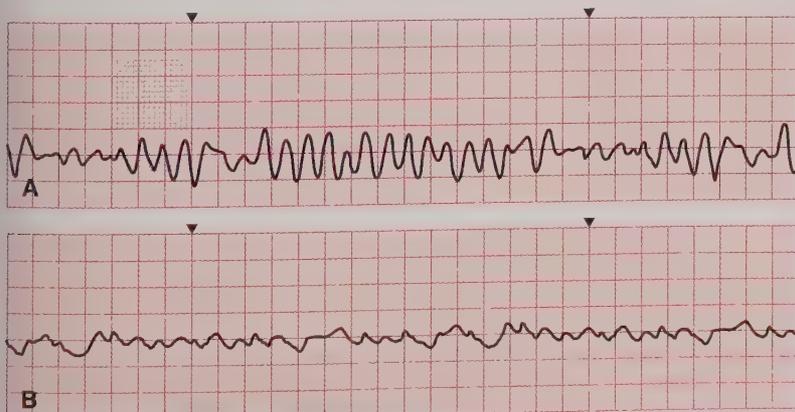

*VT with a pulse* describes a patient in VT who is maintaining a blood pressure and pulse with or without symptoms. The treatment options are antiarrhythmic medications

such as amiodarone (Cordarone, Pacerone; see Table 29.1), electrolyte replacements such as potassium or magnesium, and/or cardioversion. Cardioversion is an electrical shock given to the patient at the time of ventricular depolarization (see Table 29.3). Cardioversion is typically reserved for a patient who is symptomatic such as hypotensive, SOB or complaining of chest pain.

*Pulseless VT* describes a patient who is in cardiac arrest. The first-line treatment is cardiopulmonary resuscitation (CPR) and defibrillation. In contrast to cardioversion, defibrillation is an electrical shock delivered anytime during the cardiac cycle (see Table 29.3). Other treatments include medications such as epinephrine and antiarrhythmics (e.g., amiodarone [Cordarone, Pacerone]).

### Ventricular Fibrillation

**Ventricular fibrillation (VF)** is a lethal dysrhythmia requiring immediate treatment. It is the most frequently seen rhythm in cardiac arrests occurring outside of the hospital. Ventricular fibrillation occurs when the ventricle has multiple chaotic impulses rapidly firing (Fig. 29.24). This chaotic firing prevents the ventricles from pushing blood out of the heart, stopping CO and causing death. There are absolutely no identifiable P waves or QRS waves. The rhythm displayed on the ECG is a shaky or quivering line that can be very coarse (Fig. 29.24A) or fine (Fig. 29.24B).

**FIGURE 29.24** Ventricular fibrillation (VF). A, Coarse VF.

B, Fine VF.

## Causes

Causes of VF include:

- Hypovolemia
- Hypoxia
- Acidosis
- Hypokalemia
- Hyperkalemia
- Hypoglycemia
- Hypothermia
- Toxins
- Cardiac tamponade
- MI
- PE

## Treatment

Treatment requirements for VF start with chest compressions and include defibrillation and medication. Chest compressions and defibrillation are the most important interventions that can be done for a patient in VF. Chest compressions should be initiated immediately and maintained as continuously as possible. Compressions should not be paused/stopped longer than 10 seconds and should be paused only when applying external defibrillation pads and when discharging the electrical impulse from the defibrillator. To be effective, chest compressions need to be deep (2–2.4 inches in an adult) and fast (a rate of 100–120 bpm). Compressors need to switch every 2 minutes to limit fatigue and maintain continuous high-quality CPR.

Defibrillation (see Table 29.3) should be performed within 2 to 3 minutes (180 seconds) of the onset of VF for the best survival outcome. Studies have shown that for every minute a patient remains in VF without defibrillation, the survival rate decreases by 7% to 10%. When chest compressions are initiated prior to defibrillation, the effectiveness of the shock is increased. Shocks from biphasic defibrillators (delivering

the shock in two directions) are delivered at 200 joules (J). Research has shown this to be just as effective, if not more effective, than shocking with a monophasic defibrillator (delivering the shock in one direction) set to its highest energy level, 360 J.

Medication should be considered after the patient has been defibrillated and while CPR is being performed. The first medication of choice should be a vasopressor such as epinephrine 1 mg every 3 to 5 minutes IVP (see Table 29.1).

The second medication of choice is an antiarrhythmic such as amiodarone (Cordarone, Pacerone) 300 mg IVP followed by a second dose of 150 mg IVP.

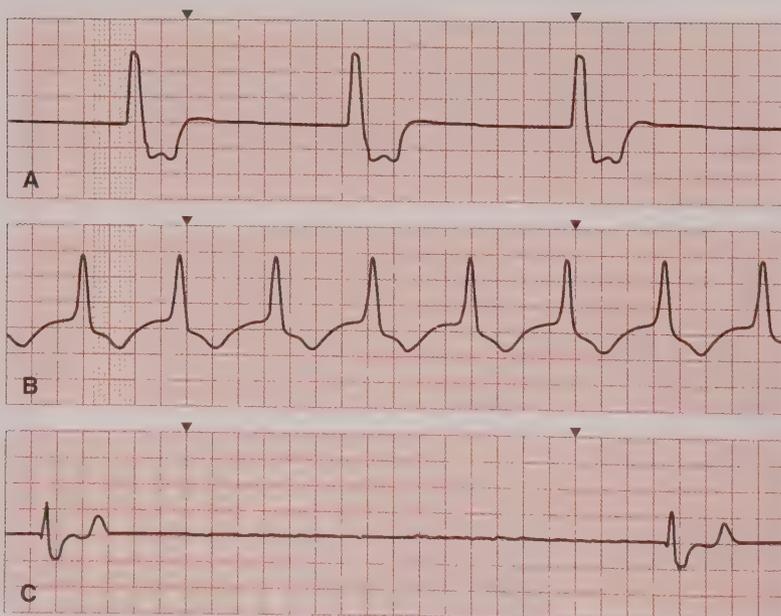

**Safety Alert** When using the defibrillator to cardiovert or defibrillate a patient, be sure to look around the patient to confirm that no one is touching the patient while you loudly say, “I am clear, you are clear, we are all clear” prior to pushing the *SHOCK* button. This is to prevent electricity from traveling from the patient to another person accidentally.

## Idioventricular Rhythm

**Idioventricular rhythm (IVR)** occurs when the SA and AV nodes fail to function and the rhythm is generated from the ventricle. The rate is usually less than 40 bpm (Fig. 29.25A) but could be between 40 and 100 bpm, which is called **accelerated idioventricular rhythm (AIVR)** (Fig. 29.25B). The HR could also be less than 20 bpm, which is often called an **agonal rhythm** or *dying heart* (Fig. 29.25C).

## Causes

Causes of IVR include MI, postcardiac arrest, medication and drug toxicities (e.g., cocaine, digoxin, anesthetics), electrolyte imbalances, myocarditis, CM, and congenital heart disease.

**FIGURE 29.25** Idioventricular rhythm (IVR). A, IVR with a rate of 30. B, Accelerated idioventricular rhythm (AIVR) with a rate of 80. C, Agonal rhythm or dying heart.

## Treatment

Treatment of IVR is based on the patient's symptoms. If the patient is symptomatic, the treatment includes correcting the cause, pacing, and atropine.

### Connection Check 29.5

The nurse understands that rhythms originating in the ventricle have which of the following characteristics? (Select all that apply.)

- A. Wide QRS complexes
- B. Narrow QRS complexes
- C. Only QRS complexes
- D. Only fast rates
- E. Only slow rates

## Asystole

**Asystole** is a condition in which there is no measurable electrical activity originating from the heart. A straight or *flat line* is produced on the cardiac monitor (Fig. 29.26). Without an electrical stimulus, the cardiac muscles cannot squeeze or contract to force blood in or out of the heart's chambers. It is important to assess the patient to be sure that it is a true asystolic event. Occasionally, a loose ECG patch or wire from the monitor will cause a false reading. However, if it is a true asystolic event, the patient will be pulseless.

Compressions should be started immediately. The patient should be assessed with a second monitor lead, pausing compressions only briefly (< 10 seconds) to rule out a fine VF. If VF is confirmed, the patient should be defibrillated. If the second lead continues to show a *flat line*, asystole is confirmed, and defibrillation is not indicated. The treatment for asystole is CPR, epinephrine, and treating the cause, which is the same as that for VF addressed previously.

See Table 29.6 for a summary of ventricular dysrhythmias.

### Connection Check 29.6

Which of the following dysrhythmias requires defibrillation?

- A. Atrial tachycardia
- B. Atrial fibrillation
- C. Ventricular tachycardia with a pulse
- D. Ventricular fibrillation

## Heart Blocks

Heart blocks are caused by the delay or blockage of electrical conduction at the AV node. The AV node's blood supply comes from the right coronary artery (RCA). If the RCA becomes partially or completely blocked, the AV node is deprived of oxygen, which causes ischemia. If the AV node tissue becomes ischemic or dies, the electrical impulses originating in the atria will have difficulty traveling through the AV node to the ventricles along the usual pathway. The electrical impulses will need to find an alternative pathway, which could cause conduction delays or even an electrical disassociation of the atria and the ventricles. There are four types of heart blocks: first degree, second-degree type I, second-degree type II, and third degree.

### Causes

The primary cause of most AV heart blocks is acute coronary syndrome. Acute coronary syndrome (ACS) is an umbrella term used to describe unstable angina, acute non-ST elevation MI (NSTEMI), and acute ST elevation MI (STEMI). Other causes of heart blocks include but are not limited to electrolyte imbalances and medication toxicities.

### First-Degree AV Block

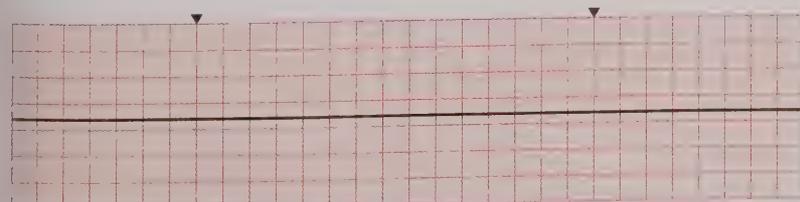

**First-degree AV block** looks very similar to an NSR except the PR interval is prolonged (> 0.20 sec or five blocks long; Fig. 29.27). This is due to the atrial depolarization being delayed in the AV node. Every atrial impulse gets through the AV node; it just takes longer. It is the same time interval each time.

### Treatment

Treatment is not typically required for first-degree AV block unless the patient is having symptoms, which is very rare. If the patient is symptomatic, then the underlying causes are treated to alleviate the symptoms.

### Second-Degree AV Block Type I

**Second-degree AV block type I** (also known as **Wenckebach** or **Mobitz I**) occurs when not all atrial impulses get through the AV node to the ventricles. There are more P waves than QRS complexes, and the PR interval gets progressively longer until a QRS is dropped (also referred to as dropping QRSs; Fig. 29.28). After the dropped QRS, the PR interval resets, and the process starts over. A helpful mnemonic is *longer, longer, longer, dropped; then you have a Wenckebach*. When identifying a heart block, look at the PR interval pattern after the dropped QRS complex. This is not considered a life-threatening dysrhythmia, and it is typically

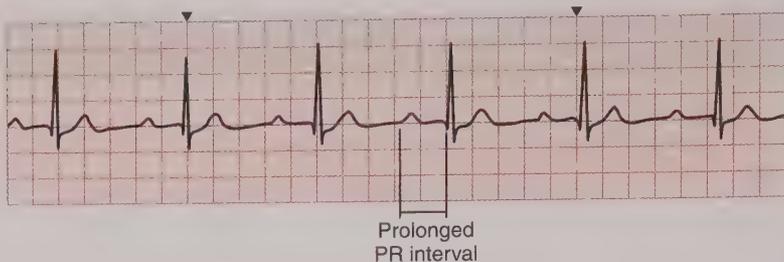

**FIGURE 29.26** Asystole; no electrical activity.

Administer emergency medications as ordered, such as: <ul style="list-style-type: none"> <li>● Epinephrine</li> </ul>	Education regarding disease management to avoid future occurrences if patient has return of circulation and survives the event

**FIGURE 29.27** First-degree atrioventricular block: the PR interval is prolonged ( $> 0.20$  sec); in this strip, the PR interval is 24.

**FIGURE 29.28** Second-degree atrioventricular block type I (Mobitz or Wenckebach).

an intermittent rhythm; however, on rare occasions, it can be continuous.

### Treatment

Treatment of second-degree AV block type I is considered only if the patient is symptomatic. Patients who cannot tolerate the loss of CO may experience symptoms such as dizziness, lightheadedness, and SOB. The treatment includes atropine 0.5 mg IVP to stimulate the heart to beat faster and, in extreme cases, temporary pacing.

### Second-Degree AV Block Type II

**Second-degree AV block type II** (also known as **Mobitz II**) also drops QRS complexes, but unlike second-degree type I, the PR intervals are exactly the same length with each complex (see Fig. 29.29). This dysrhythmia is more alarming and is considered a potentially life-threatening dysrhythmia because it can quickly progress to a third-degree AV block.

### Treatment

Treatment of second-degree AV block type II is dependent on the patient's symptoms. If the patient is symptomatic, then temporary pacing is the treatment of choice (see Table 29.7). Transcutaneous pacing (TCP) is the fastest pacing option, which is done by placing defibrillator pads on the patient's chest and back in the anterior-posterior

positions to externally pace the heart (see Fig. 29.30B). If time permits, other pacemaker options could be considered, such as a temporary transvenous pacemaker (TVP) or a permanent pacemaker.

### Third-Degree AV Block

**Third-degree AV block** or **complete heart block (CHB)** occurs when the AV node is completely blocked and prevents any impulses from entering or exiting. There is no communication between the atria and the ventricles. The ECG records more P waves than QRS complexes (Fig. 29.31). The atrial rate is usually between 60 and 100 bpm, whereas the ventricular rate is usually less than or equal to 40 bpm.

In CHB, QRS complexes march out regularly and are independent of the P waves. Similarly, the P waves march throughout the rhythm strip at a regular rate. Sometimes the P waves are hidden within a QRS complex or the T wave, making it very important to march out the P waves to see where they fall.

### Treatment

Treatment of CHB is initially based on treating the patient's symptoms, such as hypotension or SOB. Attempts are made to reverse the cause(s) if possible. Transcutaneous pacing is indicated in symptomatic CHB. Long-term treatment is typically the insertion of a permanent pacemaker (see Table 29.7; Fig. 29.32).

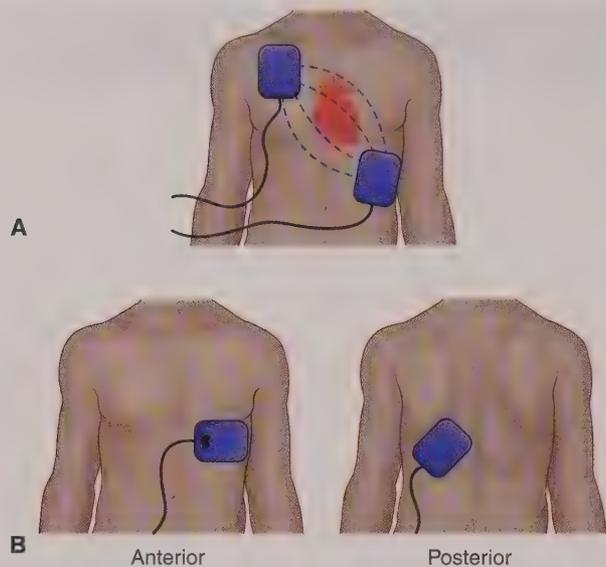

**FIGURE 29.29** Second-degree atrioventricular block type II (Mobitz II).

**Table 29.7 Pacemaker Overview**

Pacemaker Type	Placement or Location	Monitor	Nursing Care
<b>External Pacemakers</b>			
<b>Transcutaneous (TCP)</b>	Electro-pads (defibrillator pads) are placed on the patient's torso using an anterior/posterior position (see Fig. 29.30B).	Pacer spike prior to QRS	Place pads on the patient's chest and back. Medicate with sedative as ordered. Monitor patient: <ul style="list-style-type: none"> <li>● HR</li> <li>● BP</li> <li>● Rhythm</li> </ul> Stay with patient until stable. Maintain continuous cardiac monitoring to ensure detection of rhythm change or pacer failure.
<b>Transvenous (TVP)</b>	A pacer wire is inserted into the right ventricle (so that it touches the wall) through central venous access. The wire is attached to an external pacemaker.  Usually done via internal jugular (IJ) vein	Pacer spike prior to QRS	Monitor patient: <ul style="list-style-type: none"> <li>● HR</li> <li>● BP</li> <li>● Rhythm</li> </ul> Maintain continuous cardiac monitoring to ensure detection of rhythm change or pacer failure. Monitor central venous access for signs of infection.
<b>Transthoracic (TTP) (or epicardial pacer)</b>	A pacer wire is surgically placed in the atrium or the ventricle and fed out through the skin. The externalized wire is attached to an external pacemaker.	Atria = pacer spike prior to P wave  Ventricle = pacer spike prior to QRS  (see Fig. 29.32A)	Monitor patient: <ul style="list-style-type: none"> <li>● HR</li> <li>● BP</li> <li>● Rhythm</li> </ul> Maintain continuous cardiac monitoring to ensure detection of rhythm change or pacer failure. Monitor incision site for signs of infection.
<b>Internal Pacemakers</b>			
<b>Atrial</b>	<i>For all internal pacemakers:</i>	Atria = pacer spike prior to P wave	<i>For all internal pacemakers:</i>
<b>Ventricular</b>	Pacer wires are placed in the atrium, ventricle, or both and attached to a small pacemaker generator placed under the skin near the clavicle (see Fig. 29.32B).	Ventricle = pacer spike prior to QRS	Monitor patient: <ul style="list-style-type: none"> <li>● HR</li> <li>● BP</li> <li>● Rhythm</li> </ul> Maintain continuous cardiac monitoring to ensure detection of rhythm change or pacer failure.
<b>Biventricular</b>		Biventricle = double pacer spikes prior to QRS (due to having a pacer lead in each ventricle)	
<b>Dual chamber</b>		Pacer spike prior to P wave and QRS	Do not place medication patches or defibrillation pads over pacemaker. Monitor incision site for infection.

BP, Blood pressure; HR, heart rate.

See Table 29.8 for a summary of heart blocks.

### Connection Check 29.7

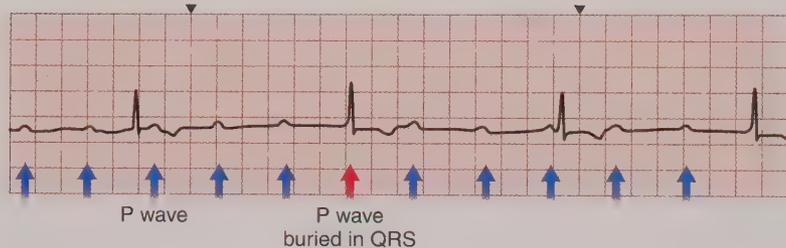

What do second-degree and third-degree heart blocks have in common?

- A. Wide QRS complexes
- B. Narrow QRS complexes
- C. Dropped QRS complexes
- D. No commonalities

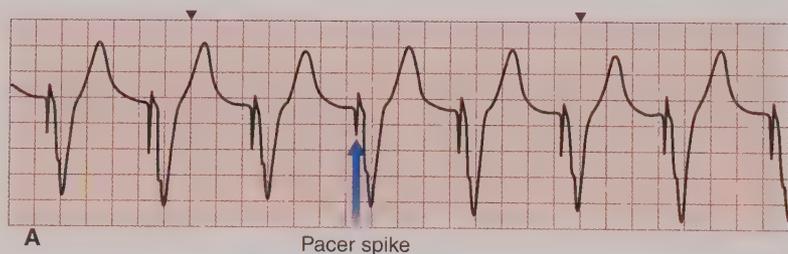

### Connection Check 29.8

Transcutaneous pacing should be considered for which of the following dysrhythmias?

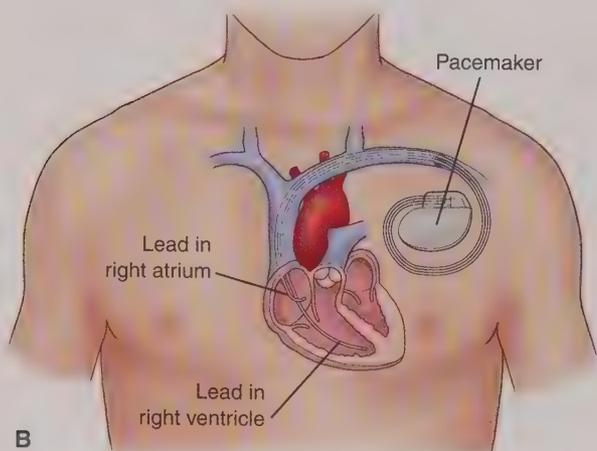

- A. VF
- B. VT
- C. Symptomatic heart block
- D. AF

**FIGURE 29.31** Third-degree heart block or complete heart block (CHB). R to R is regular, and P to P is regular, but there is no communication between the atria and the ventricles.

**A** Pacer spike

**B**

**FIGURE 29.32** A, Example of ventricular paced rhythm with pacer spikes. B, Pacemaker implantation; there may be a lead in the atrium, ventricle, or both.

Table 29.8 Summary of Heart Blocks

Dysrhythmia	Signs and Symptoms	Medical Interventions	Nursing Interventions	Patient Teaching
<b>First-degree AVB</b>	None	No specific treatment is indicated for isolated first-degree block.  Treat underlying cause if necessary.	Obtain vital signs.  Assess patient for symptoms.  Obtain a 12-lead ECG.  Assess for causes.	Educate patient about dysrhythmia, underlying causes, and when to seek treatment.
<b>Second-degree type I AVB, asymptomatic</b>	None	Treat the causes if necessary:	Obtain vital signs.  Assess patient for symptoms.	Educate patient about dysrhythmia, underlying causes, and when to seek treatment.
<b>Second-degree type II AVB, asymptomatic</b>		<ul style="list-style-type: none"> <li>● Hypoxia</li> <li>● Ischemia</li> </ul>	Obtain a 12-lead ECG.	
<b>Third-degree complete heart block, asymptomatic</b>		<ul style="list-style-type: none"> <li>● Medication toxicities (e.g., digoxin)</li> <li>● Electrolyte imbalance</li> </ul>	Assess for other causes.	
<b>Second-degree type I AVB, symptomatic</b>	<ul style="list-style-type: none"> <li>● Dizziness</li> <li>● Lightheadedness</li> </ul>	<ul style="list-style-type: none"> <li>● Oxygen</li> <li>● Atropine IVP</li> </ul>	Call for help.  Stay with the patient.	Educate patient regarding dysrhythmia medications, treatment, signs and symptoms that require seeking treatment, and how to avoid future occurrences.
<b>Second-degree type II AVB, symptomatic</b>	<ul style="list-style-type: none"> <li>● Fainting</li> <li>● SOB</li> </ul>	<ul style="list-style-type: none"> <li>● Pacing</li> </ul>	Frequent assessment for symptoms	
<b>Third-degree complete heart block, symptomatic</b>	<ul style="list-style-type: none"> <li>● Sweating</li> <li>● Anxiety</li> <li>● Hypotension</li> </ul>	Treat the causes: <ul style="list-style-type: none"> <li>● Hypoxia</li> <li>● Ischemia</li> <li>● Medication toxicities (e.g., digoxin)</li> <li>● Electrolyte imbalance</li> </ul>	Frequent vital signs  Obtain a 12-lead ECG.  Give oxygen per order.  Ensure IV access is available and patent.  Administer medication(s) as ordered.  Prepare for TCP.  Anticipate administration of antianxiety medication.	

AVB, atrioventricular block; ECG, electrocardiogram; IVP, intravenous push; SOB, shortness of breath; TCP, transcutaneous pacing.

## Nursing Management

### Assessment and Analysis

Clinical manifestations for dysrhythmias are dependent on their impact on the patient's cardiac output. Some dysrhythmias have little impact on cardiac output and so have few manifestations. The more dangerous dysrhythmias, such as atrial fibrillation and ventricular rhythms or blocks, can greatly reduce cardiac output, causing SOB, pain, hypotension, fatigue, and if severe enough, death.

### Nursing Diagnosis

- **Risk for decreased cardiac output** related to alteration in heart rhythm

## Nursing Interventions

### Assessments

- Evaluate ECG and identify the rhythm.  
*Recognizing the rhythm helps the nurse anticipate and respond appropriately.*
- Determine if the patient is symptomatic versus asymptomatic.  
*Symptomatic patients require immediate response and evaluation of causes; asymptomatic patients require observation and evaluation of causes.*
- To assess if symptomatic, evaluate:
  - Vital signs  
*The lack of efficient contractile function of a heart experiencing dysrhythmias results in a decrease in CO and hypotension.*

*In an attempt to increase oxygenation in the face of decreased CO, SOB and tachypnea may occur. The HR may be faster, slower, regular rhythm, or irregular rhythm depending on the type of dysrhythmia.*

- Change in level of consciousness  
*Decreased blood pressure and thus CO may cause a decrease in blood flow to the brain, resulting in dizziness or syncope.*
- Diaphoresis  
*Diaphoresis is the result of the stimulation of the sympathetic nervous system in response to low CO.*
- Chest pain  
*Dysrhythmias may cause an imbalance in myocardial oxygen demand and supply, potentially resulting in chest pain.*
- Poor peripheral circulation  
*Decreased CO may cause weak peripheral pulses, cool extremities, and sluggish capillary refill. Poor contractile function may cause peripheral edema.*
- Nausea and vomiting  
*Shunting of blood away from nonessential organ systems during low-flow states may cause nausea and vomiting.*
- Electrolyte levels and cardiac enzymes  
*Dysrhythmias may indicate acute cardiac injury, which may be demonstrated by elevated cardiac enzymes. Elevated potassium levels can cause changes in the shape of the T wave. Electrolyte imbalances are sometimes the cause of dysrhythmias.*

#### ■ Actions

- Administer antiarrhythmic therapy as ordered.  
*Antiarrhythmic medications limit the occurrence of dysrhythmias, helping to maintain an adequate CO and decrease the risk of life-threatening events associated with lethal dysrhythmias.*
- Perform an ECG/maintain continuous ECG monitoring as ordered.  
*Monitoring facilitates immediate recognition of dysrhythmias, which allows for prompt treatment as necessary.*

- Be prepared to administer advanced cardiac life support in the event of a lethal dysrhythmia  
*Cardiopulmonary resuscitation, defibrillation if indicated, and administration of emergency medications may restore adequate CO in a patient experiencing lethal dysrhythmias.*
- Document the occurrence of dysrhythmias.  
*Documentation helps evaluate the need for and/or the effectiveness of therapy.*

#### ■ Teaching

- Immediately report chest pain or chest discomfort.  
*Prompt treatment is one way to help maximize positive outcomes when a patient is experiencing dangerous or lethal dysrhythmias.*
  - Take antiarrhythmic medications as prescribed.  
*Maintaining adequate medication levels helps decrease the occurrence of adverse effects of dysrhythmias.*
  - Recognize signs of possible complications of dysrhythmias, such as strokes due to clot formation in AF.  
*It is important that the patient (and family) is able to detect early signs of complications to ensure prompt treatment and reduce adverse effects.*
- See Table 29.9 for a quick dysrhythmia interpretation chart.

### Connection Check 29.9

Signs or symptoms of symptomatic ventricular dysrhythmias include which of the following? (Select all that apply.)

- A. Hypotension
- B. Dizziness
- C. Fever
- D. Shortness of breath
- E. Hypertension

Table 29.9 Quick Dysrhythmia Interpretation Table

Rhythm	Heart Rate	P Wave	QRS Complex	T Wave	P-P Regular	R-R Regular	PR Interval	QRS Interval
<b>SR</b>	Normal (60–100 bpm)	Yes	Narrow	Yes	Yes	Yes	Normal (0.12–0.2 sec)	Normal (0.04–0.1 sec)
<b>SB</b>	Slow (less than 60 bpm)	Yes	Narrow	Yes	Yes	Yes	Normal (0.12–0.2 sec)	Normal (0.04–0.1 sec)
<b>ST</b>	Fast (greater than 100 bpm)	Yes	Narrow	Yes	Yes	Yes	Normal (0.12–0.2 sec)	Normal (0.04–0.1 sec)
<b>AF</b>	Varies	No	Narrow	Yes (but may be hard to identify)	n/a	Irregular	n/a	Normal (0.04–0.1 sec)
<b>AFL</b>	Varies	F wave	Narrow	Yes (but may be hard to identify)	n/a	Usually regular but can vary on the basis of conduction rate	n/a	Normal (0.04–0.1 sec)
<b>Junctional</b>	Slower (usually) 40–60 bpm	Inverted when seen	Narrow	Yes	n/a	Yes	Less than or equal to 0.12 sec (when it can be measured)	Normal (0.04–0.1 sec)
<b>SVT</b>	Fast (greater than 100 but usually 150–250 bpm)	Sometimes seen inverted after QRS	Narrow	Yes	n/a	Yes	n/a	Normal (0.04–0.1 sec)
<b>First-degree AVB</b>	Normal	Yes	Narrow	Yes	Yes	Yes	Greater than 0.20 sec (measurement is consistent)	Normal (0.04–0.1 sec)
<b>Second-degree AVB type I</b>	Varies	Yes More P waves than QRS complexes	Narrow-wide Missing QRS complexes	Yes	Yes	Irregular	Starts normal then gets longer and longer until a QRS is dropped	Normal to wider
<b>Second-degree AVB type II</b>	Normal to slow	Yes More P waves than QRS complexes	Narrow-wide Missing QRS complexes	Yes	Yes	Yes	Normal to wide (but measurement is consistent)	Normal to wider
<b>Third-degree AVB</b>	Normal to slow	Yes More P waves than QRS complexes	Narrow-wide Missing QRS complexes	Yes	Yes	Yes	Vary because the P waves do not correlate to the QRS complex	Narrow-wide

AF, Atrial fibrillation; AFL, atrial flutter; AVB, AV block; SB, sinus bradycardia; SR, sinus rhythm; ST, sinus tachycardia; SVT, supraventricular tachycardia.

## Making Connections

### CASE STUDY: WRAP-UP

After being started on heparin, Ms. Fletcher is prepared for a TEE to determine if clots are present in her atria. If there are no clots, she may be a candidate for cardioversion. If clots are visualized, anticoagulation therapy will be continued. Ms. Fletcher's TEE reveals no clots. She is electively cardioverted because of her increasing instability. Her rhythm returns to NSR. She is admitted to a cardiac telemetry bed for observation overnight. She will need further education on the signs and symptoms of AF and her new medications. She is referred for follow-up to an appropriate dysrhythmia specialist.

#### Case Study Questions

- What is the priority nursing action for Ms. Fletcher upon admission to the unit?
  - Orientation to the room
  - Initiating ECG monitoring
  - Calculating intake and output
  - Assessing pain level
- The nurse monitors for which clinical manifestations in Ms. Fletcher? (*Select all that apply.*)
  - Complaints of palpitations
  - Complaints of shortness of breath
  - Diaphoresis
  - Fever
  - Hyperglycemia
- The charge nurse is reviewing new admission orders for Ms. Fletcher. It is a priority for the charge nurse to follow up with the provider about which order?
  - Regular diet
  - Discontinuing monitor
  - Vital signs every 4 hours
  - Saline lock
- The nurse caring for Ms. Fletcher incorporates which nursing diagnoses into the plan of care? (*Select all that apply.*)
  - Risk for decreased cardiac output
  - Risk for embolic event
  - Knowledge deficit
  - Risk for poor nutrition
  - Risk for bleeding
- Which statement by Ms. Fletcher indicates that teaching has been effective?
  - "I'm just glad the problem was fixed, and I don't need to go back to the doctor."
  - "I'm glad I don't have to worry about having a stroke anymore."
  - "I guess I need to follow up with a heart doctor."
  - "I guess things will go back to normal now."

## CHAPTER SUMMARY

Electrocardiogram interpretation is a useful tool to help identify dysrhythmias that affect efficient heart function. Key points to consider when interpreting dysrhythmias include the appearance and presence of P waves and QRS complexes, rate, and regularity.

Sinus rhythms originate in the sinoatrial (SA) node. Normal sinus rhythm is a rate of 60 to 100 bpm. Sinus tachycardia is a sinus rhythm with a rate of greater than 100 bpm. Sinus bradycardia is a sinus rhythm with a rate of less than 60 bpm.

Atrial rhythms are caused by pacemaker cells other than the SA node firing somewhere within the atria. Atrial dysrhythmias include premature atrial contractions (PACs), atrial fibrillation (AF), and atrial flutter (AFL).

Supraventricular tachycardia (SVT) is an umbrella term to capture narrow-complex tachycardias, such as sinus tachycardia, atrial tachycardia, junctional tachycardia, atrial fibrillation greater than 100 bpm, and AFL greater than 100 bpm.

Junctional rhythms begin within the atrioventricular (AV) node. Examples of junctional rhythms include premature junctional contractions, junctional rhythm, accelerated junctional rhythm, and junctional tachycardia.

Ventricular rhythms are those rhythms that originate somewhere within the ventricles. Examples include premature ventricular contractions (PVCs), ventricular tachycardia (VT) with a pulse, pulseless VT, and ventricular fibrillation (VF). Both pulseless VT and VF are lethal rhythms that require immediate treatment—immediate initiation of compressions and defibrillation within 2 to 3 minutes. Idioventricular rhythm occurs when the SA and AV nodes

fail to function, which triggers the ventricles to generate an electrical impulse.

Asystole occurs when there is no electrical impulse from the heart, producing a flat line on the monitor. Treat immediately with chest compressions and epinephrine and determine

the cause. Heart blocks are caused by delaying or blocking electrical conduction at the AV node. There are four types of blocks: first-degree AV block, second-degree type I (or Wenckebach or Mobitz I), second-degree type II (or Mobitz II), and third-degree heart blocks or complete heart block.

# Chapter 30

## Coordinating Care for Patients With Cardiac Disorders

*Sherri Ulbrich*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of cardiac disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Coronary artery disease
  - b. Infectious endocarditis
  - c. Myocarditis
  - d. Pericarditis
  - e. Valvular disease
  - f. Heart failure
3. Describing the diagnostic results used to confirm the diagnosis of cardiac disorders
4. Discussing the medical management of:
  - a. Coronary artery disease
  - b. Infectious endocarditis
  - c. Myocarditis
  - d. Pericarditis
  - e. Valvular disease
  - f. Heart failure
5. Developing a comprehensive plan of nursing care for patients with cardiac disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with cardiac disorders

### CONCEPTS

- Assessment
- Infection
- Inflammation
- Oxygenation
- Perfusion

### ESSENTIAL TERMS

Acute coronary syndrome  
Angina  
Aortic stenosis  
Atherosclerosis  
Cardiac rehabilitation  
Compensatory mechanism  
Coronary artery bypass graft (CABG)  
Coronary artery disease (CAD)  
Ejection fraction  
Embolization  
Exercise stress test  
Friction rub  
Heart failure  
Infective endocarditis  
Ischemia  
Murmur  
Myocardial tissue  
Myocarditis  
Percutaneous transluminal coronary angioplasty (PTCA)  
Pericardial effusion  
Pericardiocentesis  
Pericarditis  
Prinzmetal's/variant angina  
Pulmonary edema  
Orthopnea  
Regurgitation  
Stable angina  
Stenosis  
Tamponade  
Transcatheter aortic valve replacement  
Unstable angina

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. Walter Thompson is a 57-year-old man with no significant past medical history except high blood pressure. He admits to being nonadherent with his meds because “I feel okay.” He reports he was in his usual state of health until about 3 weeks ago. At that point, he reports feeling short of breath and fatigued unrelated to physical activity. Over the past 3 weeks, his symptoms have progressed to the point where he sleeps in his recliner every night. He is admitted to the step-down unit for further management...

## CORONARY ARTERY DISEASE

### Epidemiology

**Coronary artery disease (CAD)** affects an estimated 16.5 million people over the age of 20 and occurs when the blood vessels that deliver oxygen-rich blood to the heart muscle become obstructed or dysfunctional. It is also known as coronary heart disease or ischemic heart disease. The incidence increases with age for all people; however, there are racial and gender differences. According to the American Heart Association (AHA), the prevalence of CAD was higher in Caucasian males than in African and Hispanic American males (7.7%, 7.1%, and 5.9%, respectively). Among females, Hispanic women had the highest prevalence rate of 6.1%, followed by African American females at 5.7% and Caucasian females at 5.3%. The prevalence in American Indians and Native Alaskans is estimated to be highest of all groups at 9.3%. Studies have shown that postmenopausal women are three times more likely to have clinical symptoms of CAD than women of the same age who are premenopausal. This evidence suggests estrogen may be cardioprotective.

A newer diagnosis of nonobstructive coronary artery disease is becoming better understood and more frequently identified in patients. Although both diseases, obstructive and nonobstructive, can occur in both genders, men tend to have more obstructive disease, and women have nearly double the incidence of nonobstructive disease.

Risk factors are classified as modifiable or nonmodifiable. Modifiable risk factors are amenable to intervention. Nonmodifiable factors are inherent risk factors that are not amenable to intervention. Nonmodifiable risk factors include gender, race, heredity, and age. Men of all ages have a higher risk of heart disease than women. Risk increases with a family history of CAD and aging. Modifiable risk factors include increased total cholesterol, hypertension, diabetes, obesity, smoking, and physical inactivity. Stress

and excessive alcohol consumption can also contribute to CAD risk. The risk factors for CAD are summarized in Table 30.1.

### Pathophysiology

Traditionally, coronary artery disease is characterized by the obstruction of blood flow within the coronary arteries. **Atherosclerosis**, or plaque within the lumen of the vessels, is the principal cause of obstruction to blood flow. The arterial wall is made up of three layers: the tunica intima, tunica media, and tunica adventitia (Fig. 30.1).

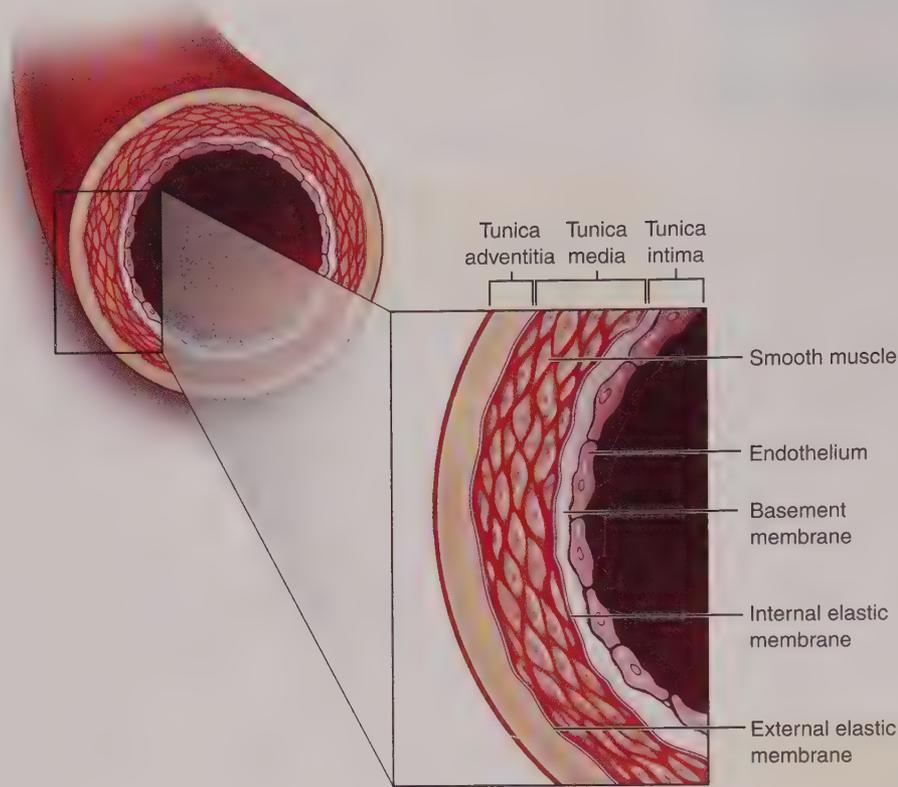

The tunica intima is composed of endothelium and basement membrane. It has been suggested that atherosclerosis begins with an injury to the endothelium that causes an inflammatory response. That inflammatory response initiates a series of specific cellular and molecular reactions that lead to the accumulation of atherosclerotic plaque. Low-density lipoprotein (LDL) enters the tunica intima layer of the arterial wall and becomes trapped. Inside the tunica intima, the trapped LDL is modified through the process of oxidation. Once modified, the LDL attracts macrophages, which absorb the LDL to become foam cells. Fatty streaks within the tunica intima are an accumulation of foam cells. As the process continues, various components in the blood, such as macrophages, calcium, and cholesterol, adhere to the injured part of the vessel, forming plaque. The plaque deposits increase in size over time, causing narrowing of the coronary arteries, which impedes oxygen-rich blood flow to the heart (Fig. 30.2). When the heart muscle does not get enough oxygen and nutrients to meet its demands, myocardial **ischemia** results. This pathology is known as obstructive coronary artery disease.

The next and most dangerous step in the development of atherosclerosis is potential plaque rupture. When that occurs, platelets aggregate on the ruptured plaque surface.

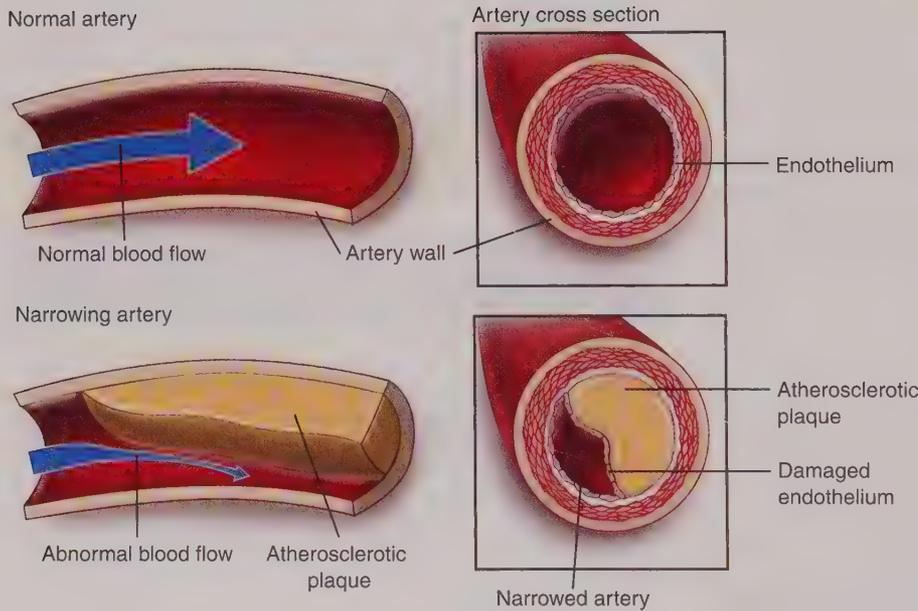

**Table 30.1 Risk Factors for the Development of Coronary Artery Disease**

Modifiable	Nonmodifiable
<ul style="list-style-type: none"> <li>● Cigarette smoking</li> <li>● High total cholesterol, high LDL level, low HDL levels, and high triglycerides</li> <li>● Hypertension</li> <li>● Diabetes</li> <li>● Obesity, particularly central obesity</li> <li>● Sedentary lifestyle/physical inactivity</li> <li>● Stress</li> <li>● Excessive alcohol consumption</li> </ul>	<ul style="list-style-type: none"> <li>● Gender</li> <li>● Race</li> <li>● Age older than 45 for men</li> <li>● Genetics/family history</li> <li>● Being postmenopausal</li> </ul>

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

**FIGURE 30.1** Layers of the arterial wall.

**FIGURE 30.2** A comparison of a normal artery with an artery narrowed by atherosclerotic plaque deposits on the wall.

The coagulation cascade is initiated, and thrombus formation is stimulated. This clotting further decreases or obstructs blood flow altogether, leading to unstable angina, myocardial infarction (MI), or sudden cardiac death.

In nonobstructive coronary artery disease, patients have symptoms similar to obstructive coronary artery disease, but

they do not have significant plaque that occludes the coronary arteries. Rather, ischemic symptoms are caused by reduced blood flow through the coronary microvascular system. In such cases, the microvascular system is not able to dilate in response to the myocardial demand for oxygen or may have stenosis.

## Clinical Manifestations

The clinical manifestations of CAD are virtually silent until the artery is approximately 40% blocked by plaque in obstructive disease. Ischemia develops when there is an imbalance between supply and demand of oxygen-rich blood to the heart tissue, resulting in insufficient oxygen to meet the demands of the **myocardial tissue**. Infarction, or cell death, occurs when that imbalance is severe or prolonged, which causes irreversible damage. The primary patient complaint is chest pain, also called **angina**. Angina is classified into two categories, stable and unstable angina.

**Stable angina** is chest pain or discomfort that is associated with physical activity. It is typically linked to fixed plaque formations and is predictable. Symptoms of stable angina are often alleviated with rest and/or medications. Nitrates such as nitroglycerin that dilate the coronary arteries, improving oxygen-rich blood flow to the heart, are typically prescribed for angina.

**Unstable angina** refers to chest pain that can occur at rest. Of the two types of angina, unstable angina is the most concerning. It is identified as the initial phase of **acute coronary syndrome** (ACS) and is defined as a disorder caused by an acute decrease in blood flow through the coronaries to the myocardial tissue. It can be a precursor to MI and should be treated as an emergency. Unstable angina is usually prolonged and may not be relieved with rest or medication.

A variation of unstable angina is **Prinzmetal's, or variant, angina**. The blockage of blood flow in this disorder is caused by coronary artery spasm rather than plaque formation, but atherosclerotic changes are commonly present. It typically occurs at rest and in clusters. Interestingly, it normally occurs at night between midnight and 8 a.m.

Angina may radiate to the left arm, back, neck and jaw. Additional symptoms may accompany angina such as chest pressure, shortness of breath or dyspnea, fatigue, nausea, vomiting, diaphoresis, weakness, syncope, and epigastric discomfort. Men are more likely to present with classic exertional chest pain, whereas women are more likely to complain of atypical chest pain not associated with exertion. Women are also more likely to report fatigue, weakness, nausea, and dyspnea. Patients with diabetes also do not consistently present with chest pain, often having no signs and symptoms of CAD.

It is important to note that not all chest pain is caused by cardiac ischemia. Nonischemic causes can be aortic dissection, pericarditis, gallbladder disease, pleuritic pain, pulmonary embolism, pneumonia, and gastroesophageal reflux disease.

## Management

### Medical Management

#### Diagnosis

As stated previously, the formation of plaque within the blood vessels is a silent process. Often CAD is suspected only when the individual presents with clinical symptoms.

The diagnosis is made on the basis of clinical presentation and diagnostic findings. Timely recognition of ischemia related to CAD is essential for prompt treatment and improved patient outcomes, particularly in cases where CAD has progressed to acute coronary syndrome or myocardial infarction. Delays in diagnosis can result in more myocardial damage from ischemia. When time is muscle, every minute counts.

#### Diagnostic Tests

Many of the blood tests performed assess for the presence of risk factors for CAD development, such as lipid profiles, inflammation, and coagulation studies. Lipid profiles evaluate total cholesterol and triglyceride levels as well as LDL and high-density lipoprotein (HDL). Specific cardiac biomarkers are used to rule out MI. Creatine kinase (CK) or creatine kinase–muscle/brain (CK-MB) and troponin (I or T) levels rise when myocardial injury occurs and are used to identify when ischemia has led to tissue damage. Because these biomarkers do not immediately rise with chest pain, they are measured every 6 hours after admission to the hospital to evaluate chest pain. This is known as serial cardiac enzyme or biomarker testing. Although most acute care facilities use both biomarkers, hospitals are increasingly using troponin alone as recommended in national guidelines. Recent evidence suggests that women may have a lower troponin threshold, which may be contributing to underdiagnosis of MI and worse outcomes. Laboratory tests diagnostic for CAD are summarized in Table 28.3 in Chapter 28.

An electrocardiogram (ECG) is often the initial test when CAD is suspected. During anginal episodes or symptoms of ACS, the ECG may show ST segment depression of greater than 0.5 mm or flat or inverted T waves that are indicative of ischemia. These changes return to normal when chest pain is relieved. It is important to note that ischemia in some patients may be electrically silent, with an ECG that appears normal. Serial ECGs may be done with cardiac biomarkers to rule out an infarction. If cardiac biomarkers and ECGs are normal, a patient may then undergo an **exercise stress test**. This is done to assess the function of the heart during exercise. Alternatively, for those who are unable to use a treadmill or stationary bicycle, pharmacological agents such as dobutamine can be used to increase heart rate, mimicking the effects of exercise on the heart. Stress echocardiograms are another option. Stress testing can be combined with nuclear imaging, such as thallium or technetium studies, to further evaluate perfusion to the heart. The goals of the stress test are (a) to determine whether there is reduced oxygen-rich blood flow to the heart tissue during physical activity and (b) to determine what parts of the heart are affected by the decreased blood flow. Descriptions of these tests can be found in Chapter 28.

The gold standard for diagnosing CAD is coronary angiography, a left-sided cardiac catheterization with the purpose of evaluating the coronary arteries for blockage.

This is performed to determine the location of the plaque within the coronary circulation, the degree of occlusion, and whether the area can be treated with percutaneous transluminal coronary angioplasty. The lack of major plaque limits the diagnostic value of this test in patients with nonobstructive CAD. Coronary computed tomography (CT) angiography, magnetic resonance angiography, and stress imaging techniques can be useful instead.

### Treatment

Medications for patients with CAD are often prescribed with the goals of (a) stopping the aggregation of blood components to the injured endothelium, (b) controlling factors that led to damage of the endothelium, and (c) relieving symptoms (Table 30.2). Patients with stable angina at low risk for ACS are often prescribed aspirin and nitroglycerin along with medications to reduce risk factors, such as antihypertensives, antidiabetic agents, and cholesterol-lowering

**Table 30.2 Medication Management for Patients With Coronary Artery Disease**

Class of Medication	Mechanism of Action
<p><b>Statins</b> Examples:</p> <p>atorvastatin (Lipitor), simvastatin (Zocor)</p>	<p>Statins reduce total cholesterol when used for an extended period. Statins reduce cholesterol synthesis in the liver and increase clearance of LDL from the blood.</p> <p>This group of medications is contraindicated in patients with active liver disease or during pregnancy because of the possibility of causing muscle myopathies and marked decreases in liver function.</p>
<p><b>PCSK9 inhibitors</b> Example:</p> <p>evolocumab (Repatha)</p>	<p>Increases LDL breakdown to reduce cholesterol level</p> <p>Available only as an injectable</p>
<p><b>Cholesterol absorption inhibitors</b> Example:</p> <p>ezetimibe (Zetia)</p>	<p>Inhibits the absorption of cholesterol through the small intestine</p>
<p><b>Fibric acids</b> Examples:</p> <p>gemfibrozil (Lopid)</p>	<p>Reduces cholesterol production and removes LDL cholesterol by reducing the liver's production of VLDLs and by speeding the clearance of triglycerides from the blood</p> <p>Should not be initiated in patients on statin therapy because of an increased risk for muscle symptoms or rhabdomyolysis</p>
<p><b>Nicotinic acid</b> Example:</p> <p>niacin (Niaspan)</p>	<p>Reduces the production of triglycerides and VLDL and increases HDL levels</p> <p>Baseline hepatic transaminases, fasting blood glucose, and uric acid should be obtained before initiation and again during up-titration. Repeat labs every 6 months.</p>
<p><b>Bile acid sequestrants</b> Example:</p> <p>cholestyramine (Questran)</p>	<p>Converts more cholesterol into bile acids, which are excreted in stool, thereby lowering cholesterol</p> <p>Usually used in combination with statin therapy, resulting in a further 10%–25% decrease in LDL levels</p> <p>Should not be used in individuals with baseline fasting triglyceride levels <math>\geq 300</math> mg/dL because severe triglyceride elevations can occur</p>
<p><b>Anticoagulants</b> Examples:</p> <p>enoxaparin (Lovenox), heparin, bivalirudin (Angiomax), ticagrelor (Brilinta)</p>	<p>Prevents intracoronary thrombosis in patients who are hospitalized with ACS</p>
<p><b>Antiplatelet agents</b> Examples:</p> <p>aspirin (Bayer aspirin, Ecotrin), clopidogrel (Plavix)</p>	<p>Inhibits platelet aggregation to prevent clot development</p>

**Table 30.2 Medication Management for Patients With Coronary Artery Disease—cont'd**

<b>Class of Medication</b>	<b>Mechanism of Action</b>
<b>Beta blockers</b> Example: metoprolol (Lopressor, Toprol XL)	Inhibits the sympathetic nervous system response to physical activity, which decreases cardiac workload and oxygen consumption
<b>ACE inhibitors and ARBs</b> Examples: lisinopril (Zestril), losartan (Cozaar)	Reduces blood pressure, which decreases workload and oxygen demands Particularly beneficial in patient with HTN, diabetes, renal disease, and heart failure
<b>Calcium channel blockers</b> Examples: nifedipine (Adalat, Procardia), amlodipine (Norvasc)	Used when patients cannot tolerate beta blockers or in patients with HF Lowers blood pressure and increases blood flow through the coronaries Also prevents coronary artery spasms in Prinzmetal's/variant angina
<b>Vasodilators</b> Example: nitroglycerin (Tridil, Nitrostat)	Dilates coronary arteries to improve blood flow and oxygen supply to the myocardial cells Can also be given to reduce afterload See Medication Safety Alert for additional information on administration of nitroglycerin for chest pain and contraindications.

ACE, Angiotensin-converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin II receptor blocker; HDL, high-density lipoprotein; HF, heart failure; HTN, hypertension; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

medications. Aspirin prevents thrombus formation in the coronary artery. Nitroglycerin, a vasodilator, is used to manage anginal episodes, both at home and in the hospital. Nitroglycerin can be administered as sublingual tabs, as a spray or powder, intravenously, through transdermal patches, as an ointment, and by mouth with extended-release capsules. During anginal episodes, the sublingual and IV routes are preferred to restore blood flow promptly. Blood pressure should be monitored carefully due to the adverse effect of hypotension. Headaches can also occur and are best treated with nonopioid analgesics such as acetaminophen. Treatment of ACS in the acute care setting includes aspirin, supplemental oxygen, nitroglycerin, and morphine and can be referred to by the acronym MONA. Morphine can be given for angina pain in patients not responsive to nitroglycerin, but its use can be associated with hypotension, nausea, and vomiting. Beta blockers, additional anticoagulants, and possibly calcium channel blockers are also prescribed in ACS management. Treatment for nonobstructive CAD is being studied. Statins, angiotensin-converting enzyme (ACE) inhibitors, and beta blockers may be beneficial.

typically one tablet or spray under the tongue not to exceed three doses taken 5 minutes apart. If the symptom of angina (chest pain) is not relieved with three doses or if the pain worsens, they should be instructed to call emergency personnel. In addition, patients using medications such as sildenafil citrate (i.e., Revatio, Viagra) should be educated on the increased risk of hypotension with coadministration with nitroglycerin.

**Percutaneous transluminal coronary angioplasty (PTCA)** is the procedure most commonly performed to relieve symptoms caused by atherosclerotic changes in the coronary vessels. During this procedure, after the patient receives monitored anesthesia care (MAC), a catheter with a small balloon on its tip is advanced under fluoroscopy through a suitable artery, commonly the femoral or radial, to the area with atherosclerotic plaque. The balloon is inflated and deflated to open the lumen of the artery. During this time, patients may experience chest pain due to vessel occlusion. Once the lumen is open, a stent may be advanced to the location to hold the artery open and maintain adequate blood flow. Stent options include bare metal stents (BMS), drug-eluting stents (DES) to prevent clots, or the newer bioabsorbable stents. Patients frequently return from the procedure with a vascular closure device, such as an angioseal, applied to the access site to maintain hemostasis. This

**Safety Medication Safety Alert:**  
**Alert Nitroglycerin**

Nitroglycerin is an effective treatment for angina. Patients should be instructed to take this medication as prescribed,

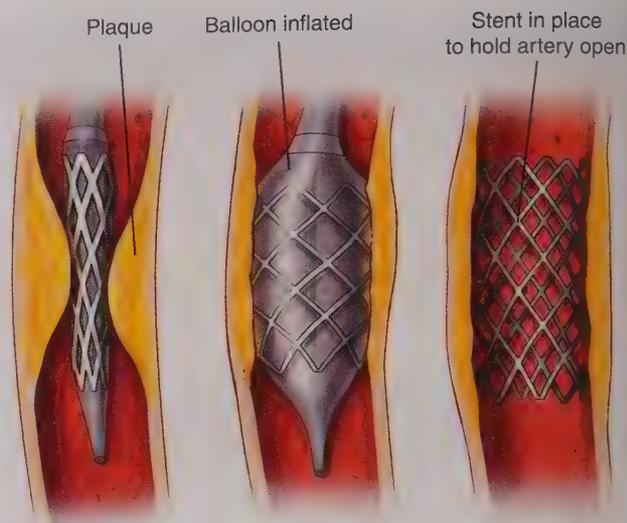

allows early ambulation. If no closure device is applied, strict bedrest for 6 to 8 hours is required until hemostasis is achieved. Figure 30.3 illustrates stent placement within the artery. Bleeding at the insertion site, abrupt vessel closure, dysrhythmias, and ruptured arteries are uncommon but potential complications from PTCA (see Genetic Connections: Pharmacogenetics and Anticoagulants). Care of the patient receiving a PTCA is outlined in Chapter 28.

## Genetic Connections

### Pharmacogenetics and Anticoagulants

Anticoagulants such as warfarin or clopidogrel are prescribed after percutaneous transluminal coronary angioplasty (PTCA). Patient responses to standard doses can vary greatly. Some patients need very low doses to reach therapeutic levels, whereas others require very high doses. Pharmacogenetics is the study of how a person's genes affect responses to medications. With scientific advances, genetic testing can now be used to determine responsiveness. In the case of warfarin, some patients are genetically fast metabolizers, which can result in an increased risk of clotting and the need for higher or more frequent doses. In contrast, slow metabolizers have an increased risk of bleeding and require lower or less frequent doses. Patients who are fast or slow metabolizers may also respond similarly to other types of medications. Pharmacogenetic testing is not widely used due to availability, clinician knowledge, and regulatory and reimbursement issues but may be valuable.

A more invasive surgical treatment is **coronary artery bypass grafting (CABG)**. With CABG, blockages in coronary arteries are bypassed using other arteries from the chest or arm or veins from the legs. In the traditional CABG, patients undergo general anesthesia. A large incision through the sternum is made, and a cardiopulmonary bypass (CPB) is begun through large catheters in the vena cava or right atrium and aorta. A CPB provides continuous gas exchange and perfusion while the heart is stopped to provide a still, bloodless field for surgery. Then arteries or veins being used as bypasses are surgically attached to the diseased coronary artery, creating an alternate path for blood to flow around the blockage. Common vessels used are the internal thoracic (mammmary) and saphenous vein. Bypasses made from arteries have greater longevity, but more bypasses can be made with saphenous veins, which require an additional incision in the leg. Multiple blockages may be bypassed in the same surgery. For example, a patient

**FIGURE 30.3** Stent placement within the artery. Step 1: A catheter with a small balloon on its tip is advanced to the area with atherosclerotic plaque. Step 2: The balloon is inflated and deflated to open the lumen of the artery. Step 3: The stent is advanced to hold the artery open and maintain adequate blood flow.

with four large coronary artery blockages would undergo a quadruple bypass.

Minimally invasive coronary surgery (MICS CABG) may be an alternative to CABG. MICS CABG involves a left chest incision and multiple smaller incisions that act as ports for instruments. A CPB is used, and multiple vessels can be bypassed. Minimally invasive direct coronary artery bypass (MIDCAB) is an option for some patients, in which incisions similar to those in MICS CABG are made. A pressor device placed through the chest incision immobilizes a part of the heart while the internal thoracic artery is used to bypass a single blockage. A similar procedure through a sternotomy incision allows for additional vessels to be bypassed. Because both procedures do not require a CPB, they are called off-pump or “beating heart surgery.” Potential advantages of all these procedures include faster recovery times and fewer complications.

Patients who undergo CABG are sent to a critical care unit for intensive monitoring and care. Multiple hemodynamic monitoring catheters, chest tubes, an endotracheal tube, mechanical ventilation, a nasogastric tube, an indwelling bladder catheter, and a temporary pacemaker wire may all be needed postoperatively. Nursing care of the patient undergoing CABG is described in Chapter 32.

The decision between PTCA and CABG is made by the healthcare team and patient based on degree of disease, surgical risk, hemodynamic stability, and symptom severity. Other, less common invasive treatment strategies, such as atherectomy and transmyocardial laser revascularization (TMLR), may be performed in patients meeting limited criteria. During an atherectomy, plaque within the coronary artery is shaved and removed through a specialized catheter during cardiac catheterization. In TMLR, a patient's heart is surgically exposed, and a laser is used to create 20 to 40 tiny

channels from the outside of the left ventricle to the chamber within. The outside openings are closed by clots, but the channels stay open on the inside. The procedure is also thought to stimulate angiogenesis; the formation of new blood vessels from pre-existing vessels.

### Lifestyle Management

Diet and physical activity play an important role in the treatment of CAD and its risk factors of hypertension, hyperlipidemia, diabetes, and obesity (see Genetic Connections: Healthy Lifestyle Counters Genetic Risk). Maintaining a healthy body weight or a body-mass index (BMI) of less than 30 kg/m<sup>2</sup> is critical in the management of CAD. A diet that is low in saturated fat and sodium as well as high in fruits, whole grains, and vegetables and considers personal and cultural preferences should be discussed. Engaging in regular moderate-intensity physical activity at least 30 minutes a day, 5 days a week is recommended. Smoking cessation and avoiding exposure to smoking should be encouraged. Screening and treatment for depression can reduce ischemic events and improve quality of life in patients with CAD. Refraining from excessive alcohol use may reduce CAD risk. Patients with ACS, especially after PCI or CABG, should be referred and encouraged to participate in a comprehensive cardiac rehabilitation program. **Cardiac rehabilitation** is a supervised program of education, counseling, and supervised physical activity. Ideally, cardiac rehab begins before discharge and continues in the outpatient setting. Participation can improve morbidity and mortality, reduce angina episodes, and decrease rehospitalizations.

## Genetic Connections

### Healthy Lifestyle Counters Genetic Risk

Genetic and lifestyle factors are independent risks for coronary artery disease (CAD). However, in a study of over 55,000 participants, those persons at highest genetic risk for CAD reduced this risk by nearly 50% with healthy lifestyles. Healthy lifestyles included not smoking, not being obese, regular physical activity, and a healthy diet.

### Complications

The primary complication of CAD is ACS, which includes unstable angina and MI. Myocardial infarction is discussed in detail in Chapter 32. Coronary artery disease may also result in dysrhythmias and heart failure. Women tend to have higher rates of adverse outcomes from CAD in general. These outcome differences have been attributed to limits in the diagnosis and treatment in nonobstructive CAD, particularly because most major diagnostic tests and treatments are focused on obstructive CAD. Gender bias in treatment has also been implicated in the higher number of adverse events in women.

## Connection Check 30.1

After a percutaneous coronary angioplasty, what assessment should most concern the nurse?

- A. Back discomfort
- B. Chest pain
- C. Capillary refill of less than 3 seconds
- D. Hypoactive bowel sounds

### Nursing Management

#### Assessment and Analysis

Careful assessment of chest pain and other manifestations of CAD is required to identify those patients with CAD and those patients who have stable angina that may be progressing to ACS. The clinical manifestations of CAD are the result of the imbalance of oxygen supply and demand to the myocardial tissue. The most common symptom is chest pain. Other, more nonspecific symptoms include:

- Epigastric discomfort
- Nausea and vomiting
- Diaphoresis
- Syncope
- Shortness of breath (SOB)
- Pain between shoulders/jawline

#### Nursing Diagnosis

- **Decreased tissue perfusion** related to inadequate blood flow secondary to the presence of plaque within the coronary arteries or microvascular dysfunction

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Tachycardia and tachypnea can be manifestations of cardiac ischemia. Hypertension is a CAD risk factor. Nitroglycerin and morphine administration can result in hypotension.*
- Pain assessment utilizing provoking factors, quality, region/radiation, severity, time (PQRST)  
*Angina can be nonspecific in some patients; establishing location and quality can aid in the diagnosis of cardiac chest pain and disease progression. Headache can result from nitroglycerin administration.*
- Electrocardiogram and continuous cardiac monitoring  
*Depressed ST segment or flat or inverted T waves are indicative of ischemia; ST elevations are indicative of acute injury. Cardiac dysrhythmias may result from ischemia or infarction.*
- Physical assessment  
*Pallor, clamminess, nausea, vomiting, shortness of breath, and diaphoresis may indicate cardiac ischemia. Xanthomas are associated with hypercholesterolemia.*
- Patient history  
*Evaluate CAD risk factors and anginal patterns. Fatigue and weakness may be indicative of CAD. Identify potential noncardiac causes of chest pain, such as gastroesophageal reflux or respiratory disorders.*

- Recreational drug use  
*Illicit drug use (i.e., cocaine) can cause vasospasm, obstructing blood flow and causing symptoms that resemble CAD.*
- Depression screening  
*Depression may increase morbidity and mortality.*
- Laboratory values
  - Cardiac biomarkers: troponin, CK/CK-MB  
*Cardiac enzymes and troponin levels rise when the heart sustains an acute injury—can help differentiate between angina and MI pain.*
  - Creatinine, blood urea nitrogen  
*Assess renal function. The contrast dye used during heart catheterization is nephrotoxic.*
  - Glycosylated hemoglobin (HgbA1c)  
*Hyperglycemia occurs with diabetes and is a risk factor for CAD.*
  - Lipid profiles: cholesterol, triglycerides, LDL, HDL  
*Assess for hyperlipidemia, a risk factor for CAD development.*

#### ■ Actions

- Administer oxygen to keep oxygen saturation greater than 93%.  
*Supplemental oxygen optimizes oxygen delivery to the myocardium. Cardiac dysrhythmias, especially tachycardia, and anxiety increase myocardial oxygen consumption.*
- Obtain ECG with the occurrence of chest pain.  
*Evaluates new anginal episode for evidence of ischemia or injury. In cases of acute chest pain, an ECG within 10 minutes is recommended.*
- Administer nitroglycerin as ordered.  
*Dilates the coronary arteries to improve flow to the heart and relieve pain*
- Administer aspirin as ordered.  
*Prevents platelet aggregation*
- Administer morphine as ordered if nitroglycerin does not relieve pain.  
*Minimizes pain and decreases the workload on the heart. Monitor for adverse effects of hypotension, nausea, vomiting, and respiratory depression.*
- Administer beta blockers/calcium channel blockers as ordered.  
*Inhibit cardiac response to physical activity, decrease oxygen consumption; may consider holding prior to exercise test*
- Administer statin medications as ordered.  
*Reduce cholesterol level and decrease the risk of increased plaque formation*

#### ■ Actions After PCI

- Perform cardiac catheterization care as described in Chapter 28.
- Report and treat chest pain immediately.  
*Reocclusion, vasospasm, or stenosis can result in ischemia and requires prompt intervention.*
- Administer additional anticoagulants.  
*Prevents vessel occlusion by thrombus*

- Maintain fluids through catheterization sheaths if left in place.  
*Allows for immediate coronary access if return to catheterization lab is needed*
- Maintaining bedrest and compression devices at the catheter insertion site.  
*Promotes hemostasis and prevents bleeding*

#### ■ Teaching

- Medication regimen  
*Medication adherence lowers mortality and risk of hospitalization and MI.*
- Angina management  
*If angina occurs during activity, stop activity and rest. Take dose of nitroglycerin. Tabs can cause tingling or taste bitter when placed under the tongue. Not to exceed three doses 5 minutes apart. Caution patient about the use of the medication in the setting of lightheadedness or dizziness because this can be indicative of hypotension. See Medication Safety Alert for more information.*
- Bleeding precautions if on anticoagulants  
*Avoiding activities that have high injury or fall risk, using a soft toothbrush and electric razor, and using caution with sharp objects reduces bleeding risk.*
- Risk factor reduction strategies: physical activity, blood pressure management, healthy diet/weight loss, smoking cessation, decreased alcohol consumption, control of glucose  
*Risk factor reduction can prevent primary disease and limits the progression of CAD.*
- When to call providers or emergency services  
*Unrelieved chest pain—chest pain at rest requires early intervention. For PCI patients: uncontrolled bleeding, swelling, redness, purulent discharge, and pain at insertion site or fever need prompt treatment.*
- Encourage participation in cardiac rehabilitation for ACS patients after PCI or CABG.  
*Reduces morbidity and mortality*

#### Evaluating Care Outcomes

Patients with CAD can achieve optimal functional status by complying with prescribed medical therapy, maintaining a healthy diet, limiting alcohol, and engaging in regular exercise. Achieving desired activity levels and meeting self-care needs with minimal or no pain indicate achievement of care goals in this patient population. It is important that the patient understands the disease process, the medications used to treat it, and when to call 911.

## INFECTIVE ENDOCARDITIS

### Epidemiology

The exact prevalence of infective endocarditis (IE) is unknown; however, it is estimated that approximately 47,000 cases occur each year, and the number of cases has

steadily risen since 2000. Infective endocarditis can be classified as native or prosthetic or as right or left sided. It most frequently affects the native mitral or aortic valves. The pulmonic valve is the least frequently affected. Individuals who abuse IV drugs tend to have right-sided or tricuspid valve infections.

Risk factors for IE include age (greater than 60), immunodeficiency, IV drug use, diabetes mellitus, the presence of prosthetic heart valves, prior history of endocarditis, congenital or structural heart disease, and the presence of an intravascular access or an implanted cardiac device. Recent studies have indicated others at risk of developing IE are persons with poor oral hygiene or periodontal disease, patients on hemodialysis, and patients with frequent exposures to the healthcare system or invasive procedures. Rheumatic heart disease is also considered a risk factor, but a sharp decline in the incidence in developed countries has lessened its impact. Mortality from IE is high, ranging from 20% to 40% of cases.

### Connection Check 30.2

The nurse determines which patient is at greatest risk for developing IE?

- A 22-year-old student undergoing a dental procedure
- A 35-year-old man with a past medical history of IV drug use
- A 65-year-old male heart transplant patient on immunosuppressive therapy undergoing a colonoscopy
- A 70-year-old female with heart failure with an intravascular access device for home infusion

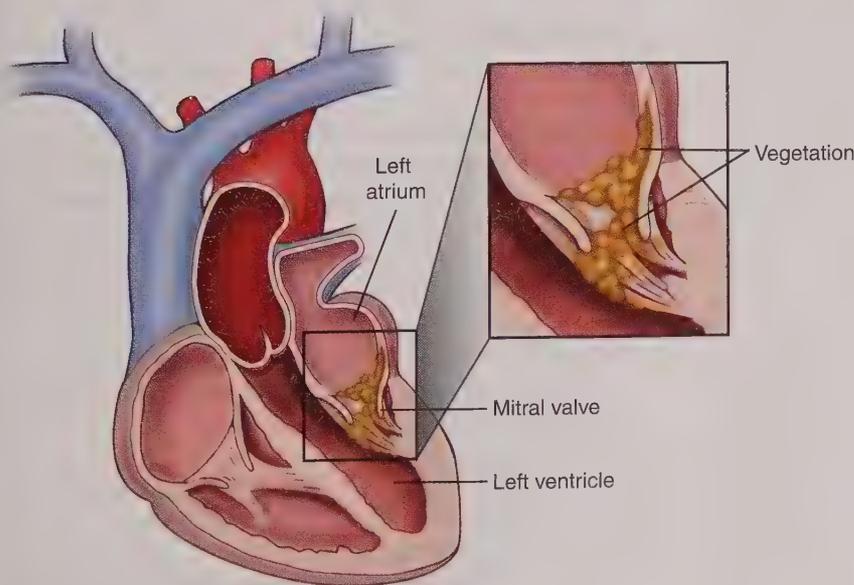

### Pathophysiology

Infective endocarditis is defined as an infection of the innermost layer of the heart, the endocardium, most typically affecting the heart valves. Infective endocarditis begins with damage to the endocardial lining of the heart, which can occur as a result of turbulent blood flow. Turbulent blood flow is often caused by valve dysfunction. Platelet and fibrin deposit onto the injured area, forming what is known as a *nonbacterial thrombotic endocardial lesion*. Microorganisms introduced into the bloodstream through patient exposures circulate and can become trapped under the layers of platelet and fibrin deposits. These microorganisms and deposits grow into clumps known as *vegetation*. This vegetation can severely damage the valves of the heart (Fig. 30.4).

The etiology of IE is generally of bacterial origin, although other pathogens have been reported. The most common causative microorganisms are *Staphylococcus aureus* and *Streptococcus*. Infective endocarditis can also be caused by other bacteria, viruses, and fungi. The source of exposure to microorganisms in the blood has been historically linked to dental and other invasive procedures. However, it has been suggested that repeated exposures to microorganisms are more likely to cause IE than random exposure during a single dental or other invasive procedure.

### Clinical Manifestations

Clinical manifestations of IE include red, painful nodes in the pads of the fingers and toes—Osler's nodes—and red, painless spots on the palms and soles, called *Janeway lesions*. *Splinter hemorrhages*, tiny blood clots that run vertically under nails, may also be present. Most patients have a heart **murmur**, the sound heard when there is

**FIGURE 30.4** Mitral valve vegetation in infective endocarditis.

turbulent blood flow across a heart valve. They can also experience heart failure (HF), arrhythmias, weight loss, or night sweats. Other symptoms are similar to those of any infectious process, which include:

- Fever
- Fatigue
- Confusion (in older adults)

## Management

### Medical Management

#### Diagnosis

##### Diagnostic Tests

Tests used to confirm the diagnosis of IE are blood cultures, two sets from different sites, and transthoracic echocardiogram (TTE) or transesophageal echocardiogram (TEE). Echocardiography can identify valve dysfunction, vegetative growth, abscesses, and changes in heart size and pumping ability that can occur with IE. Echocardiography is described in more detail in Chapter 28. An elevated white blood cell count may also be indicative of infection.

#### Medications

Medication management consists primarily of IV antibiotic therapy. The increasing trend of microbial resistance has led to the use of combination therapy. The standard duration of treatment is 4 to 6 weeks but may be longer for prosthetic valves. Patients are often discharged to home on IV antimicrobial therapy. Shorter duration is recommended for some combination therapies. Oral antimicrobial agents are rarely used as initial treatment. Repeated blood cultures may be obtained until results are negative, indicative of adequate bactericidal effects. Prophylactic use of oral antibiotics is not routinely recommended but is used for patients at high risk (see Safety Alert).

The choice of antimicrobial agents is complex and based on the organism cultured and the sensitivity report, right-sided versus left-sided IE, native versus prosthetic valve involvement, patient comorbidity, and other factors. Infectious disease specialists are often consulted. Penicillin G, ceftriaxone, vancomycin, nafcillin, and gentamicin may be considered in various combinations for the treatment of IE. Supportive treatment for the common complications of IE, especially HF, is also indicated to optimize cardiac output and tissue perfusion.

#### **Safety Alert** To prevent IE and reduce valvular disease, prophylactic antibiotics are recommended

before dental procedures, and meticulous oral hygiene should be encouraged for patients at highest risk, such as those with a history of IE, intracardiac prosthetic material such as valves and defect closure devices, cardiac transplant, and congenital heart disease.

### Surgical Management

The surgical treatment options for IE include valve repair or replacement. Surgery can remove infected tissue and reduce mortality and complications, but it also has significant risk. The timing of surgery is controversial, due to a lack of definitive evidence but early surgery is recommended for cases in which antimicrobial therapy has been ineffective in controlling the infection or when complications such as embolic events or heart failure are observed.

### Complications

Embolic events are the major complication of IE and occur in 22% to 50% of cases. **Embolization** occurs when fragments of vegetation break free from the valve and travel to other parts of the body through the bloodstream. Embolic events are often a complication of left-sided IE and are rarely seen in right-sided IE. The emboli can travel randomly to any organ or tissue, resulting in obstructed blood flow and potential spreading of infection. Emboli from left-sided IE typically travel to the central nervous system (65%) but can also affect the kidneys, spleen, bowel, and extremities. Emboli traveling to the central nervous system (CNS) cause transient ischemic attacks or strokes. Right-sided IE is associated with pulmonary emboli.

Heart failure and dysrhythmias can also occur due to valvular dysfunction and abscesses in the conduction system. Strokes, heart failure, and dysrhythmias can be a part of the presenting symptoms of IE because they compel patients to seek treatment.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of IE, such as positive blood cultures combined with fever, fatigue, and the lesions typically seen in the hands and feet, are due to infection. Sepsis can occur in conjunction with IE. Septic emboli can alter CNS and systemic perfusion. The damage to the heart valves can cause a new murmur and heart failure.

#### Nursing Diagnoses

- **Infection related** to an invading organism secondary to IE
- **Ineffective tissue perfusion** related to emboli
- **Decreased cardiac output** related to valve dysfunction, altered rhythm, and/or altered stroke volume

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Fever is indicative of ongoing acute infection. Hypotension, tachycardia, tachypnea, and low SpO<sub>2</sub> can be signs of sepsis or heart failure.*
- Auscultate breath sounds.  
*Crackles may be a sign of heart failure related to valve dysfunction.*
- Auscultate heart sounds.  
*A new or worsening murmur may occur due to valve damage.*

- Assess neurological function.  
*Neurological changes or deficits in pupils, grips, foot pushes, facial droop, and speech may be signs of CNS embolization.*
- Assess extremities.  
*Cyanosis or pallor, delayed capillary refill, and decreased peripheral pulses may indicate peripheral embolization. Edema could be a sign of heart failure related to valve dysfunction.*
- Skin assessment  
*Osler's nodes, Janeway lesions, and splinter hemorrhages are indicative of IE.*
- Monitor diagnostic test results.  
*Repeated culture reports are used to evaluate the effective treatment of IE. White blood cell (WBC) counts can indicate responsiveness to infection. Echocardiograms can evaluate the size of vegetation and valve function and can be used to predict the risk of complications.*
- History of drug use, invasive procedures, implanted vascular or cardiac devices, or valve replacement surgery  
*Common risk factors for IE*

### ■ Actions

- Administer antibiotics as prescribed.  
*Treatment for IE is long-term IV antibiotic treatment.*
- Maintain IV access for antibiotic administrations.  
*Intravenous access is essential for antibiotic administration. Long-term venous access, such as a peripherally inserted central catheter (PICC), may be considered.*
- Administer heart failure medications as needed.  
*Heart failure treatment optimizes cardiac output and tissue perfusion.*
- Provide social support during prolonged hospitalization.  
*Social isolation due to hospitalization may contribute to depression, anxiety, and anger.*
- Refer patient to addiction counseling services if drug use has caused the disease.  
*Stopping recreational IV drug use may help limit the reoccurrence of IE and lead to a better quality of life.*

### ■ Teaching

- Good oral hygiene utilizing a soft toothbrush  
*Bleeding gums provide a portal of entry for bacteria into the bloodstream. Poor dental hygiene may increase the recurrence of IE.*
- Inform healthcare provider about IE history prior to any dental or invasive procedure.  
*Prophylactic antibiotics may be prescribed to decrease the risk of IE.*
- Completion of prolonged antibiotic regimen  
*Completing the full course of antibiotics is critical to eradicating the infection and preventing recurrence and complications.*

### Evaluating Care Outcomes

Goals of care for patients with IE are control of the infectious process through antibiotic administration and minimizing complications. Patient education should focus on risk control, early detection, and prevention. A well-managed patient is free from infection and understands the signs of

IE and when the healthcare provider should be contacted. (See Geriatric/Gerontological Considerations: Infective Endocarditis.)

## Geriatric/Gerontological Considerations

### Infective Endocarditis

Older people are at higher risk for infective endocarditis (IE) due to comorbidities, increasing numbers of invasive procedures, and greater use of implanted cardiac devices such as pacemakers and artificial valves. The required prolonged hospitalization and treatment can contribute to rapid functional decline. Evaluation for early discharge and home infusion therapy should be considered to maintain functional capabilities. An increase in fat mass, reduced renal function, and lower albumin levels require careful antimicrobial adjustments to optimize outcomes and reduce adverse effects. Serum medication levels, renal function, and culture reports should be routinely monitored. Confusion and agitation can challenge the maintenance of continuous IV access. Alternate medication routes may need to be considered. Aging is not a contraindication for surgery, but comorbidities and clinical status should be evaluated.

## MYOCARDITIS

### Epidemiology

**Myocarditis** is an inflammatory disease of the myocardium that is most commonly triggered by viral infection or autoimmune diseases. Men and young persons are most affected. It is a leading cause of dilated cardiomyopathy (discussed in Chapter 32) and the third leading cause of cardiac death in young athletes. About 1% to 5% of persons with viral illnesses may exhibit a form of myocarditis.

### Pathophysiology

Viruses are the infectious agent in most cases of myocarditis. Coxsackie virus, adenovirus, parvovirus, and herpesvirus are frequent pathogens. Bacteria, parasites, and fungi can be the etiology. Autoimmune hypersensitivity reactions and toxin exposure can also cause myocarditis. Viral infection can directly damage the myocardium, and the patient's own immune responses can cause secondary damage. Myocardial inflammation and injury result, affecting the entire myocardium or localized areas of tissue.

### Clinical Manifestations

Myocarditis can be classified as acute, subacute, or chronic. Symptoms vary widely from asymptomatic and mild cases to acute heart failure and cardiogenic shock. Common

presenting symptoms are chest pain, dysrhythmias, dyspnea, palpitations, syncope, and heart failure. In the case of viral illness, sequelae such as fever, fatigue, loss of appetite, and myalgia may also be experienced.

## Management

### Medical Management

#### Diagnosis

#### Diagnostic Tests

Patient history, C-reactive protein, troponin, brain natriuretic peptide (BNP), ECG, echocardiography, and magnetic resonance imaging (MRI) are used in the diagnostic process. Myocardial biopsy, also called endomyocardial biopsy, is the definitive test but is reserved for more acute cases.

#### Treatment

Some cases of myocarditis resolve within days, whereas others progress to heart failure and acute dilated cardiomyopathy that require significant intervention, which may include heart transplantation, implanted cardiac defibrillators, or mechanical circulatory support (see Chapter 32). Medical treatment focuses on the management of heart failure, dysrhythmias, and dilated cardiomyopathy. Antiviral immunosuppressants (prednisone and azathioprine) and immunotherapies such as immunoglobulin IgG may be used but have limited evidence of effectiveness.

#### Complications

Myocarditis is the most frequent cause of dilated cardiomyopathy. Heart failure and dysrhythmias, including sudden cardiac death, especially in young athletes, are also complications.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of myocarditis, such as SOB, chest pain, fatigue, and dysrhythmias typical of the manifestations of heart failure are due to the weakened or damaged heart muscle.

#### Nursing Diagnosis

- **Risk for decreased cardiac output** related to myocardial dysfunction

#### Nursing Interventions

##### Assessments

- Vital signs  
*Hypotension, hypertension, tachycardia, tachypnea, and hypoxia are signs of heart failure. Fever is indicative of infection.*
- Cardiac rhythm  
*Dysrhythmias are a common and dangerous clinical manifestation and must be identified and treated promptly.*
- Assess for crackles, edema, jugular vein distention (JVD), weight gain, and decreased urine output.  
*These are evidence of the weakened heart muscle seen with heart failure.*

##### Actions

- Administer antivirals, antimicrobials, immunosuppressives, and immunoglobulins as ordered.  
*Medications are administered depending on the cause of myocarditis.*
- Administer heart failure medications as needed.  
*Heart failure is a common manifestation and must be treated to optimize cardiac output and tissue perfusion.*
- Provide emotional support.  
*The diagnosis of myocarditis can cause fear and anxiety.*

##### Teaching

- Complete the full medication treatment regime.  
*Patients should continue to take medications as directed even if feeling better to ensure an effective/positive result.*
- Avoid strenuous activities. Athletes should not participate in competitive sports while inflammation is present and need to be reevaluated in no less than 3 to 6 months before resuming sport.  
*Activity restrictions may reduce the risk of sudden cardiac death.*

### Evaluating Care Outcomes

The primary goal is resolution of the underlying cause and reducing the symptoms of heart failure and risks of cardiomyopathy and sudden cardiac death. A well-managed patient is free of signs of infection and heart failure and is able to tolerate normal activity levels.

## PERICARDITIS

### Epidemiology

**Pericarditis**, inflammation of the pericardium, is diagnosed in about 5% of emergency room patients with chest pain not related to ischemia. About 80% of cases are idiopathic (unknown etiology) or are presumed to occur after a viral infection. Acute pericarditis is common following MI, occurring in about 15% to 20% of post-MI patients. The true prevalence of pericarditis is difficult to determine because persons with mild cases (subclinical) do not seek treatment. Some studies show that pericarditis occurs more in men and young and middle-aged persons. Recurrence is common, with 20% to 30% of persons having an additional episode. Pericarditis can be categorized as infectious (viral, bacterial, fungal, or parasitic), noninfectious (auto-immune, neoplastic, metabolic, trauma, and drug related), and idiopathic. Pericarditis can also be described as acute, chronic, or recurrent. The prognosis is generally good, with an in-hospital mortality rate of 1.1%.

### Pathophysiology

The heart is surrounded by the two-layered pericardium, which protects the heart, reduces friction with surrounding structures, and helps to determine chamber size and pressure. The tough, fibrous outer wall is the parietal pericardium; the inner is the visceral pericardium, or epicardium. The space between contains approximately 20 to 60 mL of

pericardial fluid. This fluid acts as a lubricant to prevent friction between the two layers. When the pericardium becomes inflamed, it is termed *pericarditis* (Fig. 30.5).

## Clinical Manifestations

The most common clinical manifestation of pericarditis is pleuritic chest pain. This occurs in 85% to 90% of cases and can be differentiated from MI chest pain because it tends to be relieved by sitting up and leaning forward. Friction rubs, scratchy sounds that occur with each heartbeat, may be auscultated in 30% of cases. Box 30.1 describes how to assess for a friction rub. Other clinical manifestations include:

- New or worsening pericardial effusion (60%)
- ECG changes: diffuse ST-segment elevations or PR depression (60%)
- Fever

## Management

### Medical Management

#### Diagnosis

#### Diagnostic Tests

Tests used to diagnose pericarditis include ECG, chest x-ray, echocardiogram (transthoracic or transesophageal), cardiac CT scan, and MRI. The hallmark ECG changes include widespread ST-segment elevation or PR-segment depression (Fig. 30.6).

The finding of cardiomegaly and clear lung fields on chest x-ray may indicate a **pericardial effusion** (fluid buildup in the pericardial sac) and might be supportive of the pericarditis diagnosis. Pericardial effusion might also be evident on an echocardiogram, CT scan, or MRI.

Laboratory tests include serial cardiac biomarkers to rule out MI. Positive blood cultures, a complete blood count with a high WBC count, and positive inflammatory markers such as C-reactive protein or sedimentation rates may indicate the presence of infection or inflammation, leading to the diagnosis of pericarditis when combined with the associated clinical manifestations.

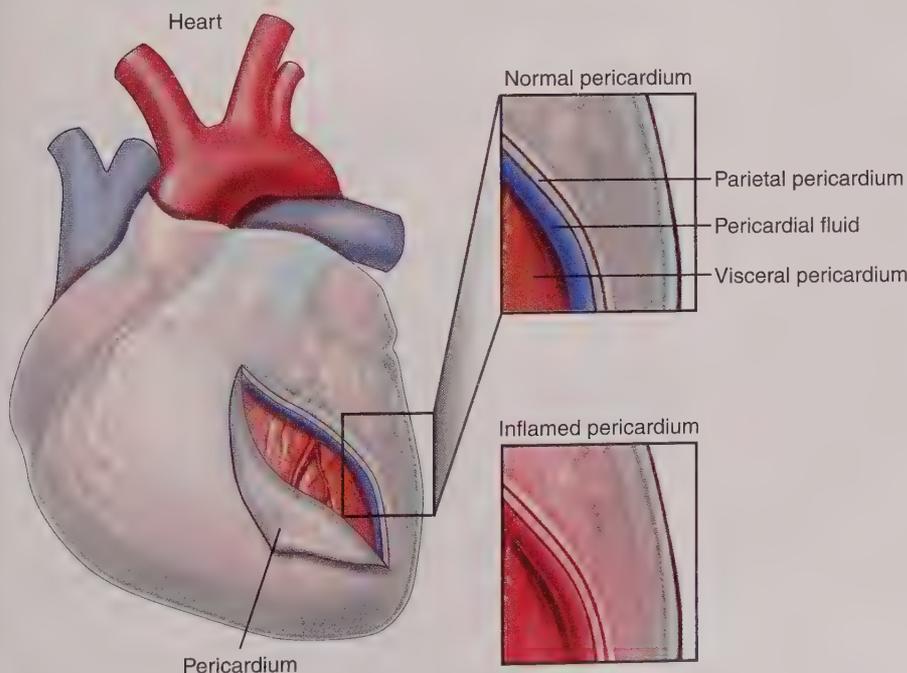

#### Medications

Medication management goals are to alleviate pain and stop the inflammatory process. Aspirin and other NSAIDs are indicated. Colchicine may be used as an additional anti-inflammatory medication with acetylsalicylic acid (ASA) or NSAIDs. If pain or inflammation is not relieved by ASA or NSAIDs, corticosteroids may be used. Additional treatment may be warranted depending on the etiology of the disease. For example, in addition to the use of anti-inflammatory agents, antimicrobial therapy may be instituted for bacterial pericarditis.

#### Complications

A complication of pericarditis is pericardial effusion. This is an accumulation of fluid in the pericardial space exceeding the typical 20 to 60 mL. Pericardial effusion is diagnosed by the use of chest x-ray, echocardiography, and ECG. Depending on the volume and clinical presentation, draining of the excess fluid, also known as **pericardiocentesis**, may be indicated. In a pericardiocentesis procedure, ultrasound guides needle insertion through the chest wall to aspirate the excess fluid.

Depending on the etiology, pericardial fluid may accumulate slowly (i.e., neoplastic), allowing the pericardium to stretch to accommodate the increased volume. Clinical symptoms in these cases gradually progress. In contrast, rapidly growing effusions overwhelm the stretching capacity of the

**FIGURE 30.5** Inflammation of the pericardium in pericarditis.

## Box 30.1 How to Assess Pericardial Friction Rub

The sound of a pericardial friction rub is a result of the friction between the inflamed layers of the pericardium when the heart moves within the pericardial sac. It is best heard over the left sternal border at the end of expiration with the patient leaning forward. It produces a high-pitched, scratchy noise and is muffled when excessive fluid is present.

pericardium, resulting in an acute decompensation. If not treated emergently, the increased volume of fluid within the pericardial space can exert pressure on the heart, resulting in cardiac tamponade. In cardiac **tamponade**, the excessive fluid in the pericardial sac compresses the cardiac structures and dramatically decreases cardiac output. Common signs of pericardial tamponade include dyspnea, tachycardia, pulsus paradoxus, JVD, an enlarged heart, and muffled heart tones. Pulsus paradoxus is an abnormal drop in systolic blood pressure during inspiration. Beck's triad is the classic finding of hypotension, muffled heart sounds, and JVD but is only present in 10% to 40% of cases of tamponade. Emergent pericardiocentesis is indicated in this clinical presentation. Surgical management of pericardial effusions and cardiac tamponade may include a pericardial window, in which a window or fistula is created to drain excess fluid from the pericardial space.

### Nursing Management

#### Assessment and Analysis

The major clinical manifestation of pericarditis is pain due to friction between the inflamed layers of the heart that occurs with movement. Excessive accumulation of fluid, or pericardial effusion, can result in acute decompensation due to the increased pressure around the heart limiting ventricular filling and contraction, resulting in decreased cardiac output.

### Nursing Diagnoses

- **Chest pain** related to swelling and inflammation secondary to pericarditis
- **Risk for decreased cardiac output** related to cardiac structure compression

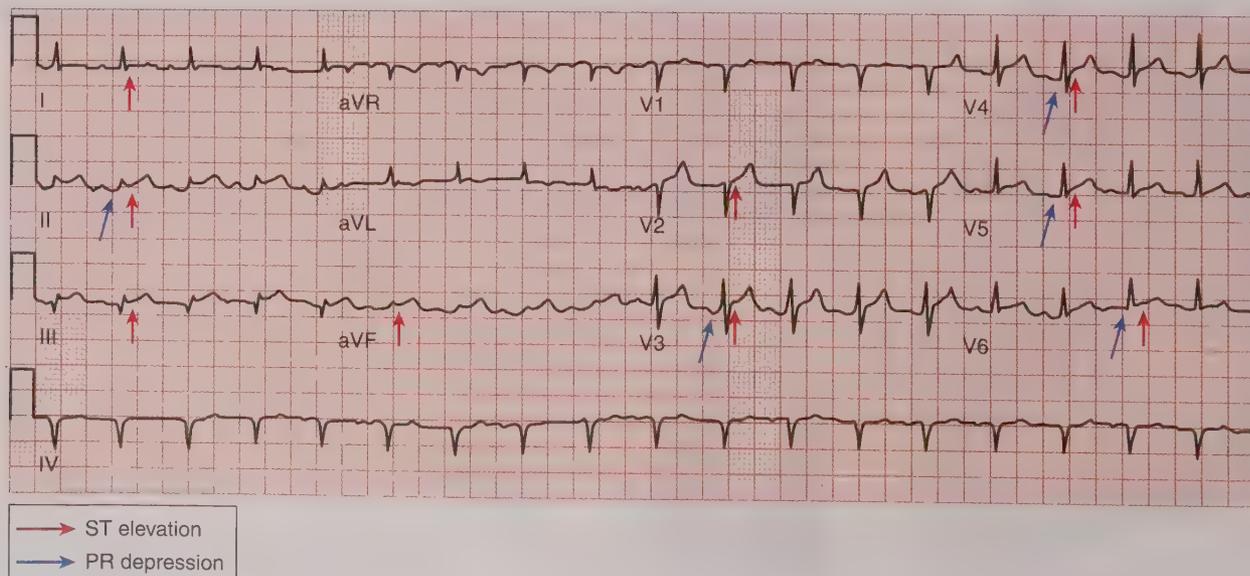

### Nursing Interventions

#### Assessments

- **Vital signs**  
*Hypotension, tachycardia, tachypnea, and pulsus paradoxus are indicative of cardiac tamponade, which is due to an excessive or sudden buildup of pericardial effusion. Fever is indicative of an ongoing infection.*
- **Pain**  
*Chest pain that is relieved by sitting up and leaning forward distinguishes pericarditis pain from the pain associated with MI.*
- **Auscultate heart sounds.**  
*A friction rub is a common finding in pericarditis. Muffled heart tones may indicate pericardial effusion or cardiac tamponade.*
- **ECG**  
*ST elevation or PR depression in all or most leads can be associated with pericarditis.*

#### Actions

- **Keep the head of the bed elevated.**  
*Pericardial effusion exerts pressure on surrounding organs, resulting in **orthopnea** (shortness of breath when lying down) and **dyspnea**. Raising the head of the bed relieves shortness of breath. Pain is also relieved by sitting in the upright position.*
- **Administer NSAIDs or ASA and colchicine medications as prescribed.**  
*Pain relating to pericarditis is associated with inflammation, so control is largely managed with anti-inflammatories. Steroids are added if necessary.*

**FIGURE 30.6** Electrocardiogram illustrating ST elevation and PR depression associated with pericarditis.

- Provide emotional support.  
*Anxiety can occur because of the fear that the pain is from a heart attack.*

### Teaching

- Avoid strenuous activities until symptoms resolve or laboratory values return to normal.  
*Activity restrictions may reduce the risk of sudden cardiac death, which is rare but has been reported.*
- Distinguish between the pain of pericarditis and heart attack.  
*Ensures patient will seek emergency help appropriately.*

### Evaluating Care Outcomes

The primary goal of care for a patient with pericarditis is pain relief. Early recognition and management of pericardial effusion are also important factors in the care of these patients. A well-managed patient is free from pain, shortness of breath, and indicators of cardiac tamponade. Ensuring that the patient and family are knowledgeable about the signs and treatment of the disease as well as the indicators of pericardial effusion is necessary to avoid the negative consequences associated with cardiac tamponade.

### Connection Check 30.3

Which order would the nurse question in the initial management of acute pericarditis?

- Aspirin
- Colchicine
- Prednisone
- NSAIDs

## VALVULAR DISEASE

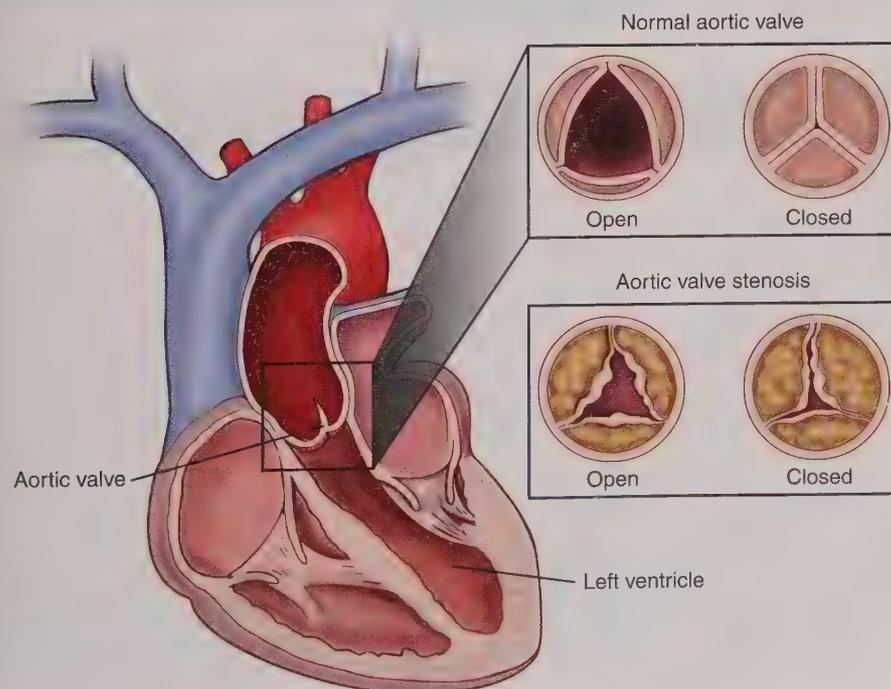

### Epidemiology

The prevalence of valvular disease in the general population is approximately 2.5%; it increases with age and occurs equally in men and women. The risk factors include infectious diseases such as IE and rheumatic fever, myocardial infarction, heart failure, congenital defects, and degenerative changes. Pregnancy has been shown to increase the risk of valvular disease because of the increased workload on the heart. Patients with risk factors for coronary artery disease are also at risk for valvular disease. The most common valvular diseases are aortic stenosis (Fig. 30.7) and mitral regurgitation. The least commonly affected valves are the tricuspid and pulmonic valves because of the low-pressure system in the right heart. Valvular disease can affect one or more valves at the same time.

### Pathophysiology

*\* MOST COMMON valve - AORTIC*

There are several types of valvular disease: stenosis, insufficiency or regurgitation, and prolapse (Table 30.3). The pathophysiology of all valvular diseases is similar. Generally, in response to backward flow through the valve, referred to as regurgitation, or resistance to forward flow through the constricted or stenosed valve, signs of right- or left-sided HF develop. For instance, mitral valve regurgitation causes backward flow of blood into the left atrium. The increased blood volume raises the pressure in the atrium and pulmonary vessels and results in pulmonary edema and left-sided HF. Aortic valve stenosis obstructs the flow of blood from the left ventricle (LV), causing increased LV pressures. Left ventricle hypertrophy occurs to generate adequate force to open the valve. Over time, the LV fails, also resulting

**FIGURE 30.7** A comparison of a normal aortic valve with a valve narrowed in aortic stenosis.

**Table 30.3 Types of Valvular Disease**

Type	Description
<b>Stenosis</b>	Stiffening and thickening of the valve leaflets, caused by calcium deposits or scarring, narrow the opening and obstruct flow.
<b>Regurgitation or insufficiency</b>	Blood flows or leaks backward—ventricle to atria, aorta to the left ventricle, pulmonary circulation to the right ventricle—because of incomplete closing of the valve.
<b>Prolapse</b>	Valve leaflets bulge backward and do not close, causing regurgitation.

in the signs of left-sided HF. Insufficiency of the tricuspid valve causes backward flow and increased pressure in the right atrium, which results in signs of right-sided HF, such as JVD, generalized edema, and ascites.

### Clinical Manifestations

Often, the first clinical sign of valvular disease is the auscultation of a murmur. A murmur can be the result of a high rate of blood flow through a valve, forward blood flow through a narrowed valve (**stenosis**), or backward blood flow through an incompetent valve (regurgitation). A cardiac murmur can be classified as systolic, diastolic, or continuous on the basis of where in the cardiac cycle it is best heard. Systolic murmurs can be heard during  $S_1$  or *lub* when the ventricles are contracting. During this time, the aortic and pulmonary valves should be open, and the mitral and tricuspid valves should be closed. Diastolic murmurs can be heard during  $S_2$  or *dub* when the ventricles are relaxing and the heart is filling. The mitral and tricuspid valves should be

open to allow for ventricular filling, and the aortic and pulmonary valves should be closed. Therefore, a systolic murmur can be heard with aortic or pulmonary stenosis or mitral or tricuspid regurgitation. In contrast, a diastolic murmur can be heard with aortic or pulmonary valve regurgitation or mitral or tricuspid stenosis. Another factor used to identify murmurs is the location of where the murmur is best heard based on the heart's auscultatory sites. Mitral valve murmurs are best heard at the apex of the heart. Table 30.4 identifies valve murmurs and their defining characteristics. Murmurs can be described in terms of sound qualities, but practice is needed to develop this skill. For instance, although it is not true in all cases, aortic stenosis typically produces a systolic murmur described as turbulent or harsh.

Most clinical manifestations of valvular disease resemble those of HF due to decreased cardiac output. They include:

- SOB, dyspnea, orthopnea
- Crackles
- Angina
- Syncope, dizziness
- Dysrhythmias
- Palpitations
- Fatigue
- Weight gain
- Edema
- Cool, pale extremities with weak pulses

### Management

#### Medical Management

#### Diagnosis

#### Diagnostic Tests

Diagnostic tests used to diagnose valvular disease include:

- Echocardiogram to identify valve abnormalities and ejection fraction

**Table 30.4 Valvular Disease Characteristics**

Valve Disease	Auscultation Location	Manifestations
<b>Mitral regurgitation</b>	Systolic, 5th ICS left mid-clavicular line	Left-sided HF, palpitations
<b>Mitral stenosis</b>	Diastolic, ICS left mid-clavicular line	Left-sided HF
<b>Mitral prolapse</b>	Systolic, 5th ICS left mid-clavicular line	Chest pain, palpitations, syncope, anxiety, left-sided HF
<b>Aortic regurgitation</b>	Diastolic, 3rd ICS left sternal border	Left-sided HF, palpitations, widened pulse pressure
<b>Aortic stenosis</b>	Systolic, 2nd ICS, right sternal border	Left-sided HF, chest pain, syncope, narrowed pulse pressure
<b>Pulmonary regurgitation</b>	Diastolic, 3rd ICS left sternal border	Right-sided HF
<b>Pulmonary stenosis</b>	Systolic, 2nd ICS, left sternal border	Asymptomatic until severe, then right-sided HF
<b>Tricuspid regurgitation</b>	Systolic, 4th ICS left sternal border	Right-sided HF, atrial fibrillation
<b>Tricuspid stenosis</b>	Diastolic, 4th ICS left sternal border	Right-sided HF

HF, Heart failure; ICS, intercostal space.

- Chest x-ray to identify left or right heart hypertrophy and pulmonary edema
- Stress testing to identify functional capacity
- Heart catheterization as a definitive test for stenosis done prior to corrective surgery
- CT or MRI

### Medications

Medication management for valvular disease is dependent on the etiology and degree of the disease. Valvular diseases with infectious etiology require antimicrobial therapy, whereas advanced valvular diseases require general HF management. That includes:

- Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), or angiotensin receptor–neprilysin inhibitors (ARNIs) with beta blockers to reduce heart rate and blood pressure
- Diuretics to decrease preload and pulmonary congestion (see Safety Alert)

Medication management is also determined by the type of valve utilized in valve replacement, if necessary. Replacement valves are generally categorized as mechanical or tissue/bioprosthetic. Patients who undergo valve replacement with a mechanical prosthetic valve will need to be anticoagulated for life to prevent thrombotic events such as strokes. Tissue valves have recommended anticoagulation for only 6 months after placement but have less longevity. They are typically considered in patients who are older or cannot be anticoagulated.

**Safety Alert** Care must be taken when managing blood pressure for patients with aortic stenosis.

These patients require higher preload in order to generate adequate pressure for blood flow through the stenosed valve. Decreasing preload can lead to decreased cardiac output and hypotension.

### Surgical Management

Surgical intervention to repair or replace diseased valves is often indicated and is based on the degree of valve dysfunction, symptom severity, and surgical risk. For patients needing valve replacement, open-heart surgery with a mechanical or bioprosthetic valve remains the standard approach. In these surgeries, patients undergo general anesthesia and are placed on cardiopulmonary bypass, and the diseased valves are replaced through a sternal incision or multiple smaller chest incisions. For patients with comorbidities, this comes with an increased risk of operative mortality; thus, fewer of these patients undergo surgical intervention. A more recent treatment option for aortic valve replacement is prosthetic valves that allow a transcatheter approach to valve replacement. In this procedure, called a transcatheter aortic valve

replacement (TAVR), a new valve is deployed through a catheter that is peripherally inserted and guided to the heart. The TAVR procedure is recommended particularly for intermediate- and high-operative-risk patients with aortic stenosis. Transcatheter mitral valve replacement is an emerging technology that is being studied and may be considered for patients who have severe regurgitation and symptoms with high surgical risk.

Overall, there is growing evidence that when possible, valvular repair yields better outcomes than replacement. Reparative surgery includes balloon valvuloplasty, commissurotomy, and mitral valve annuloplasty. Balloon valvuloplasty is a transcatheter procedure to repair stenosed valves. It involves inserting a balloon catheter through an appropriate vessel and advancing it to the heart. The balloon is inflated in the affected valve to enlarge the opening. Commissurotomy is a surgical procedure done to incise fused leaflets, widening the valve opening. Valve annuloplasty is a reconstructive procedure to repair the ring (annulus) that attaches and supports the valve leaflets. For patients with severe mitral valve regurgitation, a new procedure that partially clips the bulging leaflets together to reduce regurgitation and improve symptoms is being evaluated.

### Complications

Valvular disorders can result in heart failure; cardiogenic shock; thromboembolism, including stroke; bleeding from anticoagulation; endocarditis; and dysrhythmias.

### Connection Check 30.4

The nurse hears a loud systolic murmur at the second intercostal space right sternal border. What valve problem is the patient likely experiencing?

- Aortic regurgitation
- Aortic stenosis
- Pulmonic regurgitation
- Pulmonic stenosis

### Nursing Management

#### Assessment and Analysis

Murmurs resulting from turbulent blood flow through diseased valves are heard with valve disease. Patients may be asymptomatic until valve function becomes significantly impaired, at which time clinical manifestations of HF related to decreased cardiac output and pulmonary congestion become prevalent.

They include:

- SOB
- Angina
- Syncope
- Dysrhythmia
- Palpitation
- Dizziness

- Fatigue
- Weight gain
- Poor color, cool extremities, weak peripheral pulses

### Nursing Diagnoses

- **Decrease cardiac output** related to decreased stroke volume secondary to valve disease
- **Activity intolerance** related to decreased cardiac output secondary to HF due to valve disease

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Hypertension, tachycardia, and tachypnea are indicative of HF due to increased resistance to flow and backflow of blood to the pulmonary system. Tachycardia occurs as a compensatory mechanism to increase cardiac output and oxygenation. Fever is indicative of infection and increases metabolic demands. Decreased SpO<sub>2</sub> occurs with pulmonary congestion.*
- Pain assessment  
*Chest pain and palpitations may occur with some murmurs.*
- Monitoring for irregular heart rhythm  
*Dysrhythmias, specifically atrial fibrillation, are common in valve disease.*
- Peripheral vascular assessment  
*Poor color, cool extremities, weak peripheral pulses, delayed capillary refill, and edema can indicate inadequate cardiac output.*
- Breath sounds  
*Crackles and orthopnea indicate pulmonary congestion.*
- Activity tolerance  
*Dyspnea on exertion, weakness, and fatigue indicate worsening HF.*
- Auscultate heart sounds.  
*Murmurs are typically the initial manifestation of valvular disease.*
- Daily weights, intake and output  
*Weight increases and intake greater than output can be indicative of HF.*
- Monitor international normalized ratio (INR).  
*Patients with valve replacements on warfarin need to maintain an INR that is two to three times normal.*

#### ■ Actions

- Provide supplemental oxygen and elevate the head of the bed.  
*Oxygen and positioning increase oxygenation and ventilation.*
- Administer medications as ordered: diuretics, ACE inhibitors, ARBs, ARNIs, beta blockers, antibiotics, anticoagulants.  
*Medications are indicated for the relief of symptoms, not as a curative measure. Diuretics help decrease fluid overload; ACE inhibitors, ARBs, ARNIs, and beta blockers decrease heart rate and blood pressure, thus decreasing myocardial workload. Antibiotics are indicated if the valvular disease is caused by an infection such as IE. Anticoagulation decreases the risk of thrombus formation in patients with a prosthetic valve or patients in atrial fibrillation.*

- Restrict sodium and fluids.  
*To decrease fluid overload and reduce HF symptoms*

#### ■ Teaching

- Medication teaching  
*Understanding and adhering to the medication treatment plan are essential for effective medication treatment.*
- Consider prophylactic antimicrobials for dental procedures only for patients at high risk.  
*Prevent (re)occurrence of infectious valvular disease*
- Strict adherence to anticoagulation regimen if prosthetic valve  
*Prevent thrombotic/embolic events (i.e., stroke)*
- Anticoagulation precautions: avoid activities/sports that have a high risk for injury, report any injuries or falls to your provider, report anticoagulant use prior to any procedure, take care with shaving (electric razor preferred), take care with flossing to avoid bleeding, and limit alcohol consumption.  
*Avoid activities/actions that increase bleeding risk.*
- Maintain consistent intake of green leafy vegetables if taking warfarin.  
*Green leafy vegetables impair the effectiveness of the anticoagulant warfarin.*

### Evaluating Care Outcomes

Successful management of patients with valvular disease requires maximizing cardiac output through repair or replacement of the damaged valve and controlling the symptoms of HF. Patients with valvular disease can achieve a high functional status by complying with the prescribed medical therapy, maintaining a healthy diet, and engaging in regular exercise. Vital signs within normal limits, increased energy, and an ability to actively participate in work and activities of daily living are indicative of disease control. The patient and family should be knowledgeable about the signs of decreased cardiac output and when they should report to their healthcare provider.

#### **Safety Alert** Orthostatic Hypotension

Moving from a supine to an upright position is normally associated with a slight decrease in blood pressure. This is due to the pooling of blood in the lower extremities when the upright position is assumed, reducing the amount of blood returning to the heart and perfusion to the brain. In most people, the autonomic nervous system sends signals to the blood vessels in the lower extremities to constrict. Signals are also sent to the heart to increase rate. Both mechanisms increase cardiac output. In cardiac patients on many antihypertensive medications, the autonomic response can be impaired. Thus, moving to an upright position results in a feeling of dizziness and syncope, which puts the patient at risk for falls.

To measure orthostatic hypotension, have the patient assume a supine position for at least 2 minutes and record the blood pressure and heart rate. Then have the patient assume an upright position and record the blood pressure and heart rate. Generally, a reduction of 20 mm Hg or more in the systolic reading and/or 15 mm Hg in the diastolic value denotes the presence of orthostatic hypotension, also known as *postural hypotension*. In the patient who is highly symptomatic or with a history of syncope, this procedure can be performed in three stages: supine, sitting, and standing. The patient with orthostatic hypotension should be cautioned to transition from the supine or sitting to the standing position slowly by sitting briefly before standing. Some antihypertensive medications should be given with caution, starting with a lower dose and evaluating the patient's response, especially in older adults, to reduce the incidence of orthostatic hypotension.

### CASE STUDY: EPISODE 2

Mr. Thompson is admitted to the step-down unit for further management. On physical examination, he is lying in bed with the head of the bed in a semi-Fowler's position. He is afebrile, with a temperature of 97.7°F (36.6°C). His blood pressure is 185/102 mm Hg. His heart rate is 124 beats per minute and appears to be irregular on the monitor. His respirations are 40 per minute and labored. Auscultation of his lung fields reveals crackles throughout. At a 30° angle, his jugular vein is distended and measures at 5 cm above the sternal border. He is on oxygen at 4 L/min via nasal cannula with an oxygen saturation of 95%. He has significant pitting edema of the lower extremities. Capillary refill is decreased to the fingers, and his extremities are cool to the touch...

- Obesity
- Smoking
- High sodium dietary intake

Other conditions that can cause heart failure include valvular dysfunction; cardiomyopathies; infectious and inflammatory heart disorders, such as pericarditis and endocarditis; dysrhythmias; and cardiotoxic substance exposure, such as alcohol, chemotherapy, and illicit drugs. With advances in management, mortality rates are declining but remain high at about 40% after 5 years from the time of diagnosis. Heart failure is a leading cause of hospitalizations among persons older than 65. The large number of persons with HF and hospitalizations related to HF contribute to an estimated annual cost of \$39.2 billion.

### Pathophysiology

**Heart failure** is a progressive disease characterized by myocardial cell dysfunction, resulting in the inability of the heart to pump enough cardiac output to meet the demands of the body. The normal physiology of the heart is governed by the Frank–Starling law, which states that the contractility of the myocardial muscle is influenced by the amount of blood within the ventricle prior to systole. In other words, high end diastolic volume stretches the myocardium, increasing the force of each contraction. However, in people with risk factors for HF, such as hypertension, the constant demands on the myocardial muscles over time cause them to become weakened and unable to pump effectively.

**Compensatory mechanisms** are activated in response to decreased stroke volume and cardiac output. These responses are actions that enable the body to maintain function. The sympathetic nervous system releases epinephrine and norepinephrine, resulting in an increased heart rate, increased myocardial contractility, and increased vasoconstriction in an effort to increase cardiac output. This additional workload stimulates ventricular remodeling, which results in hypertrophy or stiffening of the ventricular walls. Although sympathetic nervous system responses and ventricular remodeling may be successful in the short term, the long-term effects are damaging. They produce an increase in cardiac workload and cardiac oxygen consumption, worsening the failure.

The neurohormonal compensatory response leads to the activation of the renin-angiotensin-aldosterone system (RAAS). This is done in reaction to decreased blood flow to the kidneys. The kidneys interpret this as decreased volume and release an enzyme, renin. Renin converts angiotensinogen, an inactive peptide released by the liver, to angiotensin I. Angiotensin I is enzymatically converted to angiotensin II by angiotensin-converting enzyme released by the lungs. Angiotensin II produces peripheral vasoconstriction, which helps increase blood pressure and venous return to the heart. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, which results in sodium and water retention. As with the sympathetic nervous system, these

## HEART FAILURE

### Epidemiology

The prevalence of heart failure (HF) is estimated at 6.5 million people aged 20 years or older in the United States, with about a million new cases each year. The lifetime risk of developing HF at age 40 is at least one in five for both men and women. The number of persons with heart failure is expected to continue rising. Heart failure is more common in people who are 65 years old or older, African Americans, people who are overweight, and people who have had a heart attack. Men have a higher rate of heart failure than women. The risk factors associated with the development of HF include:

- CAD
- Hypertension
- Diabetes mellitus
- Metabolic syndrome

changes are effective in the short term, but in the long term, they overtax an already weak heart with increased volume and workload.

Another neurohormonal compensatory response is the release of natriuretic peptides. Brain natriuretic peptide, or B-type natriuretic peptide (BNP), is a hormone produced by the ventricular cardiac muscle. It is released in reaction to “overstretching” of the ventricle in response to increased pressure and volume. The result is a natural diuresis as well as arterial and venous dilation. This action decreases both preload and afterload, which decreases the workload on the heart.

Heart failure is classified based on **ejection fraction (EF)**, which is the percentage of blood that is ejected from the ventricle with each contraction. Normal values range from 55% to 70% of the total volume. Patients with low EF are diagnosed with heart failure with reduced ejection fraction (HFrEF), formerly called systolic heart failure. Patients with HFrEF have a weakened contraction, with an EF of 45% or less. Those patients with clinical manifestations of heart failure but an EF of greater than 45% are diagnosed with heart failure with preserved ejection fraction (HFpEF), formerly called diastolic heart failure. HFpEF is characterized by the inability of the ventricles to fill. These patients tend to be older and female. Traditionally, heart failure treatment focused on HFrEF, but there is a growing body of evidence to support HFpEF treatment. It is estimated that about half of HF patients have HFpEF, and half have HFrEF.

Heart failure is also described according to anatomical dysfunction, disease progression, and severity of symptoms. Heart failure can affect one or both sides of the heart. When both sides of the heart are affected, this is known as *biventricular failure*. Left-sided HF refers to the dysfunction of the left ventricle. Right-sided HF refers to the inability of the right side of the heart to effectively pump blood to the pulmonary vasculature.

## Clinical Manifestations

Clinical manifestations of heart failure vary depending on the type, onset, and severity of the failure. The timing of onset and severity of symptoms can be used to determine if heart failure is acute or chronic. Acute heart failure has a sudden onset of symptoms and requires immediate intervention. Chronic heart failure describes the baseline set of symptoms and limitations that are relatively stable with treatment and self-management.

Some common signs include fatigue, weight gain, faster heart rates, and hypo- or hypertension. Heart murmurs may be present if the cause of HF is valve dysfunction. When auscultating heart tones, a third heart sound,  $S_3$ , may be a warning sign of worsening heart failure. An  $S_4$  is common in chronic heart failure. The point of maximal intensity may be enlarged or displaced when ventricles enlarge. The clinical presentation of HF can depend on the side of the heart most affected (Table 30.5).

**Table 30.5 Clinical Manifestations of Right- and Left-Sided Heart Failure**

### Right-Sided Heart Failure

- Jugular vein distention
- Dependent edema
- Hepatomegaly
- Ascites

### Left-Sided Heart Failure

- Shortness of breath or dyspnea or orthopnea
- Crackles on auscultation
- Pale color, weak pulses, cool temperature in extremities, delayed capillary refill
- Fatigue, weakness

In left-sided HF, the weakened contraction results in poor peripheral perfusion and backflow of blood that causes fluid accumulation in the lungs. This produces classic symptoms such as SOB (dyspnea), orthopnea, fatigue, and crackles heard on auscultation. Other symptoms of left-sided failure include fatigue, poor color, weak pulses, and cool temperature in the extremities. The weakened contraction of the right ventricle, right-sided HF, results in a backflow of blood into the right atrium and venous circulation and is characterized by JVD, generalized dependent edema, hepatomegaly, and ascites. Left-sided HF can eventually cause right-sided HF, or the entire heart may be initially affected. If that happens, the symptom classification becomes less clear. In severe HF exacerbations, the patient may present with hypotension, cool extremities, decreased or no urine output, and poor or decreasing mentation. In such cases, both  $S_3$  and  $S_4$  may be heard.

There are several classifications of HF. The AHA and American College of Cardiology (ACC) classify the stages of HF development from A through D. The New York Heart Association (NYHA) classifies functional status as I through IV according to the clinical manifestations of HF (Table 30.6). It is important to note that a patient can fluctuate between NYHA classes I and IV with interventions such as diuresis; however, patients do not regress back to a previous stage in the AHA/ACC classification.

## Management

### Medical Management

#### Diagnosis

The diagnosis of HF is heavily dependent on history and physical assessment. The symptoms are fairly nonspecific, so diagnostic tests are done to rule out other disorders and determine the underlying cause. Diagnostic tools include chest x-ray, echocardiogram, and ECG to assess the presence of structural disease, ejection fraction, heart size, pulmonary congestion, or dysrhythmias. Multigated acquisition (MUGA) scans can also determine EF. Nuclear imaging studies, stress testing, and coronary angiography

**Table 30.6 Comparison of Stages of Heart Failure Development and New York Heart Association Functional Classes****American Heart Association/American College of Cardiology Stages of Heart Failure Development**

- A: Patient with risk factors but no LV impairment
- B: Asymptomatic with LV hypertrophy and/or impaired LV function
- C: Current or past symptoms of HF
- D: Refractory HF eligible for heart transplant, inotropic and/or mechanical support

**New York Heart Association Classification of Functional Status**

- I: No symptoms with physical activity, such as dyspnea or chest pain
- II: Mild symptoms with ordinary activities
- III: Marked limitation with physical activity but comfortable at rest
- IV: Severe limitation and distress with physical activity or at rest

HF, Heart failure; LV, left ventricle.

to evaluate blood flow to the heart are performed when coronary artery disease is suspected. In severe acute heart failure, hemodynamic monitoring with a pulmonary artery catheter can be useful.

### Diagnostic Tests

Laboratory testing includes cardiac biomarkers, serum electrolytes, a complete blood count, urinalysis, glucose level, fasting lipid profile, liver function testing, and renal function tests. Electrolytes can be outside the normal range as a result of decreased kidney perfusion or medication. For example, potassium might be low because of diuretic therapy. Also, inadequate flow to the kidneys may impair renal function, resulting in elevated creatinine and blood urea nitrogen (BUN) levels. Decreased hemoglobin and hematocrit levels may indicate anemia, which may be a result of decreased blood flow to the kidneys that reduces the production and function of erythropoietin in the kidneys. Cardiac biomarkers such as troponin I or T are used to rule out an acute ischemic event. Other biomarkers, BNP and N-terminal pro-B-type natriuretic peptide (NT-proBNP), are increased because of the overstretching of the ventricles. Increased values in these tests can be used to diagnose HF; BNP and NT-proBNP can also guide clinical decision making and track a patient's response to therapy as well as indicate disease progression.

### Medications

The medical management described here is predominantly for patients with HFrEF. These strategies have not been efficacious for patients with HFpEF. Management of patients with HFpEF focuses on the treatment of the underlying cause, blood pressure control, diuretics for fluid volume overload, and symptom management.

The goals of HFrEF management are the reduction of risk factors, manipulation of the critical components of cardiac output (preload, afterload, and contractility), and control of the compensatory mechanisms. Successful management slows disease progression, prevents complications, reduces

morbidity and mortality, and improves quality of life. Risk-factor management may include blood pressure and glucose control, weight loss, optimizing serum lipids, and smoking cessation. Beta blockers are used to control the sympathetic nervous system compensatory response in HF, such as tachycardia, in order to decrease cardiac workload. Ivabradine, a new medication that slows sinus-node firing, can be added for greater control of heart rate in patients taking maximal doses of beta blockers or who do not tolerate beta blockers.

*Preload* is the amount of stretch in the heart at the end of diastole and is affected by the amount and pressure of blood returning to the heart. Aldosterone antagonist diuretics such as spironolactone (Aldactone) as well as loop diuretics such as furosemide (Lasix) are essential medications to decrease preload in patients with fluid retention. The use of spironolactone should be cautioned in patients with renal insufficiency because of the potential complication of hyperkalemia. In contrast, furosemide can cause hypokalemia and is often paired with a potassium replacement medication.

*Afterload* refers to the resistance within the vasculature. Increased afterload intensifies the workload on the heart, further impairing cardiac output. Afterload reduction is a main goal of medical management. Angiotensin-converting enzyme (ACE) inhibitors are usually the first line of medications used to control the RAAS compensatory response and reduce afterload. Angiotensin receptor blockers (ARBs) have a similar effect and can be used in patients who are intolerant of ACE inhibitors. Angiotensin receptor–neprilysin inhibitors (ARNIs) are a new class of medications that combine an ARB with a neprilysin inhibitor (valsartan with sacubitril) and can be used in place of an ACE inhibitor or ARB. Neprilysin is an enzyme that breaks down natriuretic peptides (BNP), which produces natural diuresis and vasodilation. By blocking neprilysin, natriuretic peptides remain active in increasing urine output and dilating blood vessels. Other medications that may be prescribed to reduce afterload include vasodilators such as hydralazine and isosorbide dinitrate. Calcium channel blockers, with the exception of

amlodipine, should be avoided in HF due to their myocardial depressant effect and lack of demonstrated efficacy.

### Safety Medication Safety Alert: ARNIs Alert

Like ACE inhibitors, the neprilysin inhibitor in an ARNI prevents the breakdown of bradykinin as well as natriuretic peptides. Bradykinin is a cause of angioedema. The combination of an ACE inhibitor and ARNI significantly increases the risk of angioedema. An ARNI should not be given at the same time or within 36 hours of an ACE inhibitor. An ARNI should not be given to patients who had angioedema in the past.

*Contractility* is the force of the myocardial muscle contraction. A past mainstay of HF management has been digoxin (Lanoxin), an oral positive inotropic medication used to increase cardiac contractility and reduce heart rate. Its use is being questioned. Although patients realize a reduction in symptoms, overall mortality is not decreased. Patients on digoxin (Lanoxin) are prone to toxicities, with symptoms such as nausea and vomiting and visual disturbances (e.g., yellow halos around lights). Care must be taken to monitor patients closely to avoid the later signs of toxicity, such as bradycardia and dysrhythmias. See Table 30.7 for a summary of medications used in the treatment of HF.

Medical management of heart failure often requires multiple medications from different classes to achieve optimal results. For instance, patients can be prescribed spironolactone, furosemide, and carvedilol to manage their HF along with their other routine medications. In combination, these medications have been shown to improve survival in patients with HF by slowing or stopping the progression of ventricular remodeling and dysfunction.

An acute exacerbation of HF is typically treated with IV medications that can more quickly and effectively decrease preload and afterload and increase contractility. Nitroglycerin and nitroprusside (Nitropress), potent vasodilators, are commonly used. Intravenous inotropic agents (e.g., dopamine) can be used to increase contractility, whereas inodilators, agents with both positive inotropic and vasodilator effects (e.g., dobutamine and milrinone), provide positive inotropic effects and reduce afterload. All these medications require careful monitoring of blood pressure, heart rate, and cardiac rhythm and frequent assessments to guide therapy and avoid adverse effects.

### Device and Surgical Intervention

As HF progresses, more invasive treatments are needed to support cardiac function and control the complications that result. Implantation of an automatic internal cardiac defibrillator (ICD) and a pacemaker may be considered for dysrhythmia control and ventricular resynchronization also

**Table 30.7 Medications Used in the Management of Heart Failure**

Medication	Indication
<i>Angiotensin-converting enzyme inhibitors (captopril, enalapril)</i>	Afterload reduction
<i>Angiotensin receptor blockers (valsartan)</i>	Afterload reduction
<i>Angiotensin receptor–neprilysin inhibitor (valsartan/sacubitril)</i>	Afterload and preload reduction
<i>Arterial vasodilators (hydralazine, isosorbide dinitrate, nitroprusside)</i>	Afterload reduction
<i>Venous vasodilator (isosorbide dinitrate)</i>	Preload reduction
<i>Diuretics:</i>	Preload reduction
<i>Loop diuretics (furosemide)</i>	
<i>Aldosterone receptor antagonists (spironolactone)</i>	
<i>Beta blockers (carvedilol)</i>	Decrease heart rate and myocardial workload
<i>Inodilators (milrinone, dobutamine)</i>	Increase contractility and reduce afterload
<i>Inotropes (dopamine)</i>	Increase contractility
<i>I(f) current inhibitor (ivabradine)</i>	Myocardial workload reduction by decreasing heart rate
<i>Cardiac glycosides (digoxin/Lanoxin)</i>	Enhance contractility (positive inotrope)

referred to as cardiac resynchronization therapy (CRT). Continuous IV inotrope therapy, an intra-aortic balloon pump, and other mechanical circulatory support (MCS) devices such as a ventricular assist device (VAD) can be used to support the failing heart. Depending on the cause of HF, valve replacement or heart transplantation may be considered. In addition to treatment, symptom management to improve healthcare-related quality of life (HRQOL) should always be considered. Palliative care is often indicated for patients with end-stage HF (NYHA class IV or AHA/ACC stage D).

### Self-Management

Self-management is a critical component of HF treatment. Patients must assume responsibilities for symptom monitoring, medication adherence, and lifestyle changes. Daily weights taken at about the same time each day monitor fluid retention. Weight gain indicates fluid retention. A gain of 1 kg is the equivalent of 1,000 mL of fluid retention. A gain of more than 1 kg (2 lb) in a day or 2 kg (5 lb) in a week may be significant. Lifestyle changes typically include a

sodium-restricted diet, maintaining optimal weight, and preventing cardiac cachexia. Sodium restriction to 1,500 mg/day is recommended in the early stages of HF, with a less restrictive recommendation of up to 4,000 mg/day in later stages. A high BMI is associated with a higher mortality and, although a lower BMI is generally positive, weight loss in a patient with HF may reflect cardiac cachexia which may also contribute to higher mortality.

Management interventions by the interprofessional health-care team may have a beneficial effect on self management and thus on HF-related hospitalization and quality of life. Critical interventions by the healthcare team include teaching related to medications, sodium restriction, and weight management; symptom monitoring; screening for depression and mental health comorbidities; evaluating social support structures; planning and encouraging participation in cardiac rehabilitation; and implementing behavior-change strategies, such as motivational interviewing (see Evidence-Based Practice). Intensive intervention programs can combine in-patient interventions with home care and follow-up contacts. Self-management is affected by the patient perceptions of interactions with healthcare team members. Improved self-management occurs when patients perceive that their healthcare team members are responsive, interested in their individual needs, and share information. Poor communication and lack of continuity can be barriers to self-management.

## Evidence-Based Practice

### Cardiac Rehabilitation for Heart Failure

Persons with heart failure experience reduced capacity for physical activity, which can have detrimental effects on their quality of life and contribute to hospitalizations and mortality. The American Heart Association and American College of Cardiology recommend cardiac rehabilitation in the management of heart failure. A 2015 systematic review and meta-analysis that included 33 studies and 4,740 patients found that patients who participated in exercise-based cardiac rehabilitation programs had significantly fewer hospitalizations and improved quality of life. Long-term mortality may also be improved. Despite evidence from this study and many others, as well as reimbursement by the Centers for Medicare and Medicaid Services, referral to and attendance in such programs remain low. More patients with heart failure need to be referred to and encouraged to participate in cardiac rehabilitation.

Sagar, V., Davies, E., Briscoe, S., Coats, A., Dalal, H., Lough, F., . . . Taylor, R. (2015). Exercise-based rehabilitation for heart failure: Systematic review and meta-analysis. *Open Heart*, 2(1), e000163. doi:10.11356/openhrt-2014-000163

## Geriatric/Gerontological Considerations

### Heart Failure and Older Adults

Heart failure (HF) is more common with aging. Older patients are more likely to have heart failure with preserved ejection fraction (HFpEF), for which few evidence-based treatment guidelines exist. They often have five or six additional comorbidities, which create complexities in care and a greater potential for medication interactions. Depression, anxiety, and cognitive impairment, which often go undiagnosed, can reduce self-management abilities and medication adherence, warranting careful screening for these conditions. Few studies of HF focus exclusively on the older adult. Some studies show HF medications are underused in older adults, whereas others show that more intensive medication therapy is not associated with additional benefits. Many HF medications have hypotensive effects or cause nocturia, which may increase fall risk. A careful risk-benefit analysis of interventions is required, particularly when medication changes occur. Due to declining renal function, potential poor nutritional status, and greater risk for dehydration, older patients need to be monitored more carefully for adverse effects. Telephone and telemonitoring may be useful strategies after discharge.

### Complications

**Pulmonary edema** is an acute complication of HF characterized by the accumulation of fluid in the interstitial and alveolar spaces of the lung, resulting from elevated filling pressures within the heart. The symptoms of pulmonary edema include SOB, low oxygen saturation, pink and frothy sputum, orthopnea, tachycardia, chest pain, and anxiety/fear. Treatments include supplementary oxygen administration and initiation of higher-dose or IV diuretics. Depending on the severity of the edema, the patient may need more aggressive respiratory support with continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or intubation with mechanical ventilation. Dysrhythmias can also occur as the heart enlarges and catecholamine levels increase.

Renal failure is another common complication seen in HF patients. This is due to the decrease in blood flow to the kidneys. Renal failure is discussed in more detail in Chapter 62.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of HF are due to the weakened myocardial contraction resulting in decreased cardiac output,

a backup of blood, and poor peripheral perfusion. Common findings include:

- Poor mentation
- Anorexia
- Exercise intolerance
- SOB, orthopnea
- JVD
- Dependent peripheral edema
- Weak peripheral pulses, cool extremities, delayed capillary refill
- Cardiac cachexia or generalized body wasting

### Nursing Diagnoses

- **Impaired oxygenation** related to accumulation of fluid in the lungs secondary to HF
- **Decreased cardiac output** related to altered preload, afterload, and contractility
- **Ineffective peripheral perfusion** related to decreased cardiac output secondary to HF

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Hypertension is present because of the increased afterload. Hypotension may be caused by acute heart failure or be an adverse effect of medications. Tachycardia can be present as the heart attempts to compensate for decreased cardiac output. Tachypnea and decreased oxygen saturation may be present when fluid accumulates in the lungs because of left-sided HF.*
- Breath sounds  
*Crackles indicate pulmonary congestion.*
- Monitoring for irregular heart rhythm or dysrhythmias  
*Dysrhythmias are a common adverse effect of HF and medications used to treat HF.*
- Skin color, temperature, peripheral pulses, and capillary refill time  
*Pale or cyanotic color; cool extremities, weak peripheral pulses, and sluggish refill time result from inadequate cardiac output.*
- Dry, persistent cough  
*Common complication of ACE inhibitors*
- Activity tolerance  
*Dyspnea on exertion, weakness, and fatigue indicate decreased cardiac output and worsening heart failure.*
- Urine output  
*Output may be reduced with decreased renal perfusion. It can also be used to assess the effectiveness of diuretic therapy. Less than 30 mL/br should be reported to the provider.*
- Daily weight  
*To evaluate fluid retention and effectiveness of diuresis*
- Laboratory data  
*Elevated BNP and NT-proBNP indicate overstretching of heart tissue. Elevated creatinine and BUN may be indicative of prerenal failure due to decreased cardiac output or overdiuresis. Elevated hepatic enzymes can be indicative of hepatomegaly; hypokalemia is a common complication of*

*diuretic administration. Anemia can be caused by reduced kidney perfusion resulting in decreased erythropoietin production and function*

- Depression screening  
*High rates of depression and anxiety are noted in the HF population. These can impact self-management.*
- Social support  
*Social isolation has been shown to be an independent predictor of mortality among HF patients.*

#### ■ Actions

- Oxygen therapy  
*To maintain adequate oxygenation*
- Elevate the head of the bed and provide a fan for dyspnea.  
*Maximize oxygenation and promote comfort*
- Medication administration as ordered:
  - Administer diuretics.  
*Diuretics decrease volume, thus preload.*
  - Administer ACE inhibitors, ARBs, ARNIs, and vasodilators.  
*Angiotensin-converting enzyme inhibitors, ARBs, ARNIs, and vasodilators decrease afterload, which helps to decrease the workload on the heart and decrease myocardial oxygen consumption.*
  - Administer beta blockers.  
*Beta blockers decrease the sympathetic response (heart rate), thus reducing myocardial oxygen consumption.*
  - Administer inotropic agents.  
*Enhance contractility*
- Fluid and sodium restriction  
*To prevent fluid overload*

#### ■ Teaching

- Medication management  
*Understanding and adhering to the medication treatment plan are essential for effective medication treatment.*
- Maintain activity as tolerated. Alternate rest and activity periods.  
*To reduce muscle wasting and functional losses; to decrease workload on the heart*
- Low-salt diet  
*To prevent fluid retention and exacerbation of HF*
- Daily weight at home at the same time each day, preferably in the morning after voiding  
*Evaluate fluid retention and need to call provider*
- Cardiac rehabilitation  
*Cardiac rehabilitation reduces mortality, improves functional status, reduces hospitalization, and improves quality of life.*
- Signs and symptoms of worsening HF checklist (edema, SOB, fatigue, and orthopnea)  
*Knowing the symptoms can expedite treatment and reduce hospitalizations.*

### Connection Check 30.5

What assessment would the nurse identify as a hallmark finding of left-sided heart failure?

- A. Ascites
- B. Bradycardia
- C. Crackles
- D. Edema

### Evaluating Care Outcomes

Heart failure patients are at risk for frequent exacerbations due to even small changes in fluid status, salt intake, or being exposed to common ailments such as a cold. Reducing stressors that can lead to exacerbations is key. Successful management requires collaboration with the patient and family and the interprofessional team (physician, pharmacist, respiratory care therapist, dietitian, diagnostic technicians, social workers, and palliative care) to develop and implement a treatment plan. That plan should include frequent assessment, comprehensive patient education, and self-management. A well-managed patient has reduced dyspnea and fatigue, is able to actively participate in activities of daily living, and has reduced hospitalizations.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Thompson's ECG reveals atrial fibrillation with a heart rate of 130 to 140 bpm. His blood pressure continues to be high at 185/102 mm Hg. His respirations are still slightly labored and fast at 40 per minute. He continues on oxygen at 4 L/min via nasal cannula, with an oxygen saturation of 95%. The results of Mr. Thompson's diagnostic tests reveal:

- A chest x-ray indicates LV hypertrophy.
- A transthoracic echocardiogram indicates an EF of 30%.
- Cardiac biomarkers are negative for ischemia, with troponin I less than 0.1 ng/ml.
- Renal function tests reveal borderline failure, with a creatinine of 1.5 mg/dL and a BUN of 30 mg/dL.
- His BNP value is elevated to 500 pg/mL.
- Serum electrolytes reveal elevated potassium at 6.0 mEq/L.

It is determined that Mr. Thompson is in HF, and he begins treatment. A diuretic is administered; an ACE inhibitor and a beta blocker are ordered. His SOB and color begin to improve. His transient chest pain resolves with treatment.

### Case Study Questions

1. The nurse has received the following orders for Mr. Thompson. Which order should the nurse implement first?
  - A. Furosemide (Lasix) 40 mg IV
  - B. Insert a Foley catheter
  - C. Low-sodium, low-fat diet
  - D. Apply sequential compression device
2. The nurse correlates which finding with Mr. Thompson's atrial fibrillation with a heart rate of 120 to 140 beats per minute?
  - A. Acute decompensation requiring immediate cardioversion
  - B. Loss of atrial kick requiring fluid resuscitation
  - C. Increased workload of the heart requiring beta blockers
  - D. Cardiac ischemia requiring immediate cardiac catheterization
3. The nurse understands that Mr. Thompson's sublingual nitroglycerin decreases chest pain through which mechanism of action?
  - A. Dilating the coronary arteries to improve blood flow
  - B. Decreasing preload to relieve symptoms of dyspnea
  - C. Decreasing heart rate to decrease cardiac workload
  - D. Converting atrial fibrillation into sinus rhythm
4. Which statement by Mr. Thompson indicates that teaching about hyperkalemia has been effective?
  - A. "The water pill makes my potassium level high."
  - B. "I should eat bananas because they make my potassium go down."
  - C. "My liver is not working, so it holds on to the potassium."
  - D. "My kidneys are not working which makes my potassium high."
5. The nurse providing care for Mr. Thompson should include which of the following in the discharge teaching plan? (*Select all that apply.*)
  - A. Sodium restriction
  - B. Daily weight
  - C. Medication teaching
  - D. Vigorous daily exercise
  - E. Carbohydrate counting

## CHAPTER SUMMARY

Atherosclerosis marks the beginning of coronary artery disease (CAD). The progression of plaque buildup is usually silent until occlusion of the vessel is significant enough to cause angina. Long-term effects include stable and unstable

angina, myocardial infarction (MI), and sudden cardiac death due to extreme obstruction of blood flow in the coronary arteries. Many of the diagnostic blood tests performed, such as lipid profiles, assess for the presence of risk factors for CAD development. Specific cardiac enzymes are used to rule out MI. The gold standard for diagnosing CAD is a coronary angiogram. Medication for patients with CAD is often prescribed with the goals of (a) stopping the aggregation of blood components to the injured endothelium, (b) controlling factors that lead to damage of the endothelium, and (c) relieving symptoms. Percutaneous transluminal coronary angioplasty is the procedure most commonly performed to relieve symptoms. Nursing care priorities include vital signs and physical assessment and administering medication as ordered to manage risk factors and relieve symptoms. The teaching plan includes understanding the signs of an exacerbation and managing lifestyle to limit and control risk factors.

Infective endocarditis (IE) is the result of an infection of the innermost layer of the heart, the endocardium. The heart valves are the usual location for this lesion. The transthoracic echocardiogram (TTE) is the best at detecting the presence of vegetation. The primary treatment is IV antibiotics. Infective endocarditis unresponsive to antibiotic therapy can be treated with valve repair or replacement. Nursing assessment includes monitoring vital signs, especially for the presence of fever, which can be indicative of ongoing acute infection. Teaching includes the maintenance of good oral hygiene and informing the healthcare provider about IE history prior to any dental or invasive procedure.

Myocarditis is an inflammatory disease of the myocardium most commonly caused by viral infection or autoimmune diseases. Clinical manifestations include chest pain, dysrhythmias, dyspnea, palpitations, syncope, and heart failure. Medical treatment focuses on the management of heart failure, dysrhythmias, and dilated cardiomyopathy that may occur due to the inflammation. Treatment also includes medications to treat the cause.

Pericarditis is an inflammation of the membrane surrounding the heart, the pericardium. The chief clinical manifestation is pain. Tests used to diagnose pericarditis

include an electrocardiogram (ECG), chest x-ray, TTE, cardiac computed tomography (CT) scan, and magnetic resonance imaging (MRI). The primary treatment is pain control with anti-inflammatories. Nursing priorities include pain assessment to evaluate the effectiveness of treatment and close monitoring for the complications of pericardial effusion and cardiac tamponade. Teaching priorities include distinguishing between pericarditis and heart attack to ensure the patient will seek emergency help appropriately when necessary.

Valvular disease refers to either narrowing or incomplete closure of the heart valves. In response to backward flow through the valve due to incomplete closure or resistance to forward flow through the stenosed valve, signs of right-sided or left-sided heart failure (HF) develop. Tests used to diagnose valvular disease include ECG, echocardiogram, and chest x-ray. The goals of medical therapy are to manage the manifestations of HF and prevent thrombus formation. Surgical intervention can include repair or replacement of valves. Nursing care priorities include assessment for signs of HF, which helps evaluate the effectiveness of treatment, and administration of medications as ordered to control the symptoms of HF. Medication management and anticoagulation precaution teaching are essential.

Heart failure is present when the heart loses its ability to pump blood effectively and is unable to produce enough cardiac output to meet the body's metabolic demands. Clinical manifestations of left-sided HF include shortness of breath (SOB), crackles, and poor peripheral perfusion. Symptoms of right-sided HF include jugular vein distention (JVD), hepatomegaly, ascites, and dependent edema. Treatment focuses on decreasing the workload of the heart by decreasing preload and afterload. Diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), angiotensin receptor–neprilysin inhibitors (ARNIs), and beta blockers are commonly prescribed. Nursing care priorities include assessment for signs of HF, which helps evaluate the effectiveness of treatment, and administration of medications as ordered to control the symptoms of HF. Medication and diet management and the manifestations of worsening HF are essential components of the teaching plan.

# Chapter 31

## Coordinating Care for Patients With Vascular Disorders

*Eleni Flanagan and Sarah Smith*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of vascular disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Atherosclerosis/Arteriosclerosis
  - b. Hypertension
  - c. Peripheral arterial disease
  - d. Carotid artery disease
  - e. Aortic artery disease (aneurysms)
  - f. Deep vein thrombosis
3. Describing the diagnostic results used to confirm the diagnoses of vascular disorders
4. Discussing the medical management of:
  - a. Atherosclerosis/Arteriosclerosis
  - b. Hypertension
  - c. Peripheral arterial disease
  - d. Carotid artery disease
  - e. Aortic artery disease (aneurysms)
  - f. Deep vein thrombosis
5. Developing a comprehensive plan of nursing care for patients with vascular disorders
6. Designing a teaching plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with vascular disorders

### CONCEPTS

- Assessment
- Inflammation
- Medication
- Nursing Roles
- Nutrition
- Perfusion
- Promoting Health

### ESSENTIAL TERMS

Abdominal aortic aneurysm (AAA)  
Aneurysm  
Ankle-brachial index (ABI)  
Aortic dissection  
Arteriosclerosis  
Atherosclerosis  
Carotid artery disease  
Carotid artery stenting  
Carotid endarterectomy (CEA)  
Claudication  
Deep vein thrombosis (DVT)  
Essential (primary) hypertension  
Hypertension  
Hypertensive crisis  
Hypertensive urgency  
Peripheral arterial disease (PAD)  
Plethysmography  
Pulmonary embolism  
Secondary hypertension  
Stroke  
Thoracic aortic aneurysm (TAA)  
Venous thromboembolism (VTE)  
Virchow's triad

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. Brian More is a 62-year-old African American male who is brought into the emergency department by his daughter for occasional headaches, dizziness, and nocturia over the last 2 months. His past medical history includes hypercholesterolemia, diabetes mellitus type 2, obesity, and deep vein thrombosis (DVT). When a medical and family history is obtained, it is noted that Mr. More has smoked at least one pack of cigarettes per day for the last 40 years and that both of his parents died of stroke when they were in their mid-60s. He is currently on 40 mg PO Lipitor for his high cholesterol but denies use of any other medications...

## INTRODUCTION

The overall function of the vascular system is to ensure adequate circulation of blood to all body tissues and capillary exchange between blood plasma, interstitial fluid, and tissue cells. Each tissue requires a minimum amount of blood per minute to sustain its metabolic activities and remove waste. The distribution of the cardiac output (CO) to various tissues depends on the interplay of (1) the pressure differences that drive the flow of blood and (2) the resistance to blood flow through specific blood vessels. See Chapter 28 for a more detailed overview of the anatomy and physiology of the vasculature. This chapter discusses disorders in the vasculature that impair or interfere with adequate delivery of oxygen and nutrients to the tissues.

## ATHEROSCLEROSIS/ARTERIOSCLEROSIS

The primary culprits in many vascular disorders are arteriosclerosis and atherosclerosis. The terms are frequently used interchangeably. Although both conditions are types of vascular disease and may lead to the need for intervention or surgery, they are not the same.

**Arteriosclerosis** is a generic term describing the thickening or hardening of the arterial wall that is often associated with aging. This condition not only thickens the wall of the artery but also causes stiffness and a loss of elasticity. Arteriosclerosis includes three possible pathological processes. One, medial calcific sclerosis, occurs when calcium is deposited in the arterial wall. A second process, arteriolar sclerosis, involves the thickening of the smaller arterioles. The third process, atherosclerosis, occurs when low-density lipoprotein (LDL) particles build up in the arterial wall. Atherosclerosis is described in detail in the Pathophysiology section. To clarify, a patient with arteriosclerosis or hardened

arteries may not have atherosclerosis or plaque, but a patient with atherosclerosis does have arteriosclerosis. Patients often have both conditions. The focus of this chapter is atherosclerosis.

## Epidemiology

The emerging epidemic of atherosclerotic disease in developing countries is thought to start in childhood and increase in prevalence with age. Changes occur in the arterial walls over time, which predisposes the older population to the development of atherosclerosis. Acquiring accurate data on the prevalence of the disease in the total population is difficult to obtain. It is more helpful to look at the prevalence of the disorders caused by atherosclerosis such as coronary artery disease, carotid artery disease, hypertension, abdominal aortic aneurysm (AAA), and peripheral arterial disease (PAD). This chapter reviews carotid artery disease, hypertension, AAA, and PAD. Coronary artery disease is discussed in depth in Chapter 30.

Risk factors that potentially stimulate atherosclerotic changes, causing damage to the arterial wall, include:

- Elevated cholesterol levels
- Elevated triglycerides
- Elevated low-density lipoprotein cholesterol (LDL-C)
- Low high-density lipoprotein cholesterol (HDL-C)

Other risk factors of atherosclerosis include hypertension, diabetes, smoking, family history, obesity, and a sedentary lifestyle. Hypertension acts synergistically with other risk factors in the development of atherosclerosis. It causes a mechanical injury to the arterial walls that, over time, makes them harder and less elastic.

Diabetes is linked to atherosclerosis partially because of the increased LDLs and hyperglycemia associated with the disease. Hyperglycemia is thought to damage the intimal layer of the arterial wall.

Although tobacco use has declined in the United States, it remains the second leading cause of total deaths and disability. Tobacco smoke greatly worsens atherosclerosis and accelerates its growth in the coronary arteries, aorta, and arteries in the legs. Although cigarette smoke does not directly cause atherosclerosis, cigarette smoke and the by-products of tobacco cause vasoconstriction, hypertension, endothelial cell, and platelet dysfunction and increase circulating cholesterol. Second-hand smoke has also been shown to manifest these harmful effects. Smoking increases the risk of coronary artery disease two to four times above normal levels. Even smoking a few cigarettes a day or being exposed to cigarette smoke is correlated with an increased risk.

Some individuals have a family history of hyperlipidemia and increased cholesterol levels. Obesity and a sedentary lifestyle are linked to atherosclerosis because of their link to poor diet and increased cholesterol levels. Men have a higher incidence of atherosclerosis earlier in

life than women; however, after menopause, the incidence of the disease is relatively equal in men and women. Degree of risk differs among Caucasians, African Americans, and Hispanics. There is an increased incidence of atherosclerosis among African Americans and Hispanics compared with Caucasians. This is partially because of an increased prevalence of smoking, diabetes, and hypertension in these races as compared with Caucasian Americans. Caucasians are more likely, however, to have abnormal serum lipid levels.

### Connection Check 31.1

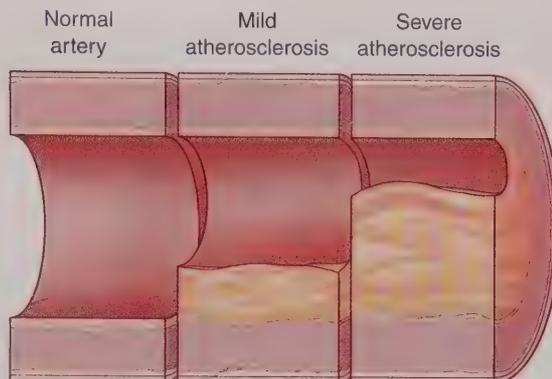

A patient teaching plan should focus on which risk factors for atherosclerosis? (Select all that apply.)

- A. Obesity
- B. Hyperlipidemia
- C. Smoking
- D. Age
- E. Race

### Pathophysiology

Atherosclerosis comes from the Greek words “athero,” meaning “gruel” or “paste,” and “sklerosis,” meaning “hardness.” Well documented in the literature, **atherosclerosis** is a disease in which LDL-C particles build up in the arterial wall.

Atherosclerosis is a slow, complex disease that typically starts in childhood and progresses while people grow older. In some people, it progresses rapidly, with symptoms becoming evident as young as 30 years of age. The lesions of atherosclerosis accumulate in large and medium-sized arteries. The exact pathophysiology remains under intense investigation, but the condition is thought to begin from vessel damage that causes an inflammatory response. After the vessel becomes inflamed, a fatty streak appears on the intimal surface, or inner lining, of the artery. Researchers believe that high circulating cholesterol levels promote the deposit of lipids into the arterial wall. In the presence of inflammatory mediators, they are oxidized by macrophages and perpetuate the inflammatory condition. It is best described as an inflammatory process comprising a series of highly specific cellular and molecular reactions that lead to the accumulation of atherosclerotic plaque. The presence of plaque thickens the inner layer of the artery significantly. The inner diameter of the artery shrinks, causing a decrease in blood flow, ultimately reducing oxygen supply to the affected tissues (Fig. 31.1). Plaques can grow large enough to significantly reduce blood flow through an artery, but a more serious problem is when they become unstable and rupture. Plaques that rupture may cause blood clots to form that can block blood flow entirely. Ruptured plaques also have the potential to travel to another part of the body.

**FIGURE 31.1** Atherosclerosis. The accumulation of atherosclerotic plaque shrinks the vessel diameter, decreasing blood flow.

### Clinical Manifestations

There may be no symptoms of atherosclerosis until there is a critical narrowing of the artery that results in an emergency. Depending on the artery involved, the coronary or carotid arteries, plaque formation and/or rupture can lead to myocardial infarction, unstable angina, sudden cardiac death, or stroke. Specifically, atherosclerotic disease in the coronaries can result in chest pain or angina, shortness of breath, fatigue, and arrhythmias. As noted, it may also result in sudden cardiac death. Atherosclerotic disease in the carotids may result in a stroke. Manifestations of a stroke include sudden weakness (sometimes noted more on one side than the other), dizziness and loss of coordination, difficulty talking, facial droop, sudden vision problems, and sudden and severe headache. If blood supply to the arms or legs is reduced in a similar manner, it can cause significant pain and difficulty walking. If blood supply is completely occluded peripherally to the affected body part, it can eventually lead to gangrene. *Gangrene* is a medical term used to describe the death of tissues of the body. Gangrene can affect any part of the body; the most common sites include the toes, fingers, hands, and feet (Fig. 31.2).

### Management

#### Medical Management

Identifying and controlling risk factors for the development of atherosclerosis are the basis of medical management. A decrease in serum LDL-C levels leads to a reduction in the risk of atherosclerotic cardiovascular disease. Medications used to lower lipid levels are the primary treatment modality. Anticoagulation is also used to decrease clot formation. Medication therapy is similar to that for coronary artery disease and is outlined in Table 30.2 in Chapter 30. Other options include modification in dietary habits, smoking cessation, and lifestyle modifications including an exercise and stress reduction plan. Proper management of diabetes is essential. Medical management for the disorders caused by atherosclerosis is discussed in detail throughout this chapter.

**FIGURE 31.2** Patient foot with gangrene secondary to inadequate tissue perfusion.

### Surgical Management

Surgical intervention is reserved for the irreversible manifestations of atherosclerosis such as chest pain or gangrene. Intractable chest pain caused by coronary artery disease requires coronary revascularization which can be done percutaneously or by surgical coronary artery bypass surgery. These management options for coronary artery disease are discussed in Chapter 30. Gangrene caused by atherosclerosis may require amputation. The use of surgical interventions must always be balanced against the risks of the procedure.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of atherosclerotic disease vary according to the arteries involved. Disease in the coronary arteries results in chest pain, shortness of breath, and fatigue. Critical disease in the carotid arteries results in signs of stroke. Disease in the peripheral vascular system results in severe pain and difficulty walking. General nursing interventions for arteriosclerosis/atherosclerosis are outlined here.

Specific nursing management for disorders caused by arteriosclerosis/atherosclerosis—hypertension, carotid artery disease, and peripheral vascular disease—are discussed in detail throughout the chapter. Coronary artery disease is discussed in detail in Chapter 30, and stroke is discussed in detail in Chapter 39.

#### Nursing Diagnoses

- **Risk for ineffective tissue perfusion:** cerebral, related to interruption of carotid blood flow
- **Pain** related to decreased blood flow

### Nursing Interventions

#### Assessments

- Complete patient history and cardiovascular assessment  
*There is a genetic and environmental link to cardiovascular disease. Patients with a family history of cardiovascular disease have a higher prevalence of the traditional cardiovascular risk factors highlighting opportunities for prevention.*
- Assess blood pressure (BP) in both arms  
*Hypertension is a strong risk factor for atherosclerotic disease.*
- Palpate pulses at all the major sites on the body and note any differences. Carotid arteries are palpated one at a time.  
*Weak pulses may suggest poor flow through the artery. Palpate the carotids one at a time so as not to risk blocking flow to the brain.*
- Auscultate for bruits  
*A bruit is a turbulent, swishing sound that can be soft or loud in pitch. It is heard as a result of blood trying to pass through a narrowed artery. Bruits often occur in the carotid, aortic, femoral, and popliteal arteries. A bruit is considered abnormal, but it does not indicate the severity of the disease.*
- Fasting lipid profile  
**Low-density lipoprotein cholesterol (LDL-C)**  
*High LDL-C levels indicate an increased risk for atherosclerosis. Target LDL-C level is less than 100 mg/dL for healthy adults.*  
**High-density lipoprotein cholesterol (HDL-C)**  
*Low HDL-C levels indicate an increased risk for atherosclerosis. The target HDL-C level is greater than 40 mg/dL.*
- Triglyceride levels  
*Triglyceride levels may be elevated with atherosclerosis. Elevated triglycerides are considered a marker for other lipoproteins. A level of 150 mg/dL or above indicates hypertriglyceridemia.*
- Homocysteine  
*Homocysteine is a sulfur-containing amino acid derived from dietary protein. High serum levels of homocysteine may block production of nitric oxide on the vascular endothelium, making the cell walls less elastic and permitting plaque to build up.*
- Glycosylated hemoglobin A1c (HgbA1c)  
*Hyperglycemia is a risk for the development of atherosclerosis. An HgbA1c of greater than 7% may indicate poor glycemic control.*

#### Actions

- Administer medications as ordered such as:
  - Antihypertensive medication
  - Lipid-lowering therapy including statin therapy  
*There is a direct relationship between hypertension and increased cholesterol levels and atherosclerosis.*

## ■ Teaching

- Blood pressure management—take medications as ordered  
*Hypertension puts patients at risk for heart disease and stroke.*
- Lifestyle changes such as:
  - Healthy diet  
*A low-fat, low-cholesterol diet helps manage risk factors and slows the progression of atherosclerosis. Elevated homocysteine levels may be lowered by a diet enriched with B-complex vitamins, particularly folic acid.*
  - Smoking cessation  
*Toxins in tobacco smoke lower a person's HDL-C while raising levels of LDL-C.  
The nicotine and carbon monoxide in cigarette smoke damage the endothelium, which sets the stage for the build-up of plaque.  
If a smoker has hypertension, smoking can increase the risk of malignant hypertension.*
  - Exercise  
*Exercise can help to lower LDL-C and increase HDL-C.  
Exercise can also help reduce other risk factors of atherosclerosis such as high BP, diabetes, obesity, and stress.*

## Evaluating Care Outcomes

Arteriosclerosis/atherosclerotic disease and the related disorders can be well managed through adherence to a healthy diet, exercise, stress management, and very importantly, smoking cessation.

## HYPERTENSION

**Hypertension** is a common and manageable chronic condition that is a major risk factor for atherosclerotic cardiovascular disease, heart failure (HF), stroke, kidney failure, vision loss, dementia, and circulation problems such as peripheral artery disease. Hypertension carries the risk for premature morbidity or mortality, which increases as systolic and diastolic pressures rise.

## Epidemiology

The prevalence of hypertension is approximately 78 million individuals in the United States. Seventy million other Americans have prehypertension now referred to as elevated blood pressure. The overall prevalence of hypertension has not changed appreciably since 2009–2010. Among hypertensive Americans, 82% are aware of their condition. Approximately 75% are using antihypertensive medication; however, target BP control is attained only 53% of the time for individuals with diagnosed hypertension. Based on national data from 2011–2012, treatment of hypertension exceeded the Healthy People 2020 target goal of 69.5%. However, the control of hypertension has not met the goal of Healthy People 2020 (61.2% by 2020). Additionally, data from the

latest blood pressure guidelines from the American College of Cardiology/American Heart (ACC/AHA) for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults indicates that 45.6% of US adults have hypertension; death rates attributed to high blood pressure increased 10.5%, and the actual number of deaths rose 37.5% from 2005 to 2015. The total direct cost of high blood pressure could increase to an estimated \$220.9 billion by 2035.

Risk factors include age, gender, race, and socioeconomic status. Blood pressure tends to rise with age. Approximately 65% of Americans aged 65 or older have hypertension. People with a normal BP at age 55 have a 90% lifetime risk of developing hypertension. Men and women are equally likely to develop high BP during their lifetimes. However, before age 45, men are more likely to have high BP than women. After age 65, the condition is more likely to affect more women than men. Race also plays a major factor in risk associated with hypertension. African American adults continue to have the highest prevalence of hypertension in the United States, and morbidity and mortality are highest in African Americans. It is also more prevalent in those of low socioeconomic status. Other major risk factors are outlined in Box 31.1.

**Essential or primary hypertension** accounts for 90% to 95% of the cases of hypertension in the adult population. Essential hypertension has no identifiable medical cause. It appears to be a multifactorial, polygenic condition. Heredity is a predisposing factor, but the exact mechanism is unclear (see Genetic Connections). It tends to be familial and is likely to be the consequence of an interaction between environmental and genetic factors. The risk for this type of hypertension can increase when heredity is combined with unhealthy lifestyle choices such as smoking or a poor diet. Essential hypertension is four times more common

### Box 31.1 Major Risk Factors for the Development of Hypertension

- Cigarette smoking
- Obesity (body mass index  $\geq 30$  kg/m<sup>2</sup>)
- Physical inactivity
- Excessive Alcohol use (more than two drinks per day for men and more than one drink per day for women)
- Diet
- Stress
- Dyslipidemia\*
- Diabetes mellitus\*
- Microalbuminuria or estimated glomerular filtration rate of less than 60 mL/min
- Age (older than 55 years for men, 65 years for women)
- Family history of premature cardiovascular disease (men younger than age 55 years, women younger than age 65 years)

\*Component of the metabolic syndrome

## Genetic Connections

### Genetic Factors Related to Essential Hypertension

More than 50 genes have been examined in association with hypertension. One of these genes, the angiotensinogen (*AGT*) gene, has been studied extensively. The results have shown that increasing the number of *AGT* genes increases blood pressure and hence may be a cause of hypertension. In general, these studies indicate essential hypertension has a large genetic component, but more research is indicated because the genetic influence upon hypertension is still not fully understood.

in African Americans than Caucasians. It accelerates more rapidly and is often more severe with higher mortality in African Americans.

Other notable risk factors associated with primary hypertension include obesity, salt sensitivity, renin elevation, insulin resistance, vitamin D deficiency, and cigarette smoking. Recent studies claim that obesity is a risk factor for hypertension because of the activation of the renin-angiotensin system and the sympathetic nervous system in adipose tissue. Other studies have linked insulin resistance with similar effects on the renin-angiotensin system and increased sympathetic nervous system activity. Salt sensitivity is an environmental factor that has received great attention. Approximately one-third of the population with essential hypertension is responsive to sodium intake. When sodium intake exceeds the body's capacity to excrete it through the kidneys, vascular volume expands secondary to movement of fluids into the intravascular compartment. This causes the arterial pressure to rise while the fluid volume and cardiac output (CO) increase. Local autoregulatory mechanisms attempt to counteract this by decreasing vascular resistance to maintain normotension.

**Secondary hypertension** is characterized by elevations in blood pressure due to a specific cause. Renal parenchymal disease affecting the renal medulla and renal cortex, where the "work" of the kidney is done, is the most common cause of secondary hypertension excluding obesity and alcohol abuse. It is responsible for 2% to 5% of all cases of secondary hypertension. Examples of renal parenchymal disease include chronic glomerulonephritis or pyelonephritis, polycystic renal disease, connective tissue disorders, and obstructive uropathy. Other causes of secondary hypertension include renovascular disease, pheochromocytoma, Cushing's syndrome, primary aldosteronism, congenital adrenal hyperplasia, hyperthyroidism, myxedema, and coarctation of the aorta. Excessive alcohol intake and use of oral contraceptives are also common causes of secondary hypertension, as is the use of sympathomimetics, NSAIDs, corticosteroids, cocaine, or licorice.

## Pathophysiology

The mechanisms that cause hypertension are complex. Because BP is the result of  $CO \times \text{total peripheral vascular resistance (PVR)}$ , pathogenic mechanisms must involve increased CO, increased PVR, or both. Cardiac output is a function of heart rate (HR) and stroke volume (SV). Peripheral vascular resistance is a function of the autonomic nervous system and circulating hormones such as epinephrine. Any factor that increases HR, such as overactivity of the sympathetic nervous system, or increases circulating volume, such as fluid retention with increased sodium intake, increases BP. Any factor that increases PVR, such as angiotensin II, increases BP. In very-early hypertension or in younger people CO is increased and PVR is normal. Later or in older adults, increased PVR is predominant. Table 31.1 describes several mechanisms that may result in hypertension.

**Table 31.1 Mechanisms That Result in Hypertension**

<b>Increased sodium intake</b>	<ul style="list-style-type: none"> <li>Increased sodium causes fluid retention, increasing stroke volume and blood pressure.</li> </ul>
<b>Renin-angiotensin-aldosterone system (RAAS)</b>	<ul style="list-style-type: none"> <li>Excess angiotensin II results in vasoconstriction and increased blood pressure.</li> <li>Excess angiotensin also results in increased aldosterone release (see below).</li> </ul>
<b>Aldosterone</b>	<ul style="list-style-type: none"> <li>Excess aldosterone release results in sodium and water retention, which results in increased stroke volume and blood pressure.</li> <li>Enhanced potassium (K) excretion also occurs, resulting in low plasma K.</li> <li>Low plasma K increases vasoconstriction through closure of K channels.</li> </ul>
<b>Sympathetic nervous system</b>	<ul style="list-style-type: none"> <li>Increased sympathetic activity is a primary precursor to hypertension. It can cause vasoconstriction, resulting in increased peripheral vascular resistance and increased blood pressure. It may also increase heart rate.</li> <li>Overactivity of the sympathetic nervous system may result from either inappropriately elevated sympathetic drive from brain centers, an increase in synaptically released neurotransmitters in the periphery, or amplification of the neurotransmitter signal at the target tissue.</li> </ul>

## Connection Check 31.2

The nurse is screening patients for their risk of developing hypertension. The nurse should consider which patients at greatest risk? (*Select all that apply.*)

- A. A 40-year-old Latino male who is obese and smokes two packs of cigarettes per day
- B. A 35-year-old Asian female who has a familial history of diabetes mellitus type 1
- C. A 78-year-old African American male with chronic renal insufficiency
- D. A 25-year-old African American female track athlete with a healthy body mass index (BMI) who takes oral contraceptives
- E. A 60-year-old Caucasian male with vitamin D deficiency and a history of cocaine use

## Clinical Manifestations

Clinical manifestations of primary hypertension are typically evident only after long-term increased BP has resulted in target organ damage (TOD), to be discussed under Complications. Some symptoms of chronic uncontrolled hypertension are headaches, chest pain, vision changes, shortness of breath, renal dysfunction, dizziness, fatigue, or nosebleeds. Clinical manifestations related to secondary hypertension are the result of the disease processes that cause hypertension.

## Management

### Medical Management

#### Diagnosis

The diagnosis of hypertension is made on the basis of the average of two or more properly measured BP readings on two or more office visits. Treatment is indicated at that time but may begin immediately if two consecutive readings during a single visit indicate an extreme elevation. New (2017) ACC and AHA guidelines for the detection, prevention, management and treatment of high blood pressure lower the definition of high blood pressure to account for complications that can occur at lower numbers and to allow for earlier intervention. See Table 31.2 for the classifications of hypertension for adults aged 18 and older.

Once the diagnosis of hypertension has been made, providers attempt to identify the underlying cause on the basis of risk factors and other symptoms. Laboratory tests are performed to identify possible causes of secondary hypertension. Additional tests for diabetes and high cholesterol levels are performed because they are risk factors for the development of heart disease that require treatment. Tests typically performed in a hypertension work-up are classified in Table 31.3.

A thorough history and physical examination are done to detect TOD. The search for the presence of subclinical target organ damage (TOD) is strongly recommended because it allows a better stratification of cardiovascular

**Table 31.2 Classification of Blood Pressure for Adults**

Blood Pressure Classification	Systolic BP	Diastolic BP
<b>Normal</b>	Less than 120 mm Hg	and less than 80 mm Hg
<b>Elevated</b>	120–129 mm Hg	and less than 80 mm Hg
<b>Stage 1 hypertension</b>	130–139 mm Hg	or 80–89 mm Hg
<b>Stage 2 hypertension</b>	140 mm Hg or higher	or 90 mm Hg or higher
<b>Hypertensive Crisis</b> (consult doctor immediately)	Higher than 180 mm Hg	and/or higher than 120 mm Hg

#### Hypertensive Crisis

**Hypertensive urgency:** DBP greater than or equal to 120 mm Hg with no obvious target organ damage (TOD)\*

**Hypertensive emergency:** DBP greater than or equal to 120 mm Hg with evidence of TOD\*

\*TOD is damage to the heart, eyes, or kidneys caused by hypertension.

DBP, Diastolic blood pressure; SBP, systolic blood pressure.

**Table 31.3 Hypertension Laboratory Diagnostic Testing**

System	Tests	Expected Findings If TOD Present
<b>Renal</b>	Microscopic urinalysis, proteinuria, serum BUN (blood urea nitrogen), and/or creatinine	Proteinuria Elevated BUN and creatinine
<b>Endocrine</b>	Serum sodium, potassium, calcium, TSH (thyroid-stimulating hormone)	↑Sodium ↑Potassium ↑TSH
<b>Metabolic</b>	Fasting blood glucose, total cholesterol, HDL and LDL cholesterol, triglycerides	Fasting glucose greater than 100 mg/dL ↑LDL, triglycerides ↓HDL
<b>Other</b>	Hematocrit, electrocardiogram, and chest x-ray	Left ventricular hypertrophy ↓Hematocrit

HDL, High-density lipoprotein; LDL, low-density lipoprotein  
Source: Jameson, J. L., Fauci, A. S., Kasper, D. L., Hauser, S. L., Longo, D. L., & Loscalzo, J. (2018). *Harrison's principles of internal medicine* (20<sup>th</sup> ed.). New York, NY: McGraw-Hill Medical

risk, encourages the achievement of a lower BP target than usual, and helps with the selection of the most appropriate medication regimen. To that end, testing is done to determine if hypertension has caused damage to the heart, eyes, or kidneys.

### Treatment

An increase in recent years of illness and death due to hypertension has prompted experts to urge more effective BP control. To bring high blood pressure down to a healthy level, treatment guidelines recommend healthy lifestyle changes, medication, or both. Lifestyle changes alone may be the first step in patients with mildly elevated (systolic between 120-129 and diastolic < 80) blood pressure readings.

### Medications

The new guidelines recommend only prescribing medication beginning at Stage I hypertension if a patient has already had a cardiovascular event such as a heart attack or stroke or is at high risk of heart attack or stroke based on age, the presence of diabetes mellitus, chronic kidney disease or calculation of atherosclerotic risk. If medications are necessary, there are a variety of medications used to treat high BP. Which medications are initially prescribed to a patient depends on numerous factors including ease of use, side effects, and coexisting medical conditions that may necessitate use of one agent versus another. Diuretics are commonly included in the treatment plan. Clinical trials have shown they enhance the antihypertensive efficacy of multiple medication regimens, are useful in achieving BP

control, and are more affordable than other antihypertensive medications. Combination therapy regimens can facilitate achievement of BP goals. Table 31.4 gives an overview of the antihypertensive medications that may be used individually or in combination with one another. When a treatment plan is considered for the patient, socioeconomic status and psychosocial stress as risk factors for high blood pressure should be considered in a patient's plan of care.

### Connection Check 31.3

Which statement by the patient about the need for antihypertensive medication indicates the need for further teaching?

- "I'm worried about a stroke if my BP is not controlled."
- "Can my kidneys fail if I don't control my BP?"
- "My BP is only slightly elevated, so I am ok."
- "I guess I need to take this medication even if I feel OK."

### Lifestyle Management

Lifestyle changes are an important component of hypertension management. These lifestyle changes include weight control, diet modification including reduced salt intake, lowering alcohol use, and regular exercise and relaxation.

### Weight

Obesity is associated with severe hypertension and the need for multiple medications to control BP. Thus, weight loss

**Table 31.4 Antihypertensive Medications**

Medication	Description
<b>Diuretics</b>	Act on the kidneys to help the body eliminate sodium and water, reducing blood volume. Diuretics are often the first but not the only choice in high blood pressure medications.
<b>Calcium channel blockers</b> Amlodipine besylate (Norvasc) Diltiazem (Cardizem) Nifedipine (Adalat CC, Procardia XL)	Help relax/dilate the muscles of the blood vessels. Some slow the heart rate. In African American adults with hypertension but without heart failure or chronic kidney disease, including those with diabetes mellitus, initial antihypertensive treatment should include a thiazide-type diuretic or a calcium channel blocker. Two or more antihypertensive medications are recommended to achieve a blood pressure target of greater than 130/80 mm Hg in most adults, especially in African American adults, with hypertension.
<b>Angiotensin-converting enzyme inhibitors</b>	Help relax/dilate blood vessels by blocking the formation of angiotensin II, a vasoconstrictor, thus reducing blood pressure
<b>Angiotensin II receptor blockers (ARBs)</b>	Help relax/dilate blood vessels by blocking the action not the formation of angiotensin II, a vasoconstrictor; sometimes used in patients intolerant of ACE inhibitors
<b>Beta blockers</b>	Reduce the afterload on the heart and dilate blood vessels, causing the heart to beat more slowly and with less force
<b>Combined alpha and beta blockers</b>	Reduce nerve impulses that promote vasoconstriction and at the same time slow the heart rate and reduce afterload
<b>Vasodilators</b>	Relax the muscle tissue in the blood vessel walls and, in turn, lower the blood pressure
<b>Central agonists</b>	Decrease blood vessels' ability to contract and cause vasoconstriction

has clear benefits in reducing BP and the number of medications required to control it. Excess weight, especially excess fat stored in your abdomen, can raise blood pressure by increasing your blood volume and by changing the balance of pressure-regulating hormones. Even modest weight loss can have a positive impact. Research shows that losing just 7.7 pounds could reduce your risk for high blood pressure by 50% or more. The 2013 European Society of Hypertension and European Society of Cardiology guidelines recommend reducing BMI to 25 kg/m<sup>2</sup> and waist circumference to less than 102 cm in men and less than 88 cm in women.

### Diet

High dietary salt intake is commonly associated with patients with resistant hypertension (hypertension resistant to treatment). High amounts of sodium found in many processed foods raise BP by facilitating water retention (which boosts blood volume) and even tightening small blood vessels. The association is more pronounced in salt-sensitive patients including older adults, African Americans, and patients with chronic kidney disease. Reducing dietary salt intake can reduce systolic BP and diastolic BP by 5 to 10 mm Hg and 2 to 6 mm Hg, respectively. African American and older adult patients tend to show greater benefits from reducing salt intake. Other dietary considerations include the minerals calcium, magnesium and potassium (found in low-fat and fat-free dairy products, such as milk and yogurt, as well as in produce and dried beans). They help the body regulate blood pressure; too little can raise blood pressure. Saturated fat (found in meat, cheese, butter, full-fat dairy products and many processed foods) may also raise blood pressure. A DASH (Dietary Approaches to Stop Hypertension) diet high in fruits, vegetables, and low-fat dairy products has been shown to lower elevated pressures (Table 31.5).

**Table 31.5 DASH Diet Table**

Type of Food	Servings on a 2,000-Calorie Diet
Grains and grain products (include at least three whole-grain foods each day)	6–8/day
Fruits	4–5/day
Vegetables	4–5/day
Low-fat or nonfat dairy foods	2–3/day
Lean meats, fish, poultry	6 or fewer/day
Nuts, seeds, and legumes	4–5 per week
Fats and oils	2–3/day
Sweets	5 or fewer/week

### Alcohol Consumption

Heavy alcohol intake is associated with higher BP and with treatment-resistant hypertension. In one study, a small group of patients who quit heavy alcohol drinking reduced their systolic BP by 7.2 mm Hg and their diastolic BP by 6.6 mm Hg. Their prevalence of hypertension decreased from 42% to 12%. Moderating alcohol is very important. Although a small amount of alcohol may relax arteries, too much seems to have the opposite effect. Men should have no more than two drinks per day and women should have no more than one drink per day.

### Exercise

Regular physical activity makes the heart stronger and may reduce weight if combined with a healthy diet. A stronger heart can pump more blood with less effort, reducing the force on the arteries, lowering BP. Becoming more active can lower systolic BP by an average of 5 to 10 mm Hg, which is as good as some BP medications. The ACC/AHA guidelines recommend at least 90 to 150 minutes per week of aerobic activity. Dynamic and isometric resistance exercise is also recommended.

### Stress Management

The body's stress response releases hormones that temporarily raise blood pressure. To date, it is not clear whether mind-body therapies have a lasting effect on blood pressure or reduce the risk of hypertension. It is well researched that regularly practicing stress-soothing techniques such as breathing exercises, progressive relaxation, and fitness activities helps the recipient feel better, finding it easier to make other healthy changes. One technique, meditation, has been shown to reduce the risk for heart attacks and strokes in people with high blood pressure.

## Connection Check 31.4

A nurse providing care for a patient whose BP readings are consistently 130/85 mm Hg should anticipate which medical plan of care? (Select all that apply.)

- A. Diagnostic testing for TOD
- B. Initiation of diuretics
- C. Modifications of diet and exercise
- D. Echocardiogram
- E. A stress test

### Complications

High BP is known as the “silent killer” because it can cause considerable damage to the heart, brain, and kidneys (target organs) before symptoms are apparent. The heart is most commonly affected by hypertension. When arterial pressure is high, the heart uses more energy to pump against the increased afterload caused by the elevated pressure in the aorta. Because of the increased afterload, the left ventricle gradually hypertrophies,

causing diastolic dysfunction. The ventricle eventually dilates, causing dilated cardiomyopathy and HF due to systolic dysfunction. Heart failure is discussed in detail in Chapter 30.

Hypertension also compromises kidney function. The principal site of damage is in the arterioles leading to the renal system. The continual high pressures exerting force against the walls cause them to thicken, which narrows the lumen. The blood supply to the kidneys is gradually reduced. In response to the reduction in blood supply, the kidneys secrete more renin, which elevates the BP even more, complicating the problem. Eventually, the reduced blood flow may lead to the death of the kidney cells.

**Stroke** is a very serious complication of hypertension. Prolonged increases in BP may cause vessel rupture, which leads to hemorrhage and a sudden loss of function, resulting from a disruption of the blood supply to a part of the brain. It is the fourth-leading cause of death in the United States and the leading cause of disability. Hypertension is the most important but modifiable risk factor related to stroke. In clinical trials, antihypertensive therapy has been associated with reductions in stroke incidence averaging 35% to 40%. Please refer to Chapter 39 for a more detailed discussion of stroke. **An aneurysm** is another very serious complication of hypertension. An intracranial aneurysm is a dilation of the walls of the cerebral artery that develops as a result of weakness in the arterial wall. The aneurysm presses on nearby cranial nerves or brain tissue causing damage or ruptures causing subarachnoid hemorrhage and stroke.

**Hypertensive crisis** is an umbrella term for acute, severe elevations in BP. It comprises two conditions on a continuum: **hypertensive urgency** and hypertensive emergency. Hypertensive urgency is severely elevated BP (diastolic BP  $\geq 120$  mm Hg) with no obvious, acute TOD. Hypertensive emergency is differentiated from hypertensive urgency by evidence of TOD, which may include signs of stroke, papilledema, HF, or aortic dissection. Hypertensive emergency is the most serious but least common form of hypertensive crisis, representing only 5% of cases. It requires emergent attention. Blood pressure must be lowered immediately to halt TOD. The incidence is higher in older adults, African Americans, and men. Most patients seen in hypertensive crisis have a prior history of hypertension and have been prescribed antihypertensive medications at some point. Sudden escalation of essential, chronic hypertension is a common precipitant of hypertensive crisis. Medication interactions and/or withdrawal of treatment are also frequently precipitating factors.

## Nursing Management

### Assessment and Analysis

Hypertension is a silent disease. There are typically no symptoms until the disease is advanced and the damage to organs has been done. A physical examination may reveal no abnormality other than high BP.

## Nursing Diagnoses

- **Risk for ineffective therapeutic regimen management** related to nonadherence to treatment
- **Risk for decreased CO** related to left ventricular hypertrophy and eventual left ventricle dilation secondary to increased afterload

## Nursing Interventions

### Assessments

- Neurological assessment  
*It is important to assess signs and symptoms that could indicate TOD and cerebrovascular disease leading to possible complications such as stroke and aneurysm.*
- Blood pressure  
*Early detection and treatment of hypertension can prevent or minimize TOD. Measurements determine the treatment regimen prescribed.*
- Heart rate  
*Increased PVR can lead to increased HR or increased SV to compensate for the increased PVR.*
- Examination of the optic fundi  
*Hypertension may lead to retinal damage and eventually retinal hemorrhage because of the vascular changes caused by hypertension.*
- Auscultation for carotid, abdominal, and femoral bruits  
*Bruits are sounds created by blood flow through a stenosed or narrow vessel.*
- Palpation of the lower extremities for edema and pulses  
*Weak pulses and peripheral edema can indicate kidney disease and/or HF.*
- Serum creatinine, blood urea nitrogen (BUN), estimated glomerular filtration rate, and 24-hour urine collection for creatinine clearance  
*Abnormal levels indicate renal disease, which may develop in patients with hypertension.*
- Albumin excretion rate  
*Microalbuminuria is a significant marker of early cardiac, renal, and retinal structural and functional changes in essential hypertension.*
- Calculation of BMI and waist circumference  
*Obesity and diet are major risk factors in hypertension.*

### Actions

- Administer antihypertensive medications as ordered  
*Clinical outcome trial data prove that lowering BP with a combination of one or several classes of medications reduces the complications of hypertension.*
- Provide patient with DASH diet for meals  
*A 1,600-mg sodium DASH eating plan has effects similar to those of antihypertensive single-medication therapy.*

### Teaching

- Adherence to antihypertensive medication regimen and lifestyle changes such as:
  - DASH diet and sodium restriction (diet rich in fruits, vegetables, and low-fat dairy products, and

reduced in saturated fat and cholesterol) greater than or equal to 1,600 mg sodium per day is recommended.

- Moderate exercise (at least 150 minutes of moderate aerobic activity per week, primarily aerobic exercise, which helps raise the heart rate to 70% to 85% of an individual's maximal heart rate, or endurance exercise supplemented by resistance exercise).
- Limit alcohol (no more than one drink per day for women, two drinks per day for men).
- Stress reduction
- Smoking cessation

*It is important that the patient and family are aware of the critical nature of adhering to the medication regimen and lifestyle changes. Long-term effects of TOD should be stressed as a risk factor with noncompliance. Expected side effects should be explained thoroughly so the patient knows what to expect and how to cope with the side effects.*

- Monitoring blood pressure at home  
*Teach and coach patients and family members to monitor BP consistently at home to improve BP management. Automatic BP cuffs can be purchased at local pharmacies.*
- Signs and symptoms of TOD, stroke, and aneurysm  
*Detecting signs and symptoms early can help prevent or stabilize renal, cardiovascular, cerebrovascular, and retinal disease.*

### Evaluating Care Outcomes

Patients need to understand and comply with the treatment regimen of antihypertensive medications and necessary lifestyle changes to achieve optimum health. A patient with well-controlled hypertension has a BP and HR within normal limits. Other indicators of well-controlled BP are increased energy and no headache, dizziness, or vision changes or other signs of TOD. The electrocardiogram (ECG) and echocardiogram remain normal or unchanged. Blood chemistries and urinalysis are within normal limits.

### CASE STUDY: EPISODE 2

Mr. More demonstrates classic signs of chronic uncontrolled hypertension—headaches, dizziness, and nocturia. Initial diagnostic results show a BP reading of 180/122 mm Hg, HR 100 bpm, O<sub>2</sub> saturation of 96%, elevated fasting blood glucose (250), an elevated BUN (28 mg/dL) and creatinine (2.2 mg/dL), protein in his urine, elevated LDL (180 mg/dL), decreased HDL (30 mg/dL), and elevated triglycerides (300 mg/dL). The results are consistent with possible kidney and heart damage. Diagnostic testing continues in order to determine the level of damage. If one more BP reading confirms hypertension, Mr. More will be admitted to the hospital for observation and started on an antihypertensive medication regimen...

## PERIPHERAL ARTERIAL DISEASE

### Epidemiology

According to data from the AHA and the ACC from 2016, approximately 8.5 million people in the United States older than 40 years have **peripheral arterial disease (PAD)**. It is estimated that PAD affects 202 million people worldwide. PAD is associated with significant morbidity, mortality, and quality-of-life impairment.

Atherosclerosis is the main contributor to PAD. Therefore, the risk factors for atherosclerosis apply to PAD as well. They include key modifiable risk factors such as smoking, hypertension, diabetes, dyslipidemia, sedentary lifestyle, obesity, and ineffective stress management. Nonmodifiable risk factors include age, gender, ethnicity, and family history. A strong family history of coronary artery disease or PAD is an important predictor of its occurrence and subsequent prognosis.

### Pathophysiology

**PAD** is a progressive and chronic condition where the obstruction of blood flow through the large peripheral arteries causes a partial or total arterial occlusion. This obstruction can be caused by a combination of atherosclerosis, inflammation, stenosis, embolus, and thrombus. Peripheral arterial disease deprives the lower extremities of oxygen and nutrients. The result of this inadequate tissue perfusion can be ischemia and necrosis, or cell death (Table 31.6).

### Clinical Manifestations

The disease may be asymptomatic, identified only by a reduced BP in the ankle, or it may manifest symptoms of intermittent claudication or, in most patients, atypical lower extremity pain. **Intermittent claudication** is defined as muscle pain—ache, cramp, numbness, or sense of fatigue, classically in the calf muscle, that occurs during exercise and is relieved by a short period of rest. Atypical leg pain is described as limited or painful joints, cold and/or ulcerated extremities, or painful stretching to name a few. Both intermittent claudication and atypical leg pain have a cycle of exercise induced and rest relief. The typical patient with PAD experiences a profound limitation in exercise capacity and quality of life. In addition to affecting the limbs, PAD is a manifestation of systemic atherosclerosis which could be affecting other major vascular systems such as the cerebral and coronary circulations. Chronic PAD can be divided into four stages (Table 31.7).

### Management

#### Medical Management

##### Diagnosis

The vascular assessment for PAD includes pulse palpation, auscultation for femoral bruits, and inspection of the legs and feet. To confirm the diagnosis of PAD, abnormal physical examinations findings must be confirmed with

**Table 31.6 Buerger's Disease/Raynaud's Disease: Disorders Related to Poor Peripheral Circulation**

	<b>Buerger's Disease</b>	<b>Raynaud's Disease (Phenomenon)</b>
<b>Description</b>	Acute inflammation and thrombosis in arteries and veins in the hands and feet	Temporary, severe vasoconstriction in the arteries of the fingers and/or toes in response to cold
<b>Causes</b>	Unknown but maybe autoimmune reaction triggered by smoking	Unknown
<b>Risk Factors</b>	Cigarette smoking	Cigarette smoking Alcohol use Connective tissue or autoimmune disorder
<b>Clinical Manifestations</b>	Claudication (exercise-induced pain) in hands/feet Numbness/tingling Raynaud's phenomenon Ulceration/gangrene of the digits	In response to cold: <ul style="list-style-type: none"> <li>● Distal extremities (finger tips, toes) turn white, then blue, then red as circulation returns</li> <li>● Numbness</li> <li>● Pain</li> <li>● Severe: Ulceration/development of gangrene in finger pads</li> </ul>
<b>Treatment</b>	Smoking cessation	Smoking cessation Use mittens rather than gloves Avoid stress Avoid sudden changes in temperature

**Table 31.7 Stages of Peripheral Arterial Disease**

<b>Stage</b>	<b>Presentation</b>
<b>Stage I: Asymptomatic PAD</b>	<ul style="list-style-type: none"> <li>● No claudication/pain is experienced by patient.</li> <li>● Bruit may be heard.</li> <li>● Pedal pulses are decreased or absent.</li> </ul>
<b>Stage II: Claudication</b>	<ul style="list-style-type: none"> <li>● Muscle pain, burning, and cramping are experienced with exercise and are relieved by rest.</li> <li>● Pain is reproducible with the same amount of exercise.</li> </ul>
<b>Stage III: Rest pain</b>	<ul style="list-style-type: none"> <li>● Pain is experienced at rest.</li> <li>● Pain often awakens patient at night.</li> <li>● Pain is described as numbness and burning and usually occurs in the distal portion of the extremity.</li> <li>● Pain is often relieved by putting the extremity in the dependent position.</li> </ul>
<b>Stage IV: Necrosis or gangrene</b>	<ul style="list-style-type: none"> <li>● Ulcers and blackened tissue occur on the toes, the forefoot, or the heel of the foot.</li> <li>● Gangrenous odor may be present.</li> </ul>

diagnostic testing. Specifically, other comorbid causes of atypical leg pain should be ruled out before diagnosing PAD. Noninvasive testing for arterial disease has become a common method of diagnosis. This includes the ankle-brachial index (ABI), plethysmography, and graded-exercise treadmill

test. These tests provide information about the arterial system with minimal risk. Anatomical imaging studies, including duplex ultrasound, computed tomography angiography, magnetic resonance angiography, and invasive angiography, are other diagnostic tools but are sometimes reserved for

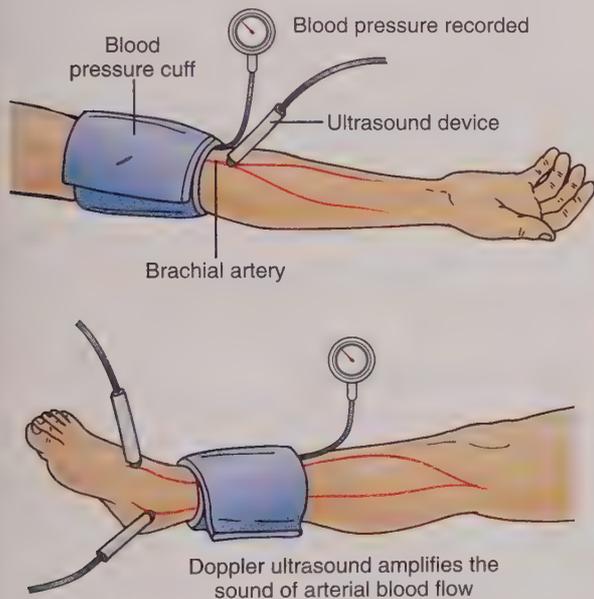

highly symptomatic patients who are being considered for revascularization.

### Ankle-Brachial Index

The **ankle-brachial index (ABI)** uses a Doppler probe to compare the BP obtained at the ankle with the pressure obtained at the brachial artery. This is an inexpensive, non-invasive method of assessing PAD. Normally, BP readings in the ankle are higher than those in the upper extremities. This test provides a ratio known as the ABI. The value can be derived by dividing the ankle BP by the brachial BP (Fig. 31.3). An ABI of less than 0.9 in either leg is diagnostic of PAD (Box 31.2). An increased ABI is indicative of poorly compressible arteries which indicates calcification of the arteries; another indicator of vessel disease. As an alternative, particularly for diabetics, a toe-brachial index may be performed in a certified vascular laboratory.

### Plethysmography

**Plethysmography** is another noninvasive test used to evaluate arterial flow in the lower extremities. Pulse volume

$$\text{ABI (Ankle brachial index)} = \frac{\text{Ankle blood pressure}}{\text{Brachial blood pressure}}$$

**FIGURE 31.3** Obtaining an ankle-brachial index (ABI). An ABI of less than 0.9 in either leg is diagnostic of peripheral arterial disease.

### Box 31.2 Interpreting Ankle-Brachial Index Values

- Greater than 1.30 = Noncompressible arteries (stiff arteries)
- 1 to 1.29 = Normal
- 0.91 to 0.99 = Borderline PAD
- 0.41 to 0.9 = Mild to moderate PAD
- 0 to 0.4 = Severe PAD

recordings are plethysmographical tracings that detect changes in the volume of blood flowing through a limb. Pressure cuffs are placed on the thigh, calf, ankle, or foot. The pressure cuffs are inflated to 65 mm Hg, and a plethysmographical tracing is recorded at the various areas where the cuffs are placed. A normal pulse volume recording is similar to a normal arterial pulse wave tracing and consists of a rapid systolic upstroke and a rapid downstroke with a prominent dicrotic notch. With increasing severity of PAD, the waveforms are decreased or flattened depending on the degree of occlusion (Fig. 31.4).

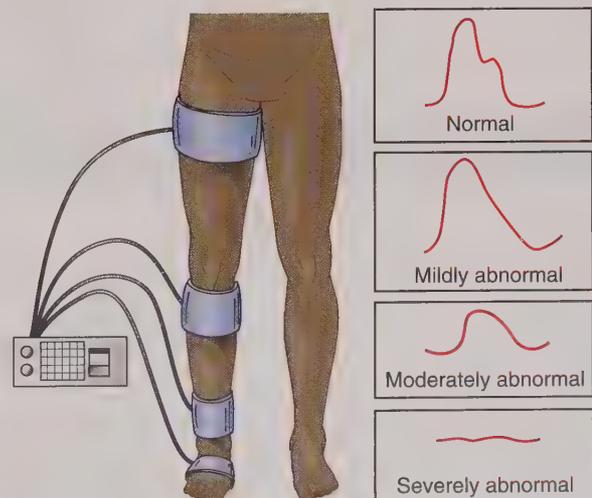

### Treadmill Test

A graded exercise treadmill test may give valuable information about the degree of peripheral arterial narrowing in patients who experience intermittent claudication. Once the resting pressures and pulse volume recordings are obtained, the patient is asked to walk on a treadmill at a constant speed, either at a constant grade (2 mph, 12% incline) or with a variable incline (0% at start, increased by 3.5% every 2–3 minutes). The former method exercises patients to a maximum of 5 minutes, whereas the latter continues for a maximum of an 18% incline. The graded exercise treadmill test:

1. Confirms the diagnosis of intermittent claudication and PAD
2. Demonstrates the objective functional limitation of PAD
3. Documents the effect of therapy on initial and absolute claudicating distances
4. Uncovers previously unrecognized coronary artery disease

### Duplex Ultrasound

**Duplex ultrasound** uses the detection of sound waves to measure the velocity of blood flow. It is used to detect and localize vascular lesions and quantify the amount and severity of damage through blood flow velocity criteria.

**FIGURE 31.4** Plethysmography; damping of the wave form is indicative of peripheral arterial disease.

### Computed Tomography Angiography

Computed tomography angiography (CTA) imaging is a CT scan that requires contrast material to visualize blood vessels. It displays a roadmap of the vasculature which identifies the issues and is sometimes essential for determining interventional strategies. Advantages of CTA include quick noninvasive testing, wide availability, high resolution, and 3D imaging. The disadvantages of CTA include the lack of hemodynamic data, exposure to radiation, and use of contrast agents.

### Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is a magnetic resonance test that focuses on the study of the vasculature. It uses contrast and noncontrast techniques when imaging the peripheral arteries. Noncontrast MRA has inferior resolution and may contain artefacts that limit the interpretation, but it is a valuable alternative for use in patients with mild to moderate chronic kidney disease for whom the use of contrast agents is not recommended. Vascular calcification can be underestimated by using MRA and this may affect revascularization procedures.

### Angiography

Angiography imaging assessment consists of arteriography of the lower extremities. This is done to quantify the narrowing of the occluded vessels. Arteriography involves injecting contrast medium into the arterial circulation through a small sheath in the groin. Treatment options can be derived and refined via arteriography. One treatment option is balloon angioplasty for the occluded vessel with stent placement. Angiography can also provide a better visual for refinements for planned peripheral bypass surgery. Balloon angioplasty and peripheral bypass surgery are described in detail later.

### Treatment

The primary goals of medical treatment and nursing care for patients with PAD are to provide relief of symptoms, prevent the progression of arterial disease and cardiovascular complications, improve quality of life, and provide education about the disease. Medications and nonsurgical and surgical interventions are options for treatment. The

majority of patients with PAD are elderly with a significantly increased risk of myocardial infarction, stroke, and cardiovascular death. Nonpharmacological interventions such as weight reduction, smoking cessation, exercise, and adherence to a low-fat diet are first-line actions.

### Medications

Medication therapies target the risk factors driving the progression of atherosclerosis in PAD. They include antihypertensive, antiplatelet, and statin agents. All of these medications have been associated with significant reductions in mortality in patients with PAD. Beta blockers can be used for BP control. They were previously thought to exacerbate intermittent claudication but are now currently recommended to achieve BP goals in PAD.

Antiplatelet agents such as acetylsalicylic acid (aspirin) and clopidogrel (Plavix) are commonly prescribed in patients with chronic PAD. Another antiplatelet agent, cilostazol, is an effective medical therapy for treatment of leg symptoms and walking impairment due to claudication. In addition to antiplatelet aggregation properties, it is also a vasodilator which can help improve blood flow through affected extremities. Unfortunately, significant side effects of headache, diarrhea, dizziness, and palpitations cause some patients to discontinue their treatment with that medication. Statin therapy is also recommended for all patients with PAD. The goal is to achieve a target LDL-C level less than 100 mg/dL. A more stringent LDL-C target is recommended (less than 70 mg/dL) in patients with PAD with multiple risk factors, especially diabetes, or severe and poorly controlled risk factors such as smoking, high triglycerides, or acute coronary syndrome. See Table 31.8 for pharmacological agents used for managing PAD.

### Nonsurgical Management

Nonsurgical management consists of positioning or promoting vasodilation by having the affected limb in a dependent position. Exercise may be used to increase blood flow to the affected limb by increasing collateral circulation. Percutaneous transluminal angioplasty, laser atherectomy, and rotational atherectomy are other nonsurgical interventions for PAD.

**Table 31.8 Pharmacological Agents Used for Managing Peripheral Arterial Disease (PAD)**

Medication	Description
<b>Hemorheological agents</b> pentoxifylline (Trental)	Decrease blood viscosity by inhibiting platelet aggregation; increase blood flow to the affected extremity
<b>Antiplatelet agents</b> Aspirin or clopidogrel	Inhibit platelet aggregation, therefore decreasing the probability of vascular events
<b>Lipid-lowering statins</b>	Successfully reduce total cholesterol in most patients when used for extended period
<b>Vasodilators</b> angiotensin converting enzyme (ACE) inhibitors	Help relax/dilate blood vessels by blocking the formation of angiotensin II, a vasoconstrictor. ACE inhibitor therapy reduced the risk of myocardial infarction, stroke, or vascular morbidity in patients with peripheral arterial disease by approximately 25%.

### Percutaneous Transluminal Angioplasty

Percutaneous transluminal angioplasty (PTA) is a nonsurgical, minimally invasive method of improving arterial blood flow. During this procedure, a cannula is inserted into or above an occluded or stenosed artery. The occluded artery is then dilated with a balloon catheter (Fig. 31.5). Success of the procedure is proven when it opens the vessel and restores or improves arterial blood flow. Stents may be used during this procedure to keep the vessel open. The transfemoral approach is the safest, most widely used, and most effective route for arteriography. If the femoral artery is not an option for catheterization secondary to surgery, arterial stenosis, or occlusion, alternative routes for arteriography include the brachial or axillary approach. Reocclusion may occur after percutaneous angioplasty. If this occurs, the procedure may be repeated. Some patients remain occlusion-free for up to 3 to 5 years, whereas other patients may experience reocclusion much sooner. The experience is patient specific. Patients must be educated on the importance of medication compliance and continued risk factor modifications. They are also educated on the signs and symptoms of reocclusion.

### Laser-Assisted Angioplasty

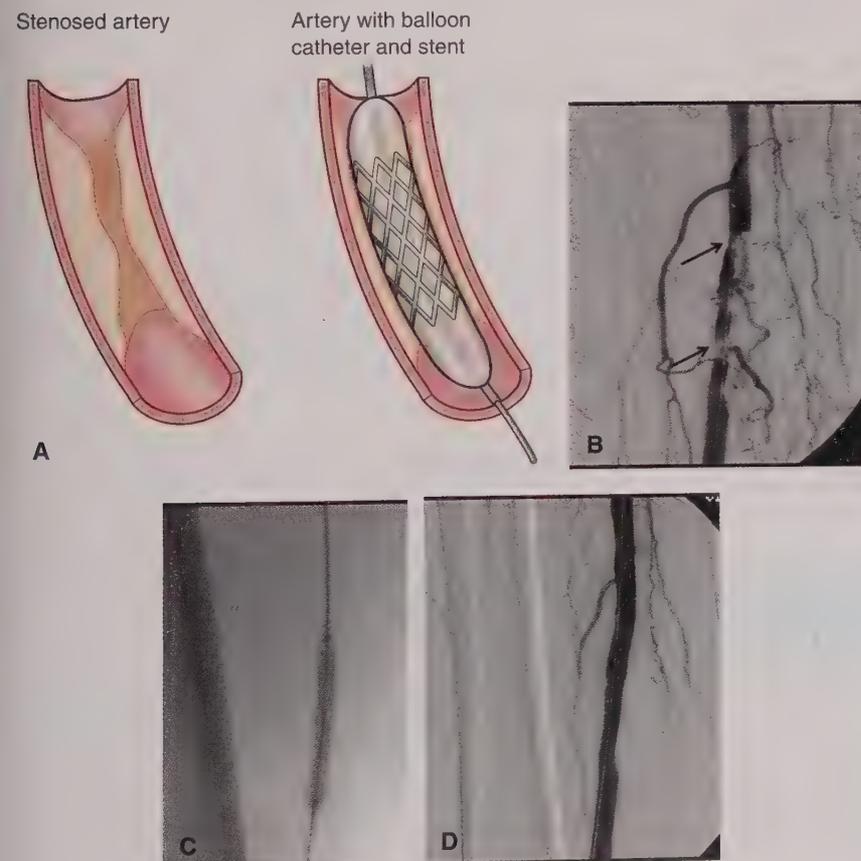

Laser-assisted angioplasty is another minimally invasive intervention that can be done for patients with PAD. During this procedure, a laser probe is advanced through a

cannula that is inserted into or above an occluded artery. This procedure is usually indicated for smaller occlusions in the distal superficial femoral, proximal popliteal, and common iliac arteries. Heat from the laser probe vaporizes the arteriosclerotic plaque to open the occluded or stenosed vessel. A PTA is often needed to further open the occlusion.

### Rotational Atherectomy

Rotational atherectomy is another technique used to improve blood flow to the ischemic limbs of people with PAD. Rotational atherectomy is more commonly used for very hard, calcified stenotic lesions that are not amenable to balloon angioplasty. Rather than compressing plaque and stretching an artery narrowed by atherosclerotic plaque, the goal of atherectomy is removal of the plaque by breaking it into microfragments.

The occlusion is accessed the same way as for PTA and laser atherectomy. The rotational atherectomy device (rotoblader) is a high-speed rotary metal burr. The distal end of the burr is coated with fine abrasive bits that reach speeds of 100,000 to 120,000 rotations per minute. When the burr comes in contact with the calcific plaque, it breaks up the blockages into very small fragments (smaller than red blood cells), which can pass harmlessly into the circulation. Often, balloon angioplasty with stent placement is performed after rotational atherectomy to improve results.

**FIGURE 31.5** Percutaneous transluminal angioplasty (PTA). A, Plaque limiting flow in an artery, the artery is dilated with a balloon catheter and a stent is placed to keep the vessel open; B, Angiogram demonstrating a severe femoral artery stenosis (arrows) amenable to PTA; C, Balloon catheter dilation; D, Blood flow restored.

### Surgical Management

Surgical or revascularization procedures are indicated when patients have severe pain at rest or claudication that interferes with the ability to perform activities of daily living (ADLs) or threatens loss of a limb.

Arterial revascularization is the surgical procedure most commonly used to increase arterial blood flow to the affected limb. Revascularization is accomplished through bypass grafting. Surgical bypass treats narrowed arteries by creating a bypass around a section of the artery that is blocked. Grafts used for bypasses are selected on an individual basis. Autogenous grafts, such as the patient's own saphenous vein, are most commonly used. If the saphenous vein is not suitable, then the cephalic or basilic arm veins may be used. Autogenous veins are often not long enough for use in vessels distal to the popliteal vessels, so composite grafts are constructed from multiple vein segments.

Synthetic grafts can be used if the patient's own vessels are not available for grafting. Synthetic grafts have been shown to be very effective in achieving patency in arteries above the knee. They have not been shown to be effective in occlusions distal to the popliteal vessels, hence the value of the autogenous composite grafts.

### Complications

#### Critical Limb Ischemia

Critical limb ischemia (CLI) is the sustained, severe decrease of arterial blood flow to the affected extremity, which leads to chronic ischemia, rest pain, ulceration, gangrene, and, ultimately, limb loss if left untreated. Obstructive atherosclerotic arterial disease is the most common cause of CLI. Other contributing factors that lead to CLI or exacerbate the situation include diabetes and/or low CO, which reduces the blood flow to the microvasculature. Typically, CLI presents after an extended course of PAD.

Once PAD progresses to chronic CLI, the patient's prognosis is generally poor. Infection, cellulitis, and tissue breakdown can occur. All of these conditions increase the requirement for oxygenated blood, which is decreased because of the disease process. Without adequate tissue perfusion, tissue breakdown and ulcers worsen, and gangrene then becomes apparent. Almost half of patients with this level of CLI need revascularization to save the affected limb. Of the patients whose limbs cannot be revascularized, approximately 40% need major amputation within 6 months of initial diagnosis.

#### Acute Limb Ischemia

Acute limb ischemia (ALI) is the sudden decrease in blood flow to an extremity that threatens tissue viability. This may be the first manifestation of PAD in a previously asymptomatic patient, or it may be caused by an acute event that leads to symptomatic deterioration in a patient with lower-extremity PAD and intermittent claudication. An embolus is the most common cause of peripheral occlusions, although a local thrombus may be the cause. Occlusions may affect the upper extremities, but they are more common in the

lower extremities. Emboli originating from the heart are the most common cause of acute arterial occlusions. Most patients with embolic occlusions have had an acute myocardial infarction (MI) or atrial fibrillation within the past few weeks.

Patients with ALI describe severe pain distal to the level of the occlusion that occurs at rest. The affected extremity is cool or cold, pulseless, and mottled. The toes may be blackened or present with gangrene. The following are the "six Ps" of ischemia:

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Poikilothermia (cool)

This patient requires immediate intervention. The goal of treatment is to preserve tissue and save the limb. Initiation of anticoagulation therapy with IV heparin is usually the first intervention to prevent further clot formation. Subsequent treatment for ALI includes interventions to restore blood flow, which relieves pain, helps heal ulcers, and possibly prevents amputation of the affected limb. Revascularization interventions include percutaneous transluminal angioplasty (PTA), bypass surgery, or surgical thrombectomy or embolectomy. Pain management and systemic antibiotics for infected skin or wounds are also indicated. If ALI is identified early and reperfusion interventions are promptly initiated, tissue may be salvaged.

### Connection Check 31.5

The nurse is reviewing orders for a newly admitted patient with PAD in the right lower extremity. The nurse should follow up with the provider about which order?

- A. Begin Plavix 75 mg PO daily
- B. Keep affected extremity elevated
- C. Begin Lisinopril 10 mg PO daily
- D. Encourage light exercise as tolerated

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of PAD vary with the tissues involved and the severity of altered blood flow. Although PAD is often unrecognized in its early stages, most patients initially seek medical attention for classic leg pain referred to as intermittent claudication, fatigue, and pain in a specific muscle group during exertion. With severe arterial disease, the extremity is cold and cyanotic or darkened. Pallor may occur when the extremity is elevated, and dependent redness may occur when the extremity is lowered. Muscle atrophy can also accompany prolonged chronic PAD.

## Nursing Diagnoses

- **Ineffective peripheral tissue perfusion** related to interruption of arterial blood flow to the peripheral tissue
- **Risk for impaired skin integrity** related to altered circulation or sensation
- **Chronic pain** related to decreased peripheral perfusion evidenced by the inability to walk for prolonged periods of time or having pain at rest

## Nursing Interventions

### ■ Assessments

- **Bilateral blood pressures**  
*Patients with diagnosed PAD have an increased risk of subclavian artery stenosis. Upper arm blood pressure difference of greater than 15 to 20 mm Hg is abnormal and suggestive of subclavian stenosis. Use the higher blood pressure measurement when calculating ABI and titrating blood pressure medications.*
- **Palpate all pulses in both legs**  
*Weak or absent pulses indicate poor blood flow through the extremity. The most sensitive indicator of arterial function is the quality of the posterior tibial pulse.*
- **Visual assessment of feet and limbs**  
*Signs of ulcer formation: sluggish capillary refill; dry, scaly, dusky, pale, or mottled skin; thickened toenails. Loss of hair on the lower calf, ankle, and foot indicate poor peripheral blood flow.*
- **Temperature**  
*Cool or cold temperature in the extremities indicates poor flow.*
- **Assess bilateral muscle tone**  
*Muscle atrophy can accompany prolonged chronic arterial disease.*
- **Assess pain**  
*Pain in the affected extremity with activity that is relieved with rest is indicative of PAD.*

### ■ Actions

- **Administer medications as ordered**
  - **Antihypertensives**  
*Controlling hypertension is necessary to help manage comorbidities, and it can improve tissue perfusion by maintaining pressures that are adequate to perfuse the periphery but not constrict the blood vessels.*
  - **Antiplatelet agents**  
*Patients with PAD and no contraindications to antiplatelet therapy should receive either aspirin or clopidogrel to inhibit clot formation.*
  - **Cilostazol**  
*Cilostazol has antiplatelet and vasodilation properties that can improve PAD symptoms.*
- **Proper positioning**  
*Keep the affected extremity dependent to facilitate blood flow.*

### ■ Teaching

- **Positioning**  
*Avoid crossing legs, which can further obstruct flow.*

- **Inspect feet daily**  
*Patients with PAD may develop ulcers on the bottom of their feet and between their toes. This should be monitored daily.*
- **Report chest discomfort or neurological changes immediately**  
*Patients with PAD have an increased risk for developing chronic angina, MI, or stroke.*
- **Lifestyle changes consistent with the management of atherosclerosis**
  - DASH diet
  - Limit alcohol
  - Smoking cessation
  - Moderate exercise*Atherosclerosis is the most common risk factor for PAD.*

## Evaluating Care Outcomes

The primary goals of medical treatment and nursing care for patients with PAD are to provide relief of symptoms, improve quality of life, provide education about the disease, and prevent the progression of arterial disease and cardiovascular complications. A well-managed patient is pain free and able to participate in normal physical activities without limitations.

## CAROTID ARTERY DISEASE

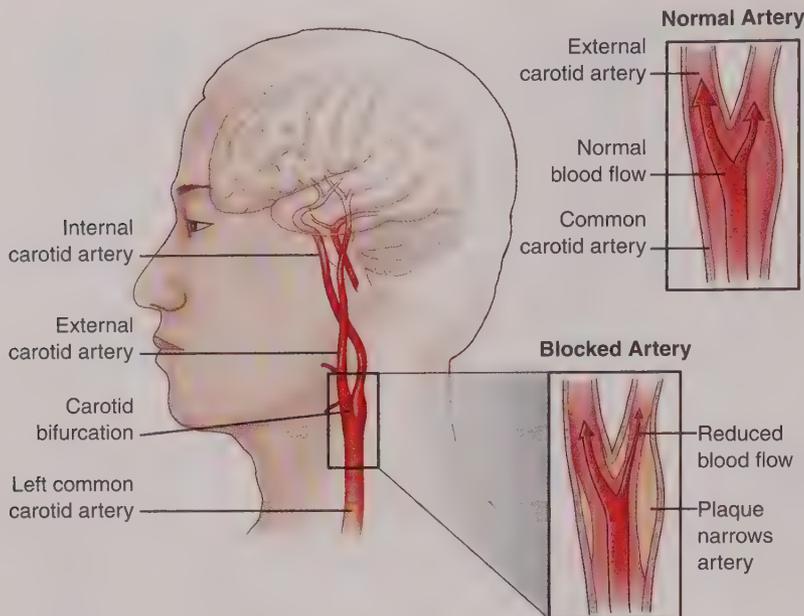

### Epidemiology

**Carotid artery disease is a common atherosclerotic vascular disease.** It can begin to develop in patients in their 40s, with the prevalence increasing with age, with as many as 11% of men 80 years of age or older presenting with the disease. It is thought that an occlusion of at least 50% will be present in 3% to 4% of the population. Men have a higher prevalence than women, and Caucasians and native Americans have a higher risk.

Risk factors associated with carotid artery disease are similar to those that cause atherosclerotic occlusive disease in other vessels: smoking, hypertension, diabetes, dyslipidemia, sedentary lifestyle, obesity, and ineffective stress management. **Nonmodifiable risk factors include age, gender, ethnicity, and family history.** Younger than 75 years, men have a greater risk than women. Older than 75 years, women have a greater risk. People with coronary artery disease have a greater risk of developing carotid artery disease.

### Pathophysiology

Similar to atherosclerotic changes in other arteries, carotid artery disease is characterized by vessel wall thickening, plaque formation, and a progressive narrowing of the carotid artery. Plaque disruption and thrombus formation contribute to progressive narrowing of the lumen of the artery, which can cause adverse clinical events. Stenosis is most significant at the carotid bifurcation. This area is known as the carotid bulb, where the common carotid artery branches into the internal and external carotid arteries (Fig.31.6). The carotid bifurcation is an area of low-flow

**FIGURE 31.6** Plaque formation in the carotid arteries around the carotid bifurcation.

velocity and low-shear stress. While the blood circulates through the carotid bifurcation, there is a separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. With increasing degrees of stenosis in the internal carotid artery, flow becomes more turbulent, increasing the risk of atheroembolization: an embolism from atherosclerotic plaque. The severity of stenosis is commonly divided into three categories according to the luminal diameter reduction:

- Mild (<50%)
- Moderate (50%–69%)
- Severe (70%–99%)

### Clinical Manifestations

Carotid artery disease is asymptomatic until the lumen of the vessel is obstructed to the point that cerebral perfusion is impaired. A bruit resulting from turbulent flow past the obstruction at the carotid bifurcation may be heard with a stethoscope.

The clinical manifestations of complications resulting from impaired cerebral perfusion such as stroke or transient ischemic attack (TIA) are discussed in Chapter 39. They include sudden weakness, sometimes noted more on one side than the other, dizziness and loss of coordination, difficulty talking, facial droop, sudden vision problems, and sudden and severe headache.

### Management

#### Medical Management

#### Diagnosis

Diagnostic testing involves physical assessment and noninvasive and/or invasive procedures. Physical assessment of carotid artery disease includes auscultation over the blood

vessels in the neck. When the bell of the stethoscope is placed over the side of the neck anterior to the sternocleidomastoid muscle, a carotid bruit may be heard. This sound occurs when blood flow becomes turbulent while it hits an obstruction at the carotid bifurcation.

Noninvasive tests include carotid duplex scanning, computed tomography angiography (CTA), and magnetic resonance angiography (MRA). Duplex ultrasound is the most commonly used screening tool to evaluate for atherosclerotic plaque and stenosis of the external carotid artery (Fig. 31.7).

An invasive test, conventional carotid angiography, is the gold standard for diagnosis of the severity of carotid artery disease. This test involves inserting a catheter into an artery, typically the femoral artery, and guiding it up to the carotids. Contrast dye is injected through the catheter that allows visualization of the carotid arteries via radiographical

**FIGURE 31.7** Doppler ultrasound of an atherosclerotic carotid artery showing plaque obscuring a portion of the vessel (arrows).

imaging. Because of the invasive nature of the test and the risks associated with it, noninvasive tests are more commonly used for diagnosis. See Table 31.9 for information on noninvasive diagnostic tests.

### Treatment

Treatment for patients with carotid artery stenosis depends on the severity of the occlusion and whether the individual is symptomatic or asymptomatic. An **asymptomatic** patient is without a prior history of stroke or TIA. A **symptomatic** patient is one who presents with TIA, stroke in evolution, or completed stroke.

The management of asymptomatic patients starts with optimal medical therapy (OMT) which includes a combination of healthy lifestyle changes such as weight management, smoking cessation, limited alcohol consumption, and control of comorbidities such as diabetes and hypertension, and use of medications to manage the cause of atherosclerotic vascular disease. Medication management includes antiplatelet therapy with aspirin. Clopidogrel is an option if aspirin is contraindicated. Antihypertensive therapy for blood pressure control is essential. The AHA recommends maintaining blood pressure below 140/90 mm Hg. Many classes of medications, such as calcium channel blockers, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers, are effective in blood pressure control. Lipid-lowering therapy with statins is also recommended. Without stating an LDL-C target level as evidence, current guidelines suggest that the use of high-intensity statins shows a 50% reduction in LDL-C levels. Somewhat controversial is the use of invasive procedures to treat the

obstruction itself. Patients would benefit from either surgical or endovascular revascularization but are at risk for the complications of the procedures, which include stroke. Current guidelines suggest revascularization in medically stable patients with carotid endarterectomy (CEA) or carotid artery stenting (CAS). Both procedures will be discussed below in detail. The management of symptomatic patients includes OMT but requires revascularization with CEA or CAS due to the presence of stroke or stroke symptoms unless excessive comorbidities put the patient at unreasonable risk of death.

### Surgical Management

Revascularization options include carotid endarterectomy (CEA) or carotid artery stenting (CAS). CEA is a more invasive approach. There have been several studies comparing the efficacy of two procedures. A large multicenter randomized control trial, Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST), was conducted in 2010 comparing outcomes for carotid-artery stenting with carotid endarterectomy. In 2016, a 10-year follow-up to CREST found no significant difference between patients who underwent carotid artery stenting and those who underwent carotid endarterectomy with respect to the risk of periprocedural stroke, myocardial infarction, or death and subsequent stroke. However, it appeared that in older patients (older than 70 years) adverse events were more common with stenting where younger patients had better results with stenting versus endarterectomy. The decision about which procedure to have requires careful consideration in regard to symptomatic versus asymptomatic, patient age, comorbid conditions, and severity of stroke symptoms.

**Table 31.9 Noninvasive Diagnostic Tests for Assessing Carotid Artery Disease**

Noninvasive Diagnostic Test	Rationale
<b>Carotid duplex ultrasonography:</b> a noninvasive test that uses high-frequency sound waves to measure real-time blood flow and detect blockages or other abnormalities in the carotids	This is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis. Ultrasonography is an accurate method for measuring the severity of stenosis.
<b>Magnetic resonance angiography (MRA):</b> utilizing IV contrast dye, the MRA uses magnetic fields and radio waves to show blockages inside the arteries	MRA is increasingly used to evaluate for atherosclerotic carotid occlusive disease. MRA can generate high-resolution noninvasive images of the carotid arteries. The radiofrequency signal characteristics of flowing blood are sufficiently distinct from surrounding soft tissue to allow imaging of the arterial lumen.
<b>Magnetic resonance imaging (MRI):</b> a test that uses a magnetic field and pulses of radio wave energy to make pictures of organs and structures inside the body without contrast dye	MRI of the brain is essential in the assessment of acute stroke patients. MRI can differentiate areas of acute ischemia, areas still at risk for ischemia, and chronic cerebral ischemic changes.
<b>Computed tomography angiogram (CTA):</b> utilizing IV contrast dye to highlight the carotid arteries, the CTA highlights any areas of blockage or stenosis using an ultrafast CT scanner	CTA has gained increasing popularity in the evaluation of carotid disease. The advantages of CTA over MRA include faster data acquisition time and better spatial resolution even in very tortuous vessels.

## Carotid Endarterectomy

**Carotid endarterectomy (CEA)** is surgery to remove the plaque causing the occlusion in the carotid arteries. During the procedure, the plaque and arterial intima, along with portions of the media of the artery, are removed. A patch of autogenous vein or prosthetic material is then put in place (Fig. 31.8). The goal of the surgery is to improve blood flow through the carotid artery and prevent stroke. Wide fluctuations in the patient's BP are common, and excessive hypertension or hypotension may produce stroke. Perioperatively, the patient should have an intra-arterial catheter inserted to monitor BP so that cerebral perfusion can be maximized.

Following CEA, the patient is monitored in a postanesthesia care unit or an intensive care setting. Postoperative priorities include tight control of BP, frequent neurological reassessments (Table 31.10), and prevention of bleeding and incision site complications. Hospital lengths of stays vary, but usually patients are discharged within 48 hours postoperatively.

Medications post-CEA include antiplatelet aggregates, antihypertensives, and statins. Aspirin is recommended before CEA and may continue indefinitely postoperatively. Beyond the first month after CEA, aspirin, clopidogrel, or the combination of low-dose aspirin plus extended-release dipyridamole (inhibits clot formation) should be administered for long-term prophylaxis against reocclusion of the carotids.

## Carotid Artery Stenting

**Carotid artery stenting** is a procedure performed in combination with carotid angioplasty. During carotid angioplasty, the common carotid artery is accessed with a guiding catheter or a long sheath. A balloon catheter is then guided to the area of the blockage or narrowing. Once in place, the balloon is inflated, and the fatty plaque is compressed against the arterial wall to increase the lumen of the vessel and improve blood flow. During the angioplasty procedure, a carotid stent (a small, metal mesh tube) is placed inside the carotid artery at the site of the blockage to provide support to keep the artery open. Prior to stent

insertion, an emboli protection device (EPD) is deployed to capture distal emboli to prevent clots from traveling to the brain. Following EPD deployment, the stent is placed (Fig. 31.9). After placement, a post inflation of the stent with a balloon catheter is performed to achieve good stent expansion and adherence to the arterial wall. After stent placement, the EPD is removed.

The patient's neurological status, particularly level of consciousness, speech, and motor function, should be monitored throughout the stent procedure by the provider or the circulating nurse. It is important to avoid excessive sedation to facilitate this ongoing assessment. Intra-procedural management also includes adequate anticoagulation and hemodynamic monitoring.

Patients undergoing CAS are commonly pretreated with aspirin and clopidogrel prior to the procedure. Aspirin is continued life long, and clopidogrel is given for at least 1-month postprocedure. Administration of antihypertensive medication is recommended to control BP before and after CAS.

Nursing assessments postprocedure include frequent monitoring of vital signs, complete neurological assessment, and frequent access site monitoring. As with CEA, the focus is on recognizing and preventing the complications associated with carotid stenting.

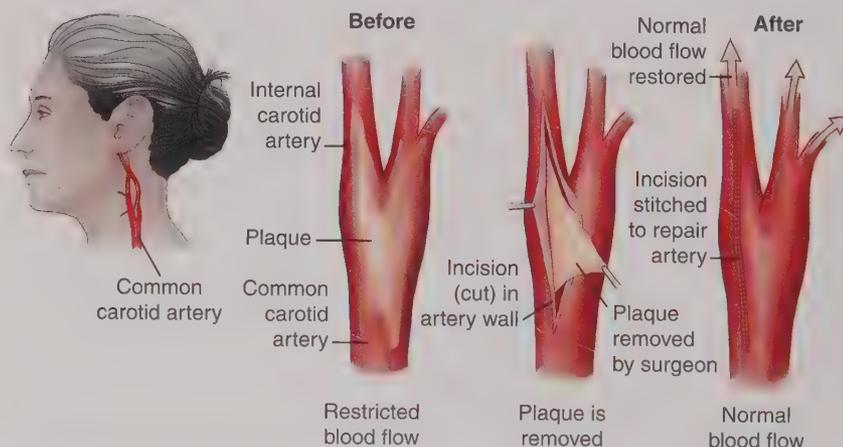

## Nursing Management

### Assessment and Analysis

Carotid artery disease is asymptomatic until the lumen of the vessel is obstructed to the point that cerebral perfusion is impaired. A bruit resulting from turbulent flow past the obstruction at the carotid bifurcation may be heard with a stethoscope. Symptoms of a stroke—slurring of words, weakness, severe headache, sudden vision loss, facial droop, or dizziness—are secondary to impaired perfusion to the cerebral tissues.

### Nursing Diagnoses

- **Risk for ineffective tissue perfusion: cerebral**, related to interruption of carotid blood flow
- **Risk for injury** related to loss of motor, sensory, or visual function

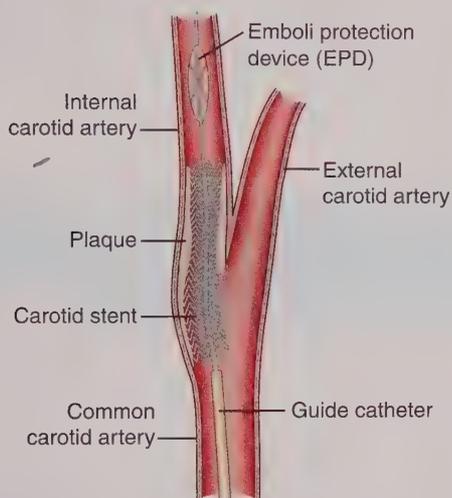

**FIGURE 31.8** Removal of plaque from the carotid artery.

**Table 31.10 Cranial Nerve Assessment Post-Carotid Endarterectomy (CEA)**

The incidence of cranial nerve injury during carotid endarterectomy ranges from 3% to 23%. Lesions on the lower cranial nerves are mainly due to surgical maneuvers. Nurses must assess the function of these nerves after surgery. The damage can be temporary or permanent.

Cranial Nerve Name	Assessment
<b>VII: Facial</b>	Symmetry of face when smiling and showing teeth
<b>X: Vagus</b>	Swallowing, gag reflex, ask the patient to say "Ah"
<b>XI: Spinal accessory</b>	Shrug shoulders, rotate head side to side
<b>XII: Hypoglossal</b>	Tongue control and movement, ask patient to stick out tongue

**FIGURE 31.9** Carotid stenting with distal emboli protection device filter.

- **Anxiety** related to the invasive procedure or surgery, uncertainty of the outcome of the procedure

### Nursing Interventions

#### Assessments

- Vital signs  
*Hypertension is a risk factor for carotid artery disease. Fluctuations in blood pressure and bradycardia may be complications of treatment.*
- Neurological assessment  
*Difficulty speaking, weakness, facial droop, acute vision problems, and acute headache may be signs of stroke.*
- Auscultation of the carotid arteries  
*Asymptomatic carotid artery stenosis may be identified by the presence of carotid bruits, sounds created by blood flow through a stenosed vessel, on auscultation.*

- Stroke history/signs of stroke  
*Determines if patient is symptomatic or asymptomatic which impacts treatment*

#### Postprocedure CEA/CAS

- Respiratory rate, SpO<sub>2</sub>, stridor, tracheal deviation  
*In CEA—Hematoma formation at the incision site can cause tracheal pressure resulting in respiratory distress, which can escalate rapidly as the hematoma enlarges.*
- Vital signs: HR, BP  
*In CEA—Prior to treatment, the carotid baroreceptor sensed a low pressure in the stenotic carotid artery. Following CEA, a new “normal” pressure may be sensed as a high pressure signalling the vagus nerve to respond, resulting in vasodilation, bradycardia, and hypotension. Prolonged hypertension may result in damage to the arterial graft, causing hemorrhage as well as placing the patient at risk of intracerebral haemorrhage.*  
*In CAS—Bradycardia, related to manipulation of the carotid sinus baroreceptors located in the carotid bulb, may occur during the procedure just after the stent implantation; Persistent hypotension can be caused by the effect of the stent on the carotid sinus baroreceptors.*
- Post-CEA—Cranial nerves, specifically VII, X, XI, and XII (see Table 31.10)  
*Retraction on the lower cranial nerves during surgery can result in temporary or permanent nerve damage due to trauma or edema.*
- Post-CAS - Renal function  
*Angiogram dye is nephrotoxic, especially in those patients who already have kidney disease.*

#### Actions

- Administer antihypertensive medication as ordered to maintain BP below 140/90 mm Hg  
*Prolonged increases in BP may cause vessel rupture, which leads to hemorrhage and stroke.*
  - Administer lipid-lowering medication as ordered  
*Reducing LDL-C helps reduce plaque formation in the carotid vessels.*
  - Administer antiplatelet aggregates as ordered  
*Antiplatelet therapy helps reduce platelet aggregation, resulting in decreased risk of obstruction in the vessel.*
  - Manage diabetes mellitus/maintain blood glucose within normal levels  
*Poorly controlled diabetes mellitus results in increased plaque formation in the vessels due to the breakdown of fats for energy, increasing the risk for ischemic stroke.*
- #### Postprocedure CEA/CAS
- Keep systolic blood pressure strictly within ordered parameters  
*To maintain integrity of the graft and/or flow through carotids*
  - If patient is hypotensive:
    - Reposition patient flat  
*Increase blood flow to increase cerebral perfusion*

- Anticipate orders for vasoactive drips or intravenous fluid bolus  
*Vasoactive drips cause vasoconstriction to increase blood pressure. Fluid bolus increases circulating volume, increasing BP.*
- If patient is hypertensive:
  - Maintain head of the bed at 30 degrees  
*Facilitates venous drainage and avoids excessive increases in cerebral blood volume.*
- Post-CEA—Keep head in neutral position  
*Decreases strain on incision site and carotid artery.*
- Post-CAS - Encourage fluid intake/Maintain IV fluids  
*Flush the contrast dye through the kidneys*

### ■ Teaching

- Clinical manifestations of a stroke: severe headache, facial drooping, loss of strength on one side, change in gag reflex, slurred speech, inability to stick out tongue and shrug shoulders equally; instruct patient and family to report neurological changes immediately.  
*The best outcomes occur with rapid treatment.*
- Lifestyle changes consistent with the management of atherosclerosis
  - DASH diet
  - Exercise
  - Smoking cessation
  - Limit alcohol  
*Atherosclerosis is implicated in the development and progression of carotid artery disease.*

## Connection Check 31.6

A nurse is performing the immediate postoperative assessment of a patient who has just undergone CEA. What is the most important assessment to be reported immediately?

- A complaint of 7/10 pain
- Falling back to sleep after assessment
- An asymmetric smile
- Complaint of a sore throat

### Evaluating Care Outcomes

A patient effectively managing carotid artery disease articulates awareness of risk factor modification such as compliance with the medication regimen and necessary lifestyle changes to limit complications. Adequate outcomes of care are demonstrated when the patient has no clinical manifestations of stroke or procedural complications such as pain, swelling, or bleeding.

## AORTIC ARTERY DISEASE (ANEURYSMS)

### Epidemiology

Approximately 15,000 people in the United States die each year of **abdominal aortic aneurysms (AAAs)**. Men develop AAAs four to five times more often than women. Caucasians develop AAAs more commonly than other racial

groups. **Thoracic aortic aneurysms (TAAs)**, the most common site for a dissecting aneurysm, occur most often in men between the ages of 40 and 70 years and have a high mortality rate even with surgical intervention.

Risk factors include family history, advanced age, male gender, smoking, atherosclerosis, treated and untreated hypertension, high total serum cholesterol, known coronary artery disease, and genetic and/or metabolic abnormalities. Atherosclerosis accounts for 75% of all AAAs, but of these risk factors, smoking is one of the most important. It is a risk factor that the patient can control, thus modifying the risk.

Genetics are a major factor in aortic aneurysms. Familial clustering of aortic aneurysms has been observed, with an estimated 15% to 20% incidence occurring in first-degree relatives of the individual with an aneurysm. Marfan's syndrome is the hereditary disease most closely linked to aneurysm. This syndrome results in the degeneration of the elastic fibers of the aortic media. Syphilis, patients born with bicuspid aortic valve, and Ehlers-Danlos syndrome, a rare genetic disorder, are other causes of AAAs. Chronic inflammation (aortitis) is implicated in the development of aneurysms. Blunt trauma, usually from motor vehicle crashes, can cause aneurysms in the descending thoracic or abdominal aorta. More importantly, blunt trauma can cause rupture of the aorta.

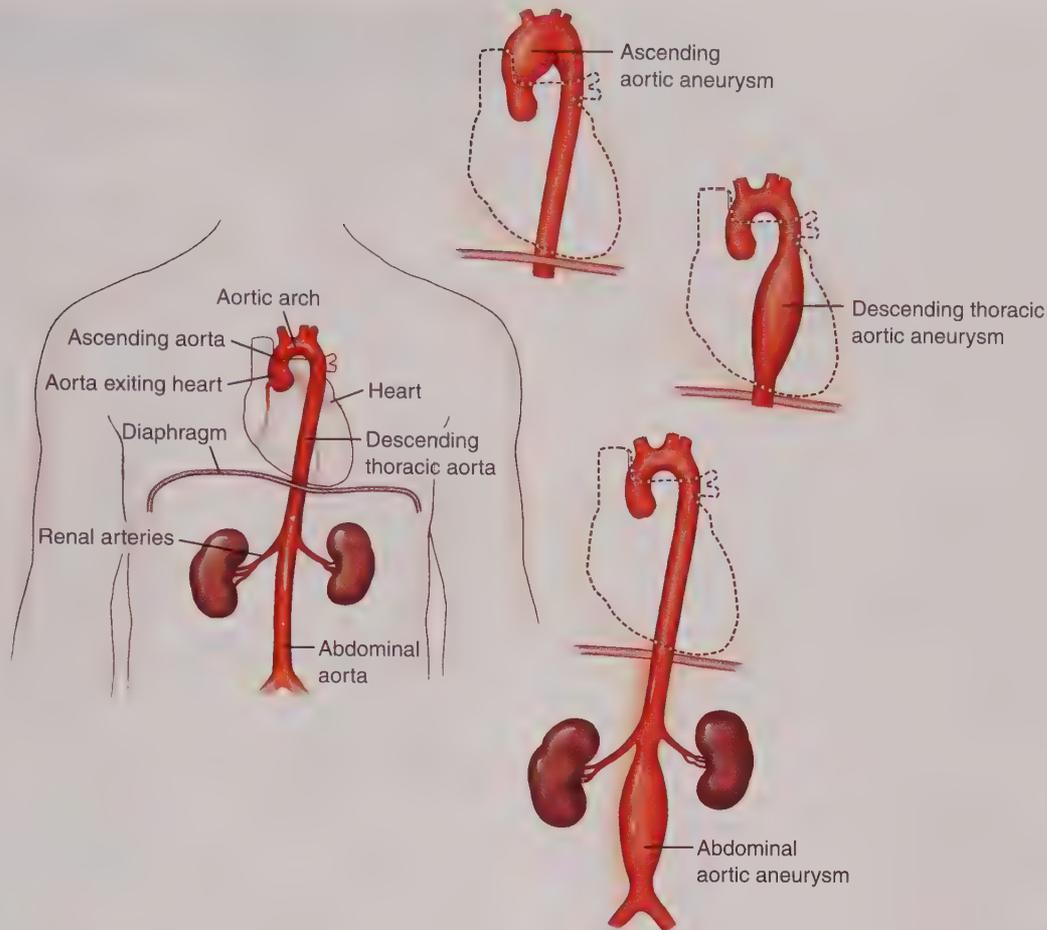

### Pathophysiology

An aneurysm is a permanent localized dilation of an artery that forms when the middle layer (media) of the artery is weakened, producing a stretching effect in the inner layer (intima) and outer layers of the artery. While the artery widens, tension in the wall increases, further widening occurs, and the aneurysm enlarges. The diameter of the artery can be enlarged to at least two times the normal circumference. Hypertension is one cause of that tension and enlargement within the artery. Other causes include congenital problems such as Marfan's syndrome or acquired problems such as atherosclerosis.

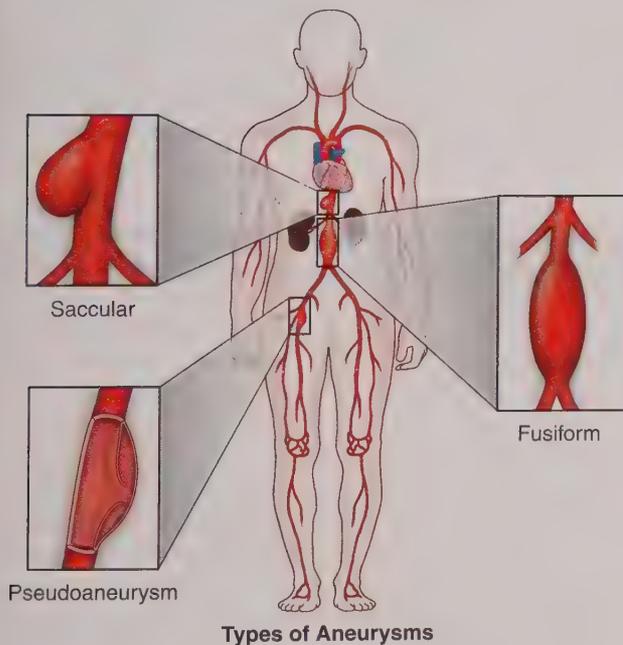

Aneurysmal degeneration of the aorta and iliac arteries is referred to as aortic aneurysm. Aneurysms can occur in three different areas of the aorta. Ascending aortic aneurysms are located in the arch of the aorta, descending aortic aneurysms or thoracic aneurysms are located above the diaphragm, and abdominal aortic aneurysms (AAAs) are located below the diaphragm in the abdomen. The abdomen is the most common location (Fig. 31.10).

Aneurysms are classified as true or false. In true aneurysms, all three layers of the arterial wall are weakened. True aneurysms are further classified by their shape or form (Fig. 31.11). The most common forms are saccular and fusiform. A saccular aneurysm projects from only one side of the vessel. If an entire arterial segment becomes dilated, a fusiform aneurysm develops.

A false or pseudoaneurysm is not a distortion of the vessel wall but rather a leak from the artery. The leak is confined by the surrounding tissues, and eventually a blood clot forms. Pseudoaneurysms are typically caused by iatrogenic trauma

**FIGURE 31.10** Thoracic and abdominal aneurysms; ascending aortic, descending aortic and abdominal aortic aneurysms.

**Types of Aneurysms**

**FIGURE 31.11** Types of aneurysms; saccular aneurysms project from only one side, a fusiform aneurysm is present when the entire arterial segment becomes dilated, a false or pseudoaneurysm is a leak from the artery typically caused by iatrogenic trauma that punctures the artery.

that punctures the artery. They are a known complication of percutaneous arterial procedures such as arteriography.

### Clinical Manifestations

In most cases, aortic aneurysms cause no symptoms and are found when the patient is evaluated for another medical condition.

Clinical manifestations typically occur when a complication such as dissection or rupture occurs. There may be a palpable pulsatile mass in the abdomen with the AAA. Sometimes the patient presents with chest, back, or flank pain depending on the location of the aneurysm. The pain is typically not related to any activity and occurs spontaneously. Pain generally reflects a change in the aneurysm that needs immediate attention.

### Management

#### Medical Management

#### Diagnosis

A number of imaging modalities can be used to detect and diagnose aortic dilation. Computed tomography scanning with IV contrast is considered the gold standard for

assessing the size and location of an abdominal or thoracic aneurysm. Abdominal ultrasound or transthoracic echocardiography (TTE) have also been preferred screening modalities because they can be done quickly and efficiently at the bedside and because of their noninvasive nature and lack of radiation. Cardiac MRI is an imaging modality that has shown improved sensitivity and specificity versus TTE in detecting aortic dilation. The lack of radiation exposure with MRI compared with CT may make it the imaging modality of choice for aortic dilation. An ECG is also routinely done to rule out an MI because complications of aneurysm usually involve chest pain.

### Medications

Treatment is focused on reducing the growth rate and preventing the complications of aneurysms. Hypertension is an important risk factor for rupture, so BP is aggressively managed with antihypertensive medications such as angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers (ARBs), and/or beta blockers. In addition to antihypertensive medications, macrolides and tetracyclines, antibiotics that may inhibit secondary infections implicated in aneurysm development, have been proposed as a treatment for AAA with varying rationales and degrees of success. There is also evidence from a number of studies suggesting that statins may influence aneurysm growth rate by reducing the progression of atherosclerosis (Table 31.11).

### Surgical Management

The size and location of the aneurysm along with the presence of symptoms are the determining factors for patient management (Table 31.12).

Currently, surgical intervention is shown to be the only treatment effective in preventing AAA rupture and aneurysm-related death. The most common surgical procedure for AAA has traditionally been a resection and repair (aneurysmectomy). In this procedure, the aneurysm is excised, and a graft is applied. Surgical repair is associated with risks that include bleeding, infection, MI, renal failure, and graft

**Table 31.11 Medications Used in Aneurysm Management**

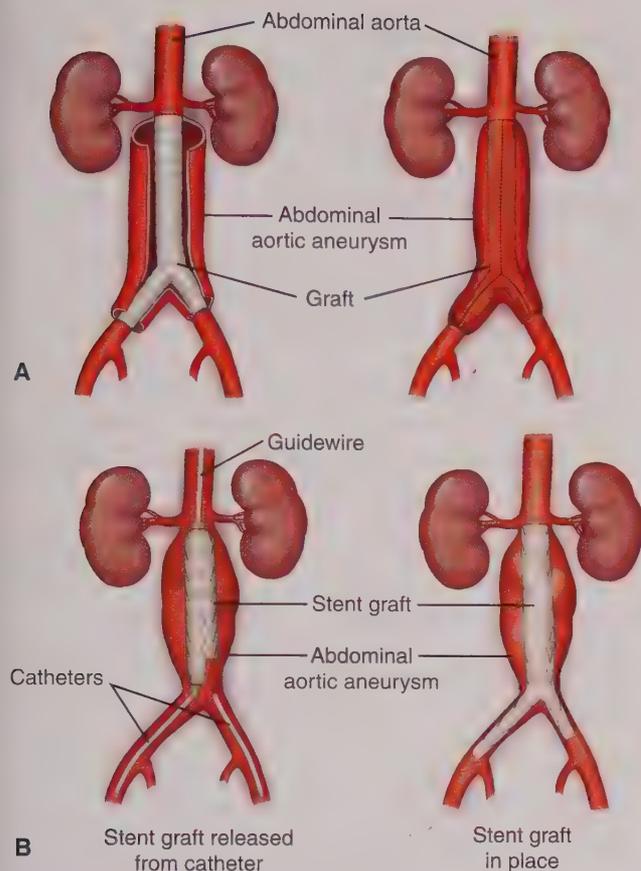

Medication	Description
<b>Macrolides</b>	(Antibiotics) Inhibit abdominal aortic aneurysm (AAA) progression by reducing secondary infection within aortic wall
<b>Tetracyclines</b>	(Antibiotics) Inhibit matrix metalloproteinase (MMP), which is involved in aneurysm formation; decrease the rate of aneurysm expansion
<b>Statins</b>	Reducing the progression of atherosclerosis may influence aneurysm growth.

**Table 31.12 Assessment and Analysis for Aneurysms**

Assessment Data	Analysis/Explanation
<b>Thoracic Aneurysm</b>	
Pain (constant)	Caused by stretching of the aortic tissue and impingement on adjacent structures
Heart failure	Ascending aneurysms may produce heart failure and its associated symptoms by causing aortic regurgitation. As the aortic root enlarges, the aortic valve leaflets are pulled away from each other, permitting backward leakage of blood.
Dyspnea	Respiratory symptoms caused by distortion and obstruction of trachea by the aneurysm
Cough	
Hoarseness of voice	Caused by distortion of the phrenic nerve or direct impingement on the esophagus by the aneurysm
Dysphagia	
<b>Abdominal Aneurysm</b>	
Pain	Pain occurs in the back and abdomen because of impingement on adjacent structures and stretching of aortic tissue
Abdominal throbbing	Noticeable, small pulsating mass near the navel due to increased aortic pressure
Cyanosis	Blood can pool in the part of the aorta that is bulging, and a blood clot can develop inside the aneurysm. If the clot breaks loose, symptoms such as pain, numbness, tingling, and cyanosis may result.
Blood clots	

occlusion. Benefits versus risks should be weighed when considering an elective surgical repair of the aneurysm. More recently, endovascular aneurysm repair (EVAR) has gained acceptance as an alternative to open surgical repair with reduced periprocedural risks. The endovascular alternative is an endothelial stent graft or EVAR, which involves the transluminal placement and attachment of a sutureless aortic graft prosthesis across an aneurysm. The aneurysm eventually shrinks down onto the stent graft (Fig. 31.12).

Most people with an aneurysm less than 5 cm in diameter are advised not to have immediate surgery. The goal for patients who do not require immediate surgical intervention is to monitor the growth of the aneurysm over time and to maintain the BP at a normal level to decrease the risk of rupture. For those with small or asymptomatic aneurysms, regular ultrasounds or CT scans are necessary to monitor the growth of the aneurysm.

**FIGURE 31.12** Aneurysm repair with surgery compared with stent placement. *A*, Aneurysmectomy; the aneurysm is excised, and a graft is applied. *B*, Endovascular aortic repair; placement and attachment of a sutureless aortic graft prosthesis across an aneurysm.

Patients with TAAs measuring 2.8 in. (7 cm) in diameter or with AAAs measuring 2 in. (5 cm) in diameter or those with smaller aneurysms that are producing symptoms are advised to have elective surgery (see Geriatric/Gerontological Considerations). A small aneurysm that expands more than 0.5 cm over a 6-month period of time should also be repaired surgically.

## Geriatric/Gerontological Considerations

### Elective Surgery

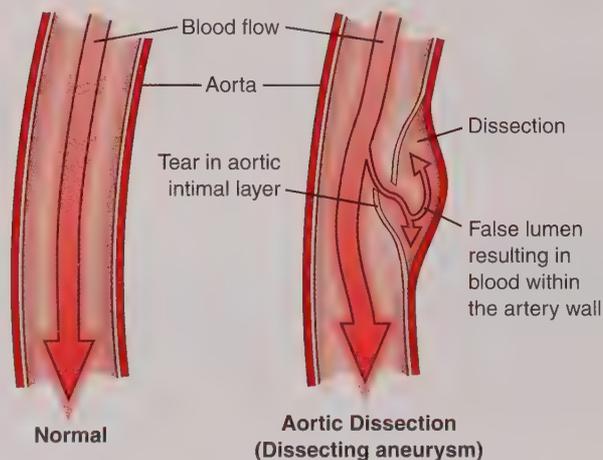

Most abdominal aortic aneurysms occur in patients between 60 and 90 years of age. Rupture is likely with coexisting hypertension and with aneurysms more than 6 cm wide. At this point, the risk of rupture is greater than the risk of death during surgical repair. Therefore, elective surgical repair should be considered carefully if the patient is able to withstand surgery and anesthesia. It is important that the healthcare team provides the patient and family with all the facts regarding the risk and benefit in order for the patient and family to make the most informed decision.

## Complications

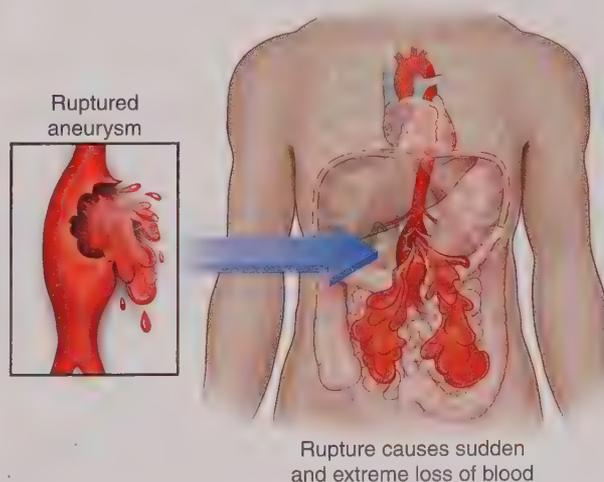

**Aortic dissection** (dissecting aneurysm) is thought to be caused by a sudden tear in the aortic intima creating a false lumen in the artery opening the way for blood to enter the aortic wall. Degeneration of the aortic media may be the primary cause for this condition, with hypertension being an important contributing factor. Dissection is also frequently linked with Marfan's syndrome. This is a life-threatening emergency because of the loss of circulation to any major artery arising distal to the dissection. The ascending and descending thoracic aortae are the most common sites, but dissections can also occur in the abdominal aorta (Fig. 31.13).

Classic signs and symptoms of aortic dissection are sudden onset of severe and persistent pain described as "tearing" or "ripping" in the anterior chest or back and extending to the shoulders, epigastric area, or abdomen. Diaphoresis, nausea, vomiting, faintness, and tachycardia are also common. Blood pressure is often markedly different from one extremity to another and often decreases because of loss of blood.

Rupture of the aortic aneurysm is the most life-threatening complication (Fig. 31.14). Rupture causes sudden and

**FIGURE 31.13** Aortic dissection (dissecting aneurysm).

**FIGURE 31.14** Ruptured aneurysm.

extreme loss of blood. Patients may present similar to those with a dissection with symptoms such as pain, tachycardia, and differing BPs between extremities, but in extreme cases, pain occurs then loss of consciousness due to hypovolemic shock from massive blood loss. The death rate in all patients with a ruptured abdominal aortic aneurysm (RAAA) or dissection is around 80%. One-third of all patients with an RAAA do not reach the hospital alive, and one-third do not have an intervention. Of the patients having an intervention, only half survive the intervention and admission.

Emergency surgical procedures are indicated for patients with a ruptured or dissecting abdominal aortic or thoracic aneurysm. Mortality rates increase dramatically once dissection or rupture has occurred as compared to the mortality rate if surgery is performed electively.

### Connection Check 31.7

A nurse is assessing a patient in the emergency department with the complaint of sudden onset of severe back pain, tachycardia, and hypotension. Which interventions should the nurse anticipate? (Select all that apply.)

- A. Electrocardiogram
- B. Aortic arteriography
- C. Ultrasonography
- D. Chest x-ray
- E. Computed tomography scan

### Nursing Management

#### Assessment and Analysis

Most AAAs are small and do not cause any symptoms. The vast majority of thoracic aneurysms are silent, with rupture or dissection constituting the first symptoms. Overall, only 5% to 10% of patients experience symptoms such as chest, back, or flank pain depending on the location of the aneurysms.

#### Nursing Diagnoses

- **Risk for ineffective peripheral tissue perfusion** related to interruption of arterial blood flow
- **Acute pain** related to vascular enlargement, dissection or rupture
- **Fear** related to threat of injury or death or the surgical intervention

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Hypotension and tachycardia may indicate hypovolemia secondary to a loss of circulating volume. Blood pressure may vary between extremities if dissection is occurring because of the lessening of blood flow distal to the dissection. Hypertension, elevated diastolic pressure, and tachycardia can further weaken the vessel wall, increasing the risk that the aneurysm will enlarge, dissect, or rupture.*

- Neurological assessment  
*An aneurysm of the aortic arch can cause neurological symptoms similar to those of a TIA or stroke. The bulging aorta exerts pressure on the subclavian artery, decreasing blood flow through the common carotid arteries to the brain, causing neurological effects.*
- Pain  
*Persistent abdominal, chest, or back pain indicates that the aneurysm is pushing on adjacent organs and structures and may help pinpoint the location. Pain is also an indicator of a change such as dissection or rupture.*
- Peripheral pulses, skin color, and temperature  
*Weak peripheral pulses, poor color, and cool extremities indicate lack of arterial flow, potentially because of dissection or thrombus formation in the aneurysm.*
- Peripheral sensation and motor response  
*Paresthesias or paralysis may indicate pressure against the arteries supplying the spinal cord.*
- Gentle abdominal auscultation and palpation  
*Pulsatile abdominal masses may indicate an AAA. A bruit is caused by turbulent flow through the aneurysm.*

##### ■ Actions

- Administer antihypertensives as ordered  
*Antihypertensives control high BP, which is a major risk factor for aneurysm rupture.*
- Administer statins as ordered  
*Statins lower cholesterol and therefore reduce the risk of atherosclerosis, which may reduce the aneurysm growth rate.*
- Administer tetracyclines and macrolides as ordered  
*These types of antibiotics may inhibit AAA progression by reducing secondary infections within the aortic wall.*
- Administer stool softeners as ordered  
*Prevent strain on the aneurysm during defecation*
- Create calm environment to reduce stress  
*Reduction in stress has been shown to reduce BP and therefore lessen stress on the aneurysm.*

##### ■ Teaching

- Signs and symptoms of aortic aneurysm and aortic dissection such as any new chest, abdominal, or flank pain, especially new pain not associated with increased activity  
*It is important that the patient is able to detect signs and symptoms of an aortic aneurysm and aortic dissection to allow prompt intervention.*
- Patients with Marfan's syndrome should be encouraged to do regular screening and call their provider with any new chest, abdominal, or flank pain.  
*Patients with Marfan's syndrome are at increased risk for aneurysms due to the degeneration of the elastic fibers of the aortic media that occurs with that disease. Because of the emergent nature of aortic dissection, immediate recognition is essential to allow emergent repair.*

- Following a strict treatment regimen which includes
  - Compliance with medications
  - Smoking cessation program if the patient is a smoker
  - Maintaining a healthy weight
  - Regular exercise
  - Avoid crossing or elevating legs to decrease pressure on the aorta and iliac arteries
  - Stress reduction
  - Following diagnostic testing and screening recommendations (includes regular blood pressure and cholesterol checks).
  - Obtaining regular ultrasounds to measure the aneurysm's growth

*Compliance with the treatment regimen is essential in successful management of aortic disease.*

### Connection Check 31.8

Which statements by a patient with a AAA indicate that teaching has been effective? (Select all that apply.)

- A. "I need to quit smoking."
- B. "I need to go to the emergency department immediately if I have new severe abdominal pain."
- C. "The doctor may put me on blood thinners."
- D. "I need to stay on my blood pressure medication."
- E. "I should keep my legs elevated whenever possible."

### Evaluating Care Outcomes

Patients with aortic aneurysms can achieve a good outcome by complying with the prescribed therapy. Blood pressure and HR within normal limits, strong peripheral pulses, normal skin color and texture, no complaints of abdominal, back, or chest pain, no complaints of wheezing and shortness of breath, no complaints of dysphagia or hoarseness, and a normal neurological assessment indicate a stable aneurysm.

## DEEP VEIN THROMBOSIS

### Epidemiology

Deep vein thrombosis (DVT) is a blood clot in a large vein, usually in the leg or pelvis. The prevalence of DVT is about 1 per 1,000 persons per year. Sometimes a DVT detaches from the site of formation and becomes mobile in the bloodstream. If the circulating clot moves through the heart to the lungs, it can block an artery supplying blood to the lungs. This condition is called **pulmonary embolism (PE)**. It is estimated that approximately 350,000 to 900,000 Americans each year suffer from DVT and PE. The disease process that includes DVT and/or PE is called **venous thromboembolism (VTE)**. At least 100,000 deaths may be directly or indirectly related to these diseases. Also, of note, approximately 10% to 30% of persons who survive the first occurrence of VTE develop another VTE within 5 years.

VTE is receiving increased attention from patient safety experts. A specific focus is on hospitalization as a risk factor as injury and surgery are causes of vascular injury and the prolonged bedrest often associated with hospitalization can cause venous stasis leading to clot formation. Approximately half of new VTE cases occur during a hospital stay or within 90 days of an inpatient admission or surgical procedure, and many are not diagnosed until after discharge.

Deep vein thrombosis is much less common in the pediatric population. Approximately 1 in 100,000 children younger than 18 years experience a DVT. This is possibly because of a child's higher heart rate, relatively active lifestyle, and fewer comorbidities when compared with adults. In pregnant women, it has an incidence of 0.5 to 7 per 1,000 pregnancies. It is the second-most common cause of maternal death in developed countries after bleeding.

Risk factors include increasing patient age, active cancer with or without concurrent chemotherapy, varicose veins, prior venous thrombosis, pregnancy, postpartum period, and oral contraceptive and hormone therapy. Surgery, trauma, hospital or nursing home confinement resulting in immobility, and procedures such as central vein catheterization or transvenous pacemaker insertion also increase the risk.

### Pathophysiology

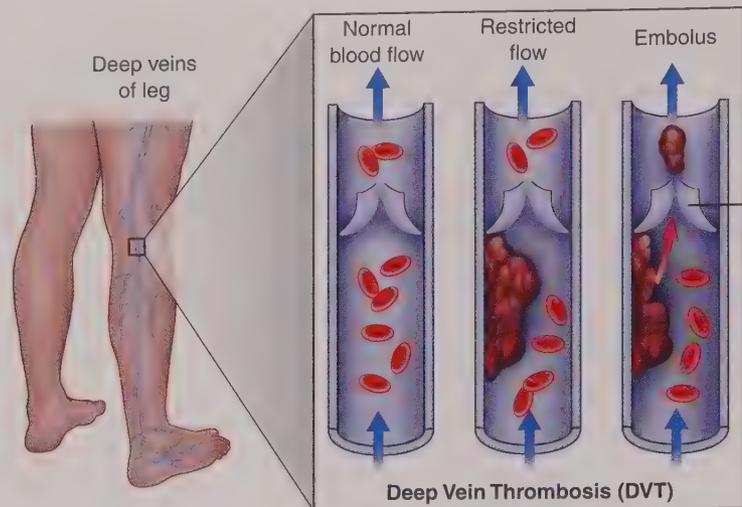

**Virchow's triad** describes the factors implicated in the formation of a venous thrombosis; decreased flow rate of the blood or stasis of blood flow, damage to the blood vessel wall; endothelial injury, and an increased tendency of the blood to clot (hypercoagulability).

Deep vein thrombosis, more common in the veins of the lower extremity, develop in the deep veins of the calf muscles or, less frequently, in the proximal deep veins of the lower extremity or upper arm. The deep veins that lie near the center of the leg are surrounded by powerful muscles that contract and force deoxygenated blood back to the lungs and heart. One-way valves prevent the backflow of blood between the contractions. Blood is squeezed up the leg against gravity, and the valves prevent it from flowing back to the feet. When the circulation of the blood slows down because of illness, injury, or inactivity, blood can accumulate or "pool," which provides an ideal setting for clot formation.

See Figure 31.15 for an illustration of DVT formation.

### Clinical Manifestations

People with DVT may or may not have symptoms. The clot(s) can cause partial or complete blockage of circulation in the vein, which can lead to pain, swelling, tenderness, discoloration, or redness and warmth in the affected area. The clinical manifestations vary depending on the size, location, degree of vessel occlusion, and adequacy of collateral circulation. Table 31.13 describes common clinical manifestations associated with calf, femoral, iliofemoral, and upper extremity thrombosis. The presence of Homans' sign, calf pain elicited on dorsiflexion of the foot, may

**FIGURE 31.15** Deep vein thrombosis with the possibility of an embolus breaking off and traveling to the lungs.

indicate the presence of a DVT but its routine use in evaluation is not recommended as it is frequently misinterpreted and is not a reliable predictor.

## Management

### Medical Management

#### Diagnosis

Diagnostics include a combination of pre-test probability (PTP) testing, D-dimer testing, and compression ultrasonography (CUS). These have proven to be the most accurate, safe, and effective diagnostic tools for DVT. The evaluation of a patient with a suspected DVT begins with

an assessment of a set of clinical prediction rules, pre-risk probability, for DVT. The Wells score is a PTP scoring system that categorizes patients as high, moderate, or low probability. This is based on the presence of clinical features commonly associated with DVT and identification of an alternative diagnosis. Box 31.3 outlines both the PTP and DVT risk classification.

In patients with a low or moderate probability the next step is D-dimer testing. The D-dimer test is a global

**Table 31.13** Common Signs and Symptoms Associated With Deep Vein Thrombosis

Site	Clinical Manifestations
<b>Calf thrombosis</b>	Calf tenderness Distal swelling of affected extremity
<b>Femoral thrombosis</b>	Tenderness and pain in distal thigh and popliteal regions Swelling more prominent than with calf vein thrombosis alone Swelling may extend to knee
<b>Iliofemoral thrombosis</b>	Massive swelling in affected extremity Tenderness and pain involving entire extremity
<b>Upper-extremity thrombosis</b>	Swelling of affected extremity Dilated superficial veins Tenderness and pain Impaired mobility of extremity

### Box 31.3 DVT Prerisk Probability Testing

#### Wells Score or Criteria: (Possible Score -2 to 8)

PRETEST – One point is given for each positive finding in the pretest, and 2 points are subtracted if an alternative diagnosis as likely as DVT is identified.

- Active cancer (treatment within last 6 months or palliative) = 1 point
- Calf swelling greater than 3 cm compared to other calf (measured 10 cm below tibial tuberosity) = 1 point
- Collateral superficial veins (nonvaricose) = 1 point
- Pitting edema (confined to symptomatic leg) = 1 point
- Previously documented DVT = 1 point
- Swelling of entire leg = 1 point
- Localized pain along distribution of deep venous system = 1 point
- Paralysis, paresis, or recent cast immobilization of lower extremities = 1 point
- Recently bedridden greater than 3 days, or major surgery requiring regional or general anesthetic in past 4 weeks = 1 point
- Alternative diagnosis at least as likely – subtract 2 points

#### DVT RISK CLASSIFICATION

- High probability = 3 points
- Moderate probability = 1–2 points
- Low probability = 0 points

marker of coagulation activation by measuring fibrin degradation products produced from fibrinolysis (clot breakdown). A negative D-dimer test can exclude DVT without an ultrasound. Conversely, an elevated D-dimer suggests DVT but requires further testing to confirm the diagnosis because of the low specificity of the test. This low specificity is caused by the increase of the D-dimer level in other conditions, including infection, inflammation, cancer, surgery and trauma, extensive burns or bruises, ischemic heart disease, stroke, PAD, ruptured aneurysm or aortic dissection, or pregnancy. In the presence of a positive D-dimer or high probability PTP the next step is compression ultrasonography (CUS). It allows rapid and clear visualization of thrombi, including identification of unstable or floating thrombi, which may cause emboli.

Contrast venography, CT venography and MRI venography are other diagnostic tools but are rarely needed or utilized. These alternatives to ultrasound may be beneficial in selective cases, such as in the morbidly obese or when pelvic or abdominal thrombosis is suspected.

### Prevention

The first step in treatment is prevention. In low risk patients, early ambulation may be all that is necessary. Venous thromboembolism (VTE) prophylaxis is indicated in at-risk hospitalized populations. In patients with a low bleeding risk pharmacological prevention is recommended. Preferred medications include low molecular weight heparin (LMWH), unfractionated heparin, or, in patients with heparin-induced thrombocytopenia (HIT), fondaparinux can be used. In patients with a higher risk of bleeding mechanical VTE prophylaxis is indicated. This includes the use of graduated compression stockings, venous foot pumps, and active external intermittent compression devices. The benefits of these methods include their effectiveness, ease of application, and safety especially in respect to bleeding. Intermittent compression devices apply external pressure to the limb which promotes blood flow velocity, reduces venous stasis, and increases levels of systemic fibrinolysis. Despite widespread use, there is limited evidence regarding the use of graduated compression stockings, venous foot pumps, or combined medical and mechanical prophylaxis.

### Medications

Medication therapy typically consists of anticoagulation with unfractionated heparin or low molecular weight heparin (LMWH) followed by long-term oral anticoagulation with warfarin. These conventional anticoagulant therapies are widely used but have limitations. They require regular monitoring to maintain safe levels (see safety alert). Newer oral anticoagulant agents, including direct thrombin inhibitors (e.g., dabigatran etexilate) and direct factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban) have been developed to overcome some of the limitations of conventional anticoagulant therapy.

These new oral agents have been evaluated for safety and efficacy in large, randomized clinical trials in the treatment and secondary prevention of VTE with results that are comparable to conventional therapy. These medications are important new treatment options for patients with VTE because they are effective and do not require regular monitoring.

The use of thrombolytic therapy such as tissue plasminogen activator (tPA) is not routinely administered in patients with DVT. These thrombolytic agents have a more rapid and complete thrombolysis, thus potentially preventing PE and decreasing the incidence of reoccurring DVT but are not associated with decreased mortality and are associated with increased risks for bleeding. Because of this, thrombolytics are only used under certain circumstances. They include patients who have failed conventional therapy with a clot that has been present for fewer than 14 days and have a low bleeding risk. Further assessment is made based on individual patient circumstances such as size and location of the clot and preexisting conditions. See Table 31.14 for a comparison of anticoagulant therapies.

#### **Safety Alert** Essential teaching points for patients on warfarin:

1. Immediately report blood in sputum, emesis, stool, or urine.
2. Take the medication at the same time every day.
3. Never skip a dose of the medication.
4. Have laboratory values (international normalized ratio [INR]) checked on a regular basis.
5. Ensure that laboratory levels are safe to continue current dosage or change dosage.
6. Limit intake or maintain a consistent intake of green leafy vegetables that contain vitamin K (kale, spinach, collard greens, broccoli, okra, cabbage) that may counteract the action of warfarin.
7. Consult with your care provider before taking aspirin or Plavix in addition to warfarin.
8. Limit any physical activities that will increase bleeding risk such as contact sports.
9. Use an electric razor when shaving.
10. Use a soft toothbrush.

### Surgical Management

Surgical management is rarely utilized to remove a DVT unless there is a massive occlusion that does not respond to medical treatment and the thrombus is of recent (1–2 days) onset. Thrombectomy is the most common surgical procedure for removing a clot.

Other less-invasive surgical procedures include balloon angioplasty, stent placement, and vena cava interruption. Balloon angioplasty widens the vein after a blood clot has

been dissolved. As with other balloon angioplasty procedures, expanding the balloon in the vein causes the vein to widen and improves blood flow. Stent insertion can be utilized for DVT patients who have a vein that is prone to collapse. The stent expands once inserted and acts as a support for vein walls.

The purpose of vena cava interruption is to prevent PE. In this procedure, a provider surgically positions a filter inside the inferior or, not routinely, the superior vena cava between the DVT and the heart. Blood flows normally through the umbrella-like filter, but emboli are trapped, ensuring that they do not reach the lungs.

**Table 31.14 Anticoagulant Therapy**

Anticoagulant	Action	Possible Complications	Nursing Implications
<b>Unfractionated heparin (UFH)</b>	Inhibits clot formation by inhibiting clotting factors IIa (thrombin) and Xa, which in turn inhibits fibrin formation. Over a long period, the existing clot is slowly absorbed by the body.	Heparin-induced thrombocytopenia (HIT) – platelet aggregation caused by heparin-induced antiplatelet antibodies leads to thrombocytopenia	<ul style="list-style-type: none"> <li>● Baseline laboratory determinants; *aPTT, **PT with ***international normalized ratio (INR), platelet count, and stool for occult blood are required before initiation</li> <li>● Dosage is weight based and nomograms typically using aPTT are used to measure therapeutic blood levels</li> <li>● Heparin should be continued 5–10 days</li> <li>● Oral anticoagulation should overlap</li> <li>● Protamine sulfate is an antidote for excessive bleeding</li> </ul>
<b>Low molecular weight heparin (LMWH)</b> Enoxaparin (Lovenox) Dalteparin (Fragmin) Ardeparin (Normiflo)	Inhibits clot formation by inhibiting thrombin formation due to reduced factor IIa; has less of an effect on thrombin compared to heparin but maintains the same effect on factor Xa	Bleeding and thrombocytopenia (less bleeding risk than with UFH)	<ul style="list-style-type: none"> <li>● Growing trend of using LMWH as replacement for UFH</li> <li>● Benefit is no laboratory monitoring unless treatment exceeds 7 days</li> <li>● Oral anticoagulation therapy should overlap</li> <li>● Home administration is a benefit</li> </ul>
<b>Xa inhibitors</b> Rivaroxaban (Xarelto) Apixaban (Eliquis) Edoxaban (Savaysa) Dabigatran (Pradaxa)	Exert anticoagulant effect via direct inhibition of a single factor within the coagulation cascade (such as Factor Xa or thrombin), thereby prolonging clotting times	Bleeding	<ul style="list-style-type: none"> <li>● Advantages include: rapid onset and offset of action which reduces having to use additional anticoagulants to bridge treatment, do not require frequent monitoring or redosing, have few medication interactions, and little to no food interactions.</li> <li>● No antidote available in the event of a major bleed</li> <li>● Diet and lifestyle teaching regarding bleeding risk are essential</li> <li>● Contraindicated in patients with severe renal impairment</li> </ul>
<b>Warfarin (Coumadin)</b>	Works in the liver to inhibit synthesis of four vitamin K–dependent clotting factors	Bleeding	<ul style="list-style-type: none"> <li>● Close monitoring required with laboratory values; PT/INR</li> <li>● Therapeutic levels monitored by INR</li> <li>● Takes 3–4 days to achieve therapeutic anticoagulation</li> <li>● Medication usually taken 3–6 months after deep vein thrombosis (DVT)</li> <li>● Vitamin K is the antidote for warfarin</li> <li>● Diet and lifestyle teaching are essential</li> </ul>

**Table 31.14 Anticoagulant Therapy—cont'd**

Anticoagulant	Action	Possible Complications	Nursing Implications
<b>Thrombolytics</b> (streptokinase, urokinase, recombinant tissue plasminogen activators)	Dissolve existing thrombi and impair coagulation by increasing fibrinolytic activity through the conversion of circulating plasminogen to plasmin	Significant risk of hemorrhage, intracranial bleeding	<ul style="list-style-type: none"> <li>● Nurse should watch for signs of bleeding and alert provider of fibrinogen level less than 100 mg/dL because of high bleeding risk</li> <li>● May prevent valvular damage and venous insufficiency</li> <li>● Contraindicated after surgery, trauma, strokes, or spinal injuries (increased bleeding risk)</li> </ul>

\**APTT* or *aPTT* = Activated partial thromboplastin time evaluates the intrinsic and common coagulation pathways. It is used to evaluate the effectiveness of heparin

\*\**PT* = Prothrombin time evaluates the extrinsic coagulation pathway

\*\*\**INR* = International normalized ratio (a standardized measure of *PT*) evaluates the extrinsic coagulation pathway. It is used to evaluate the effectiveness of warfarin

## Complications

The most serious life-threatening complication that can arise from DVT is a PE, which occurs in more than one-third of DVT patients. A PE occurs when a dislodged blood clot travels first to the heart and then to the lungs, where it can partially or completely block a pulmonary artery or one of its branches. The hemodynamic response to PE depends on the size of the embolus, coexistent cardiopulmonary disease, and neurohormonal effects. Clinical manifestations include:

- Shortness of breath
- Decreased oxygen saturation
- Tachycardia, hypotension
- Sweating
- Sharp chest pain (especially during deep breathing)
- Hemoptysis (bloody sputum)

These clinical manifestations are due to the clot in the pulmonary vasculature blocking flow through the lungs preventing oxygenation and ventilation, increasing pulmonary vascular resistance (PVR), increasing the workload on the right heart, and decreasing oxygen supply to the lung tissue itself. Hemodynamic decompensation occurs not only because of physical obstruction of blood flow but also because of the release of humoral factors such as serotonin from platelets, thrombin from plasma, and histamine from tissue. Pulmonary embolism can frequently cause death, particularly when one or more of the vessels that supply the lungs with blood is completely obstructed. For almost one-quarter of PE patients, the initial clinical presentation is sudden death.

Another complication that develops in 25% to 50% of patients after a DVT is post thrombotic syndrome (PTS). It is a chronic disorder with clinical features that range from minor limb swelling and discomfort to severe leg pain, intractable edema, irreversible skin changes, and leg ulceration. Prevention of PTS with the use of thromboprophylaxis is important because treatments are not very effective. Elastic compression stockings (ECSs) have the potential to prevent

PTS by reducing venous hypertension and reflux, which are thought to be principal factors in the pathophysiology of PTS. However, a survey of thrombosis providers showed a lack of agreement on the benefits of ECSs or the optimum timing, indication, and duration of their use.

## Connection Check 31.9

A patient has been admitted to the hospital for a PE. What is the priority nursing intervention?

- Insert an IV line
- Begin heparin drip as ordered
- Check oxygen saturation
- Determine patient allergies

## Nursing Management

### Assessment and Analysis

The clinical manifestations of DVT vary depending on the size, location, degree of vessel occlusion, and adequacy of collateral circulation. Patients may complain of pain, and there may be redness, swelling, and warmth due to obstruction of flow in the affected extremity.

### Nursing Diagnoses

- **Ineffective peripheral tissue perfusion** related to interruption of venous blood flow
- **Acute pain** related to vascular inflammation and irritation and edema formation
- **Risk for impaired physical mobility** related to pain and discomfort of the affected extremities

### Nursing Interventions

#### ■ Assessments

- Vital signs with oxygen saturation  
*Hypotension, tachycardia, and decreased oxygen saturation could indicate the presence of a PE or bleeding, especially if the patient is anticoagulated.*

- Assess extremity for pain, tenderness, warmth, redness, or swelling  
*Common symptoms of DVT that occur because of obstruction of blood flow and may indicate location of the clot*
- Compare right and left calf, thigh, or arm circumferences  
*Localized edema due to obstruction to blood flow in one extremity may suggest a DVT.*
- Gentle palpation to inspect for induration  
*Induration (hardening) helps to locate the placement of the clot in the blood vessel.*
- D-dimer test  
*Measures fibrin degradation products produced from clot breakdown. A positive result stratifies the patient into a high-risk category for DVT.*
- Laboratory values: INR, PT/aPTT, hemoglobin, and hematocrit
  - The INR and PT/aPTT should be prolonged.
  - The hemoglobin and hematocrit should be within normal limits.  
*The PT/INR evaluates the extrinsic coagulation cascade and is used to evaluate the effectiveness of warfarin.*  
*The aPTT evaluates the intrinsic coagulation cascade and is used to evaluate the effectiveness of heparin.*
- Assess for signs of bleeding such as bruising, petechiae, hematuria, bloody stools  
*Signs of bleeding may indicate a need to modify or decrease anticoagulation therapy.*

### ■ Actions

- Early ambulation  
*Bedrest has been recommended in the past, but recent studies show early ambulation does not result in more complications (see Evidence-Based Practice) and is key to prevention.*
- Leg elevation  
*When at rest, the affected extremity should be elevated at least 10 to 20 degrees above heart level to enhance venous return and reduce swelling.*
- Compression stockings  
*Should be worn at all times. Compression promotes venous return and decreases leg swelling.*
- Avoid use of sequential compression devices (SCDs) in affected extremity  
*An SCD may cause the thrombus to break away, resulting in an embolus.*
- Encourage adequate fluid intake  
*Prevents dehydration and sluggish blood flow, which exacerbates DVT growth*
- Administer anticoagulation medications as ordered  
*Anticoagulation with unfractionated heparin followed by long-term oral anticoagulation prevents the formation of new thrombi and inhibits the growth of the existing thrombi.*
- Administer thrombolytic agent as ordered  
*Thrombolytic agents dissolve existing thrombi and decrease the instance of vascular damage.*

### ■ Teaching

- Prevention of reoccurrence with activities such as:
  - Early ambulation and active leg exercises
  - Monitor for adequate fluid intake to prevent dehydration and changes in blood flow
  - Avoid constricting clothing on the legs that might decrease venous flow, sitting with knees bent or crossed for long periods, standing for long periods
  - Remind patients that long car or airplane trips can increase the risk of DVT, so they should stay well hydrated and move around whenever possible or do leg exercises while sitting  
*Encourage patients to engage in activity that decreases the incidence of DVT by maintaining adequate blood flow through the extremity and avoid activities or actions that constrict or limit blood flow.*
- Signs and symptoms of bleeding such as bruising, bloody stools, petechiae  
*It is important when taking anticoagulants that the patient (and family) is able to detect signs and symptoms of bleeding.*
- Compliance with regular laboratory monitoring  
*It is important that the patient (and family) understand the importance of compliance with laboratory draws and the medication regimen to reduce bleeding risk.*
- Safety precautions when taking anticoagulants (see Safety Alert)

## Evidence-Based Practice

### Early Ambulation for Deep Vein Thrombosis (DVT): Bedrest versus early ambulation and standard anticoagulation in DVT management

Although it is not evidence-based, bedrest has been considered the cornerstone of management of deep vein thrombosis (DVT). A meta-analysis published in 2015 demonstrated that early ambulation combined with anticoagulation did not result in a higher incidence of complications such as pulmonary embolism (PE), progression of DVT, or death related to DVT.

Liu, Z., Tao, X., Chen, Y., Fan, Z., & Li, Y. (2015). Bed rest versus early ambulation with standard anticoagulation in the management of deep vein thrombosis: A meta-analysis. *PLoS One*, 10(4), e0121388. <https://doi.org/10.1371/journal.pone.0121388>

## Connection Check 31.10

The nurse is caring for a patient on a heparin drip who was admitted for DVT 2 days ago. Which laboratory value is most important to report to the provider immediately?

- A normal INR
- An increased hematocrit
- An increased platelet count
- A normal aPTT

## Evaluating Care Outcomes

Patients with a DVT can be safely managed by complying with prescribed anticoagulation therapy in combination with ambulation, compression stockings, and extremity elevation when resting. Stable vital signs and oxygen saturation along with decreased pain, swelling, and tenderness indicate a resolving DVT. Adjustments in anticoagulation therapy may be needed to maintain target laboratory values or prevent bleeding. Preventive patient teaching for high-risk individuals is essential to prevent initial and reoccurring DVT and PE. Patients should be able to maintain a healthy, active lifestyle by making adjustments in daily life that decrease DVT risk and by maintaining compliance with the treatment regimen.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. More's BP readings continue to be elevated at 180/100 mm Hg with a high HR in the 100s. He is in a sinus rhythm. He is started on 40 mg Lasix, 400 mg PO labetalol, and 25 mg lisinopril and continued on his Lipitor 40 mg PO every day. An hour after his diuretic and antihypertensives are administered, his BP decreases to 150/90 mm Hg. After the next four doses over the next 2 days, his blood pressure normalizes to 125/80 mm Hg, and his HR is 72 bpm. After further diagnostic testing, Mr. More is diagnosed with left ventricular hypertrophy on echocardiogram and retinal damage to both of his eyes. Both can be prevented from progressing further with a combination of medication and heart-healthy lifestyle. His kidneys are responding well to the antihypertensive treatment, and his BUN and creatinine have normalized. A diabetic teaching consult and a nutritional assessment as well as an assessment of his lifestyle are completed by the nurse. It is determined that his diabetes will be managed through diet control; insulin will not be necessary at this time. He will be followed weekly for at least 3 months to ensure that his HgbA1c and blood glucose are normalized with diet control. Intensive teaching about the DASH diet, exercise regimen, and medication adherence is presented to Mr. More and his daughter. At the end of his admission, he is able to verbalize and demonstrate understanding of his treatment regimen and goal of care. Mr. More understands that he must follow up with outpatient care providers frequently for support with his disease.

## Case Study Questions

- Prior to admission to the unit, Mr. More's BP is 180/122 mm Hg and he is complaining of a headache and blurry vision. These signs and symptoms combined with his laboratory results suggest a concern for which of the following?
  - Hypertensive emergency
  - Stroke
  - Hypertension urgency
  - Diabetes
- Upon admission, Mr. More's BP continues to be elevated at 188/122 mm Hg. Which order is most important for the nurse to implement first?
  - Administer labetalol 400 mg PO
  - Obtain a finger stick glucose reading
  - Begin oxygen via nasal cannula at 2 L
  - Administer Lipitor 40 mg PO
- On the basis of patient history and the results of diagnostic tests, what are the priority assessments for Mr. More? (*Select all that apply.*)
  - Strict intake and output
  - Vital signs
  - Finger stick blood glucose
  - Cranial nerve assessment
  - Swallowing evaluation
- Priority teaching needs for Mr. More include which of the following? (*Select all that apply.*)
  - Anticoagulation therapy
  - Smoking cessation
  - DASH diet
  - Slow posture changes
  - Eat a banana a day
- Which statement by the patient about his medication regimen indicates the need for further teaching?
  - "I will call my doctor if I am dizzy and short of breath."
  - "I will take my BP medication only if my blood pressure is up."
  - "One of my medications, Lasix, will make me urinate a lot."
  - "I am able to take my labetalol and lisinopril at the same time."

## CHAPTER SUMMARY

Atherosclerosis is a progressive inflammatory process that causes plaque formation within the artery. Plaque rupture can lead to myocardial infarction, unstable angina, or sudden death. Risk factors for atherosclerosis include elevated cholesterol levels, hypertension, smoking, diabetes, obesity, sedentary lifestyle, and family history. Risk factor modification is the initial action for patients who are at risk or evidenced to have atherosclerosis. Medication management is aimed at reducing lipid levels.

Hypertension is known as the “silent killer” because it can cause considerable damage to the heart, brain, and kidneys (target organs) before symptoms become evident. Early detection, prevention, and treatment are essential. The patient with the greatest risk of hypertension is a male over the age of 65 who is African American and of poor socioeconomic status. Definitive treatment is through antihypertensive medications, but diet and lifestyle modifications are essential. Nurses play a major role in effective prevention and treatment through education and follow-up regarding the importance of medication compliance, weight loss, diet, exercise, smoking cessation, and alcohol modification.

Peripheral arterial disease (PAD) is a progressive and chronic condition where the obstruction of blood flow through the large peripheral arteries causes a partial or total arterial occlusion leading to inadequate tissue perfusion and tissue ischemia. Patients with PAD often have atherosclerosis in the medium to large arteries including the aorta, the coronary arteries, and the carotid arteries. The treatment goals for patients with PAD are directed at providing symptom relief, education on risk factor modification, and reducing the risk of systemic cardiovascular morbidity and mortality.

Carotid artery disease is characterized by vessel wall thickening, plaque formation, and a progressive narrowing of the carotid artery. Treatment for patients with severe

carotid stenosis includes antiplatelet aggregation medications combined with carotid revascularization such as carotid endarterectomy (CEA) or carotid artery stenting. Patients with carotid artery disease are at great risk for stroke. The risk of stroke is dependent upon the severity of the stenosis and the previous appearance of symptoms. Regular nursing assessment of neurological status is essential to detect signs of stroke. Patients need education on lifestyle modifications, adherence to the medication regimen, and reportable conditions such as neurological changes.

An aortic aneurysm is a permanent localized dilation of the ascending, descending, or abdominal aortic artery. Patients with greatest risk of aortic aneurysms are white males between the ages of 40 and 70. Atherosclerosis, family history, genetic diseases such as Marfan’s syndrome, and smoking are the most frequent risk factors for AAA. Atherosclerosis accounts for 75% of aortic aneurysms. Aortic aneurysms may be asymptomatic. Following a strict regimen of medication compliance, healthy lifestyle, and regular screening is essential to successful management of aortic disease. A critical life-threatening complication of aortic aneurysm is rupture or dissection. Emergency surgery is the only treatment option. Symptoms of a ruptured or dissected aneurysm are severe back, chest, or flank pain; decreased BP; decreased red blood cell count; nausea; diaphoresis; pallor; and tachycardia.

Deep vein thromboses, or DVTs, typically form in the large vessels of the lower extremities. Risk factors include increasing patient age, surgery, trauma, hospital or nursing home confinement, active cancer with or without concurrent chemotherapy, pregnancy, postpartum period, oral contraceptives, and hormone therapy. Medical treatment with anticoagulants is indicated. Patient monitoring and teaching on the bleeding risk associated with anti-coagulation are imperative. Pulmonary embolism is a serious, life-threatening complication of DVT with clinical manifestations that include shortness of breath, tachycardia, sweating, and/or sharp chest pain especially during deep breathing.

# Chapter 32

## Coordinating Care for Critically Ill Patients With Cardiovascular Dysfunction

*Sharon Owens*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the indications and nursing implications for hemodynamic monitoring in the critically ill patient
2. Explaining the physiological relationship of hemodynamic parameters (preload, afterload, and contractility) to cardiac function
3. Correlating the clinical manifestations to the underlying pathophysiology of:
  - a. Myocardial infarction
  - b. Cardiomyopathy
  - c. Cardiogenic shock
4. Explaining the rationales for relevant medical interventions in the treatment of patients with myocardial infarction, cardiomyopathy, and cardiogenic shock
5. Analyzing the nursing management of patients with myocardial infarction, cardiomyopathy, and cardiogenic shock
6. Developing a teaching plan for patients who have had a myocardial infarction or cardiogenic shock or who have cardiomyopathy

### CONCEPTS

- Assessment
- Infection
- Medication
- Nursing Roles
- Nutrition
- pH Regulation
- Perfusion
- Safety

### ESSENTIAL TERMS

Acute coronary syndrome (ACS)  
Afterload  
Angina  
Arterial blood gas (ABG)  
Arterial line  
Cardiac index (CI)  
Cardiac output (CO)  
Cardiogenic shock  
Cardiomyopathy  
Central venous pressure (CVP)  
Central venous oxygen saturation (ScvO<sub>2</sub>)  
Contractility  
Mechanical Circulatory Support (MCS)  
Mixed venous oxygen saturation (SvO<sub>2</sub>)  
Myocardial infarction (MI)  
Oxygen delivery (DO<sub>2</sub>)  
Oxygen consumption (VO<sub>2</sub>)  
Oxygen utilization  
Phlebostatic axis  
Preload  
Pulmonary artery wedge pressure (pulmonary artery occlusive pressure) (PAWP/PAOP)  
ST elevation myocardial infarction (STEMI)  
Non-ST elevation myocardial infarction (NSTEMI)  
Stroke volume (SV)  
Sympathetic nervous system  
Unstable angina (UA)  
Venous oxygen saturation

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. Martin King is a 68-year-old male who presents to the emergency department with complaints of crushing chest pain that starts in the center of his chest and radiates to the left shoulder. He is pale and diaphoretic and is complaining of nausea. His blood pressure (BP) is 105/60 with a heart rate of 110 bpm. Oxygen saturation is 90%. An electrocardiogram (ECG) is performed immediately. Admission orders include two liters of oxygen via nasal cannula, 1 tablet sublingual (SL) nitroglycerin to be repeated every 5 minutes for a total of 3 tablets as necessary, 325 mg of aspirin, and 2 mg of morphine sulfate IV if nitroglycerin does not relieve the pain. Two large-bore IVs are started. Blood work including a cardiac panel: troponin, creatine kinase (CK), creatine kinase-MB bands (CK-MB), complete metabolic panel (CMP), complete blood count (CBC), arterial blood gas (ABG), and coagulation studies is obtained. Metoprolol 5 mg IV is given cautiously. A chest x-ray is performed...

## OVERVIEW OF HEMODYNAMIC MONITORING

Invasive hemodynamic monitoring is important to allow early identification and treatment of the complex medical problems of the critically ill patient. Physical examination can provide only a limited assessment of the patient's hemodynamic status. Advanced hemodynamic monitoring enables the nurse to assess for the presence of shock and cardiac and pulmonary abnormalities, as well as complications following myocardial infarction (MI). With the use of advanced monitoring systems, the nurse can evaluate the patient's immediate response to treatments including inotropic medications and mechanical support. Important concepts to understand when discussing hemodynamic monitoring include cardiac output, oxygen delivery, oxygen utilization and oxygen consumption.

### Cardiac Output

**Cardiac output (CO)** is the volume of blood pumped by the heart each minute. It is dependent on stroke volume (SV) and heart rate (HR). Heart rate is the number of ventricular contractions per minute. It can be affected by many variables such as stimulus from the autonomic nervous system or hormones from the adrenal medulla. Changes in blood pressure (BP) can also affect HR.

**Stroke volume** is the volume of blood pumped by the left ventricle with each heartbeat. Stroke volume is

dependent on three important factors: preload, afterload, and contractility.

**Preload** is the end diastolic pressure or volume that stretches the right or left ventricle. It reflects a patient's fluid volume status. The values obtained to measure preload are sometimes referred to as *filling pressures*. Factors affecting preload include blood volume, heart rate, body position, intrathoracic pressure from respirations, venous return of blood, atrial contraction, and valvular regurgitation.

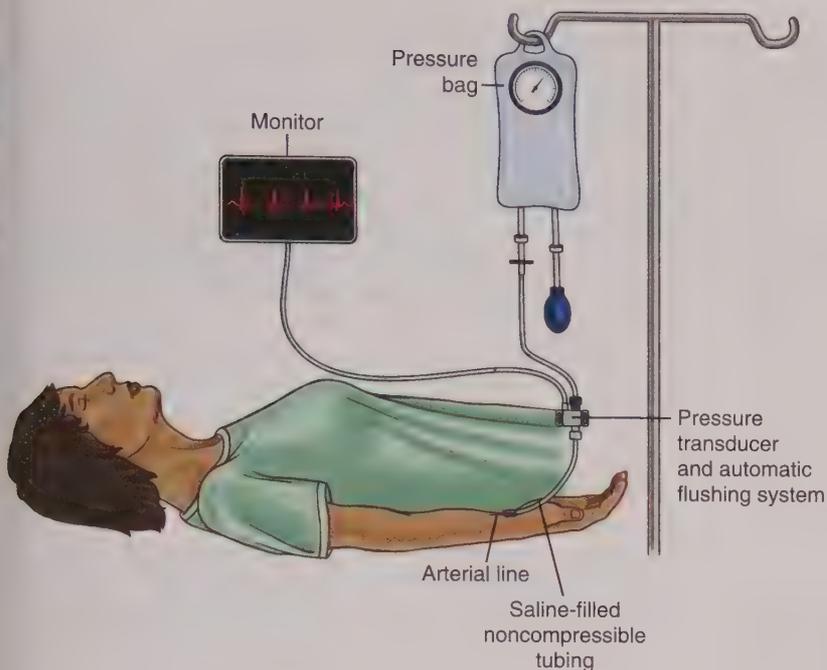

**Afterload** is the force or resistance the ventricles must overcome to eject blood into the pulmonary circuit or aorta. Right heart afterload is reflected in the pulmonary vascular resistance (PVR). Left heart afterload is reflected in the systemic vascular resistance (SVR) and is representative of the force that the left heart must pump against to deliver the SV into the periphery.

**Contractility** is the inherent ability of the heart muscle to contract independent of preload and afterload. Effective contractility is a component of SV, helping to produce an adequate CO. Poor contractility directly affects CO and decreases SV.

**Oxygen delivery (DO<sub>2</sub>)** is the amount of oxygen delivered to the tissues. It is determined through the evaluation of cardiac output and arterial oxygen content; hemoglobin levels, haemoglobin oxygen saturation, and the amount of oxygen dissolved in the plasma. **Oxygen utilization and oxygen consumption (VO<sub>2</sub>)** reflects the relationship between oxygen delivery and oxygen extraction at the tissue level. It can be measured through a blood sample, a **venous oxygen saturation** that reflects the amount of oxygenated blood returned to the right heart. Oxygen consumption is typically stable at the tissue level. Normal VO<sub>2</sub> values are between 60% and 75%. When that value falls below normal it means the tissues are extracting more oxygen than normal. That results from a decreased DO<sub>2</sub> which may be a decrease in oxygen content, hemoglobin, or cardiac output. It may also reflect an inability to increase delivery in response to stressors such as pain or fever.

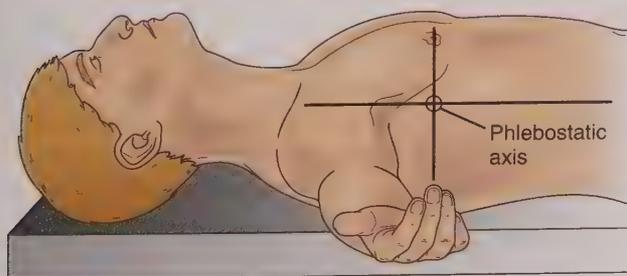

## Hemodynamic Monitoring Systems

Hemodynamic monitoring systems include arterial, central venous, and pulmonary artery (PA or Swan-Ganz) catheters. When correctly assembled and attached to a monitor, these systems provide pressure readings that correspond to BP, right atrial (RA) or **central venous pressure (CVP)**, and pulmonary artery pressures. The readings are displayed as waveforms on the monitor. The system consists of transduced catheters attached to noncompressible pressure tubing and a pressurized normal saline flush bag to prevent backup of blood. The bag is pressurized to 300 mm Hg for the arterial catheter and 150 mm Hg for the central venous and PA catheters. Evidence has demonstrated flush bags only need to be pressurized, not heparinized; therefore, most institutions have changed their policies to reflect this standard (Fig. 32.1).

**FIGURE 32.1** Pressure bag and transducer setup for invasive hemodynamic monitoring.

In order to obtain accurate readings, several conditions need to be present. First, the transducer should be secured at the **phlebostatic axis** (Fig. 32.2). This is the external reference point for the anatomical position of the right and left atria and the pulmonary artery. It is the midpoint of the left atrium, estimated as the fourth intercostal space in the midaxillary line with the patient in the supine position. If placed lower than the phlebostatic axis, the readings will be inaccurately high. If placed higher, the readings will be falsely low. Second, the tubing between the transducer and the cannula must be stiff, nonpliant, and less than 120 cm in length. Third, the transducer must be routinely calibrated, commonly referred to as “zeroing,” to offset the atmospheric and hydrostatic pressures that may alter the reading. Finally, the transducer and tubing need to be free from blood and air to ensure accurate readings and waveform. This also helps avoid the introduction of emboli into the systemic circulation. The transducer includes a port for flushing blood and air bubbles from the system and obtaining blood samples. Many hospitals use an in-line closed system for blood sampling to reduce catheter-associated blood stream infections and reduce blood loss. The Venous

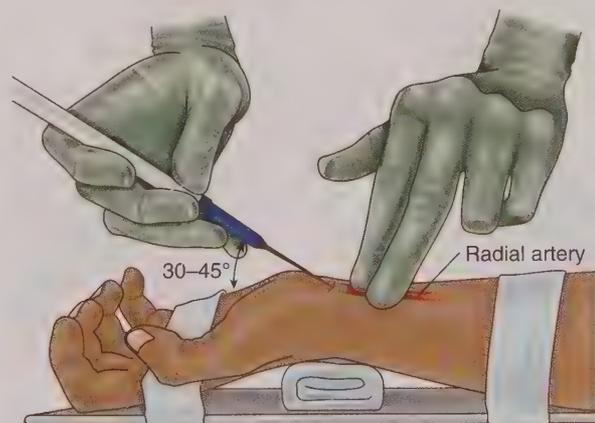

**FIGURE 32.2** The phlebostatic axis; midpoint of the left atrium, at the fourth intercostal space in the midaxillary line.

Arterial blood Management Protection (VAMP) system (Edwards Lifesciences, Irvine, CA, USA) is one type of closed in-line system. It is crucial that the nurse be aware of these implications when caring for the patient with invasive monitoring. Inaccurate readings could result in inappropriate and potentially harmful interventions to the patient.

### Arterial Line

An arterial line is a small catheter inserted into an artery used to display a constant systemic BP. This allows for continual evaluation of interventions for the critically ill patient, especially those patients with a labile BP on vasoactive medications. This catheter can also be used to obtain **arterial blood gas (ABG)** samples, which are used to monitor a patient's acid-base and oxygenation status.

An arterial line is usually inserted into the radial artery (Fig. 32.3) but can also be inserted into the axillary, brachial,

**FIGURE 32.3** Arterial line insertion.

femoral, or dorsalis pedis artery. Normal systemic BP parameters are systolic BP less than 120 mm Hg, mean arterial pressure (MAP) 70 to 105 mm Hg, and diastolic BP less than 80 mm Hg. A MAP of 65 mm Hg is considered necessary for end-organ perfusion (Box 32.1).

### Nursing Implications for Use of an Arterial Line

Providers, including physicians, physician assistants, nurse practitioners, and nurse anesthetists who have been trained, are responsible for arterial line insertion. Prior to insertion of a radial arterial line, the nurse must ensure that the provider performs an Allen test to confirm there is sufficient blood supply through the ulnar artery should the radial artery be damaged as a result of the cannulation. A negative Allen test indicates that it is not safe to place a radial arterial line; therefore, another site should be used (Box 32.2).

### Box 32.1 Formula for Calculating Mean Arterial Pressure

Formula for calculating mean arterial pressure (MAP)

$$\text{MAP} = [(2 \times \text{diastolic}) + \text{systolic}] / 3$$

### Box 32.2 Performing an Allen Test

Ask the patient to elevate the hand and make a fist for approximately 30 seconds. While the hand is elevated in a fist, the ulnar and radial arteries are occluded via pressure. While still elevated, the hand is opened and should appear pale/whitish. While pressure over the radial artery is maintained, pressure over the ulnar artery is released. Normal color returns in 7 to 10 seconds in a positive test. A negative test, in which color does not return in 7 to 10 seconds, indicates insufficient blood supply through the ulnar artery.

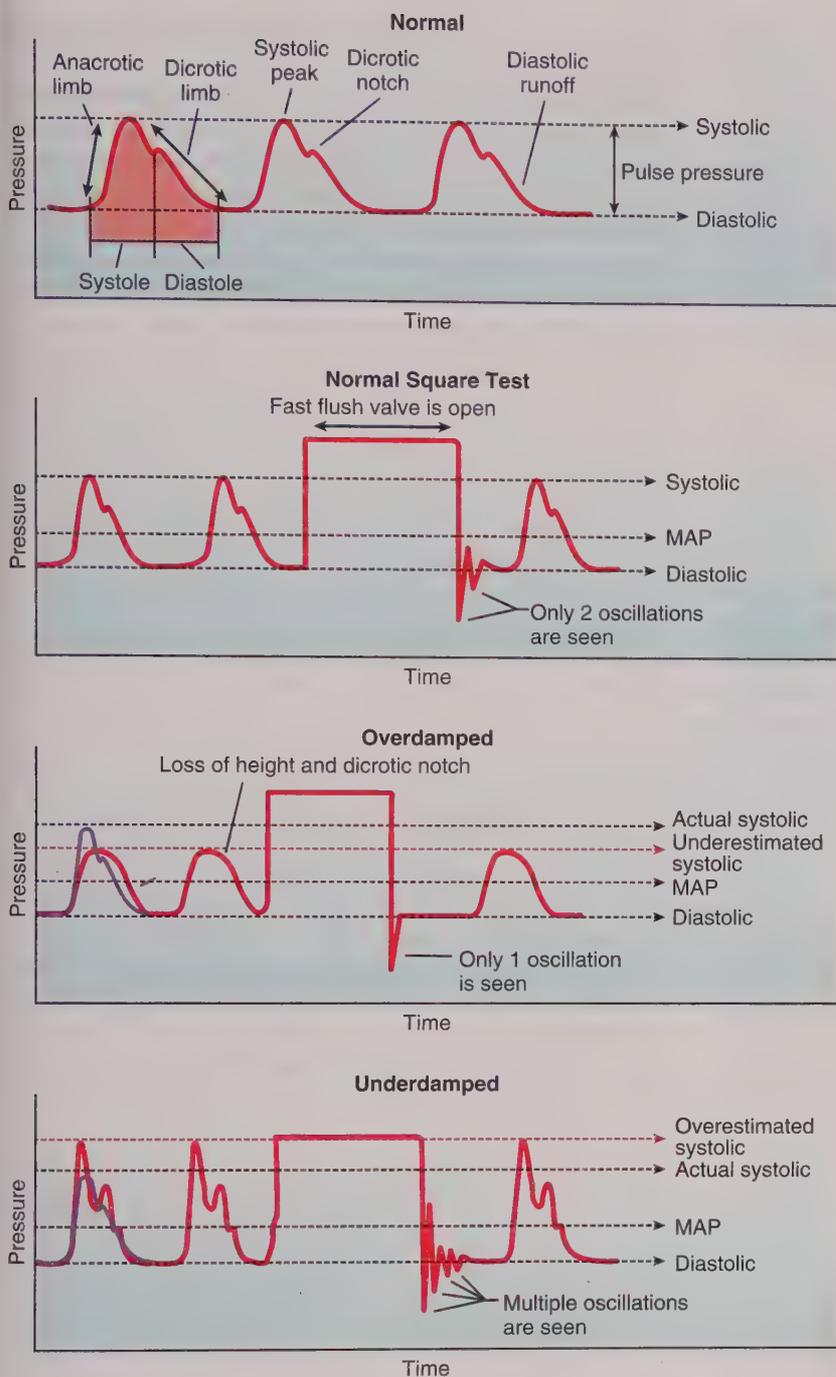

The nurse is responsible for setting up the monitoring system, which includes the transducer, tubing, and flush bag, securing the arterial line at the phlebostatic axis, zeroing or calibrating the line once it is secured, verifying the presence of an appropriate waveform (Fig. 32.4), and troubleshooting the line as needed. The arterial waveform should contain four components: the systolic phase with (1) an anacrotic (upstroke) limb, (2) a spike for the systolic pressure, followed by a rapid decline to (3) a dicrotic notch representing the closure of the aortic valve, and (4) the diastolic phase or runoff following the closure of the aortic valve which is a part of the dicrotic (downstroke) limb. Evaluation of the waveform to ensure accuracy of readings is called dynamic response testing or the square wave test. The nurse can do a quick flush of the arterial line which exposes the transducer to high pressure. This causes the transducer to vibrate and produces a square waveform on the monitor; the natural resonance frequency. As a result of the vibrations, oscillations appear following the square wave called the damping coefficient. An adequately damped waveform (normal) has two oscillations. An overdamped waveform has only one oscillation (little transducer vibration) and the tracing will lose its dicrotic notch. This may be caused by a clot in the catheter tip, or an air bubble in the tubing. When over-dampening occurs, the systolic BP may be underestimated and the diastolic BP may be overestimated. The underdamped trace will show numerous amplified oscillations, overestimate the systolic BP, and underestimate the diastolic BP. This may be caused by catheter artifact, noncompliant tubing, hypothermia, or tachycardia. The MAP remains the same in spite of damping.

The arterial site should be kept in view to prevent risk of catheter dislodgment and hemorrhage. The insertion site and area distal to the site must be monitored for adequate perfusion by checking color, warmth, capillary return, and movement. Observing the pulse oximetry waveform, with the probe placed distal to the insertion site, is an additional way that the nurse may continually observe for adequate perfusion. Additionally, appropriate alarms levels should be set on the monitor to alert the nurse with any change in pressure to allow prompt recognition and response.

When the arterial line is being discontinued, the dressing and sutures are first removed. The catheter is then removed, and pressure is applied over and above the insertion site for 3 to 5 minutes or until hemostasis is achieved. If the patient is at risk for bleeding, such as when receiving systemic anticoagulation, pressure should be applied for 10 minutes or longer to ensure hemostasis is achieved. A pressure dressing is then applied. The insertion site should be monitored to assure that hemostasis is maintained.

### Complications

Complications from the use of arterial lines include blood loss that may occur if tubing becomes disconnected or

**FIGURE 32.4** Arterial waveform. A, Normal arterial waveform. B, Normal square test. C, Overdamped waveform. D, Underdamped waveform.

the arterial line is accidentally displaced. There can be damage to the artery or occlusion of the artery, resulting in decreased flow distal to the site. As with any invasive device, infection is a risk (Box 32.3).

**Safety Alert** Arterial lines should be clearly marked so that IV medications are not given via this route. Inadvertent intra-arterial IV infusion can lead to tissue necrosis, gangrene, and loss of limb.

### Box 32.3 Potential Arterial Line Complications

- Infection
- Occlusion of artery
- Hemorrhage due to tubing disconnection or line dislodgment
- Air emboli
- User error (inaccurate readings)
- Damage to artery

### Connection Check 32.1

The nurse is managing the care of a patient with an arterial line. Which assessment finding warrants immediate intervention by the nurse?

- An overdamped waveform on the monitor
- Tubing disconnected from the arterial line
- IV medications being infused into an arterial line
- Redness at the arterial line insertion site

### Central Venous Monitoring

Central venous monitoring utilizes a long catheter placed in the internal jugular (IJ), subclavian (SC), or femoral vein. It is threaded through the superior vena cava with the distal port or tip resting at the junction of the superior vena cava and right atrium. CVP monitoring can be done through this line. The CVP level indicates mean RA pressure and is typically used as an estimate of right ventricular filling pressures or volume returning to the right heart from the systemic circulation (preload). It is also used as an indication of right ventricular function. Normal CVP is 2 to 6 mm Hg. The CVP value may be influenced by many factors including intravascular volume, venous return, venous tone, sympathetic response, intrathoracic pressure, and right heart function. A decreased CVP reading may be indicative of a low volume state caused by hypovolemia or peripheral vasodilation which occurs in sepsis and reduces venous return. The treatment may be a fluid bolus, vasopressor therapy, or both. An elevated CVP may indicate increased volume that may occur with right heart failure. Central venous pressure may also be elevated when intrathoracic pressures or pressures in the pulmonary circuit are increased, requiring pressure in the right heart to increase to facilitate flow. This can occur with tension pneumothorax, pulmonary

hypertension, or pericardial tamponade. Treatment is determined by cause.

Venous oxygen consumption via central venous oximetry (ScvO<sub>2</sub>) may also be monitored with a central line. It allows monitoring of venous oxygenation in the superior vena cava and reflects the oxygen in the blood returning to the heart from the upper body. A decreased ScvO<sub>2</sub> may indicate an inadequate cardiac output and potential tissue hypoxia. Early detection allows earlier intervention in the clinical course which may improve outcomes.

### Nursing Implications for Central Venous Monitoring

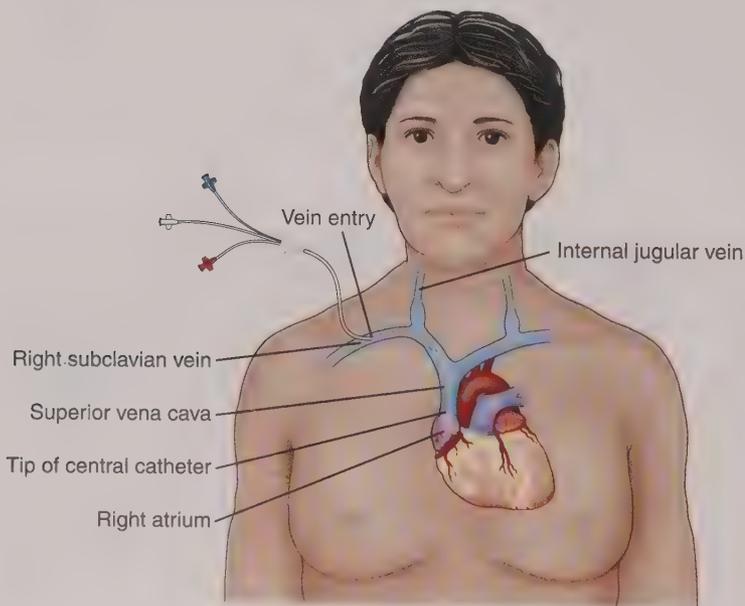

The central venous catheter often has multiple ports to facilitate many uses in addition to CVP and ScvO<sub>2</sub> monitoring (Fig. 32.5). They include:

- Routine fluid and medication administration
- Volume resuscitation
- Frequent blood draws
- Long-term IV antibiotics
- Parenteral nutrition administration
- Transvenous pacemaker insertion

These catheters may also be used when IV therapy is needed, and peripheral veins are not accessible or when infusing medications that are caustic to tissues when given through peripheral administration. These medications include calcium chloride, hypertonic solutions, amiodarone, potassium, and vasoactive medications.

### Central Line Insertion

The central venous monitoring setup is similar to that of an arterial line. The central line is attached to a transducer via stiff, noncompressible tubing. The tubing is kept flushed and open with the pressurized normal saline flush bag. Informed consent, including explanation of the procedure, benefits, risks, and complications, must be obtained prior

**FIGURE 32.5** The central venous pressure catheter with multiple ports inserted in the right subclavian vein with the tip resting at the junction of the superior vena cava and right atrium.

to line placement. Positioning the patient for an SC or IJ site may include placing a towel under the scapula to make the insertion site and landmarks more prominent. The patient should be placed in a Trendelenburg position (patient flat on back with feet 15 to 30 degrees higher than the head) unless the femoral vein approach is used, to reduce the risk of air embolism. Additionally, for the IJ approach, the Trendelenburg position will improve vessel distention, increasing the target size. Postprocedure, the catheter is secured by a suture, and an occlusive dressing is applied. The central line position must be verified by chest x-ray prior to its use.

The nurse plays a very important role during catheter insertion. Studies have demonstrated that using a checklist to assure adherence to evidence-based catheter insertion guidelines can significantly reduce catheter-related bloodstream infections. The nurse is empowered and obligated to stop the procedure if a violation of these guidelines is observed (Box 32.4).

### Nursing Implications for Central Line Maintenance

The patient with a central line should be closely monitored, and maintenance of the catheter site and system should be closely observed. The central line must be well secured to the patient to avoid accidental removal or displacement. Patency of the central line can be maintained by normal saline or heparin flush, continuous IV fluids, or pressurized flush solution. Monitored lines must have appropriate alarm limits set. The transducer location reference point is the phlebostatic axis (see Fig. 32.2). Waveforms should be monitored with appropriate scale and assessed for dampened waveforms, which could be a sign of line malfunction or complications such as air or blood in the transducer. Invasive lines disrupt the integrity of the skin, increasing a patient's risk for infection. Infection may spread to the bloodstream,

leading to hemodynamic instability and sepsis. It is the nurse's responsibility to assess the insertion site for bleeding and signs of infection. To minimize risk of infection the nurse must use aseptic technique with any line care, minimize line handling, and maintain an occlusive dressing. Daily evaluation of line necessity and prompt removal when not necessary decreases infection risk. Conditions that should be reported to the provider include pressures outside ordered parameters, inability to correct a dampened waveform, impaired circulation, catheter dislodgement, bleeding or swelling at the insertion site, and signs of infection such as presence of swelling, redness, or discharge.

### Nursing Implications for Central Line Removal

Prior to discontinuing the line, the nurse should prepare the patient by explaining the procedure. The dressing is removed, and the patient is placed in the Trendelenburg or supine position to prevent air embolism. The suture holding the central venous catheter are removed while ensuring it does not accidentally migrate out. Make sure all suture material has been removed. Ask the patient to hold his breath as the catheter is removed, again to prevent air embolism, and immediately cover the area with sterile gauze and apply pressure until hemostasis is achieved. Observe the patient after line removal for signs and symptoms of bleeding, air embolism, or infection of the site.

### Complications

More than 5 million central venous catheters are placed each year in the United States, with an associated complication risk of greater than 15%. They include but are not limited to infection, air embolism, arrhythmias, and bleeding (Box 32.5).

### Pulmonary Artery Catheter Monitoring

A PA (Swan-Ganz) catheter is a flexible, balloon-tipped catheter that is guided through the right side of the heart and into the pulmonary artery. The PA catheter may be inserted through the SC, internal or external jugular, or femoral vein. The typical catheter is 110 cm long and has four lumens, the distal, proximal, thermistor, and inflation lumens, each of which leads to a specific port. Some PA catheters have a second proximal lumen used for IV medication infusion (Fig. 32.6).

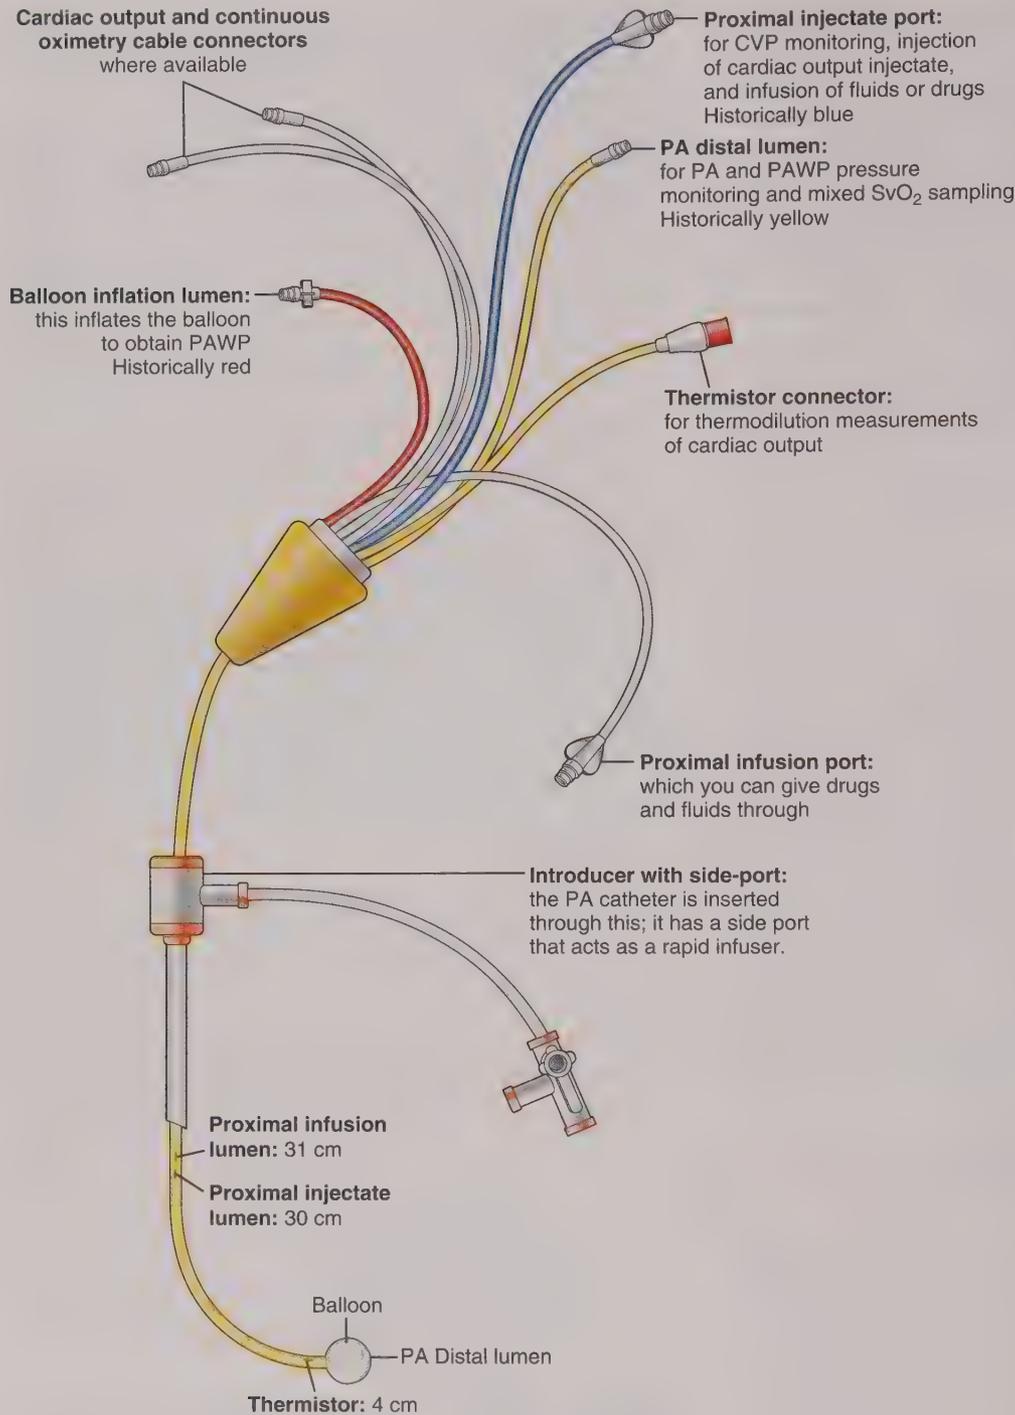

## Box 32.4 Central Line Insertion Guidelines

Central line insertion guidelines shown to reduce bloodstream infections

1. Experienced provider inserting a line or providing supervision
2. Perform a time-out
3. Use proper hand hygiene
4. Don appropriate attire during insertion to include cap, mask, a sterile gown and gloves, and eye protection
5. Prep site with chlorhexidine antiseptic skin prep and let air dry
6. Drape patient utilizing sterile technique
7. Insert line; maintain sterile technique
8. Clean site with chlorhexidine and cover with sterile occlusive dressing
9. Optimal catheter site selection (attempting to avoid use of the femoral vein)
10. Daily review of the necessity of the line and prompt removal when unnecessary

## Box 32.5 Potential Central Venous Line Complications

- Accidental arterial insertion
- Pneumothorax
- Nerve injury
- Vessel perforation
- Guidewire-induced arrhythmias
- Air embolism
- Venous thrombosis
- Bleeding
- Infection

**FIGURE 32.6** Pulmonary artery catheter.

The distal lumen port is located at the tip, or end, of the PA catheter. Through this port, systolic, diastolic, and mean pulmonary artery pressures can be measured providing information about the left heart. Pulmonary artery pressures reflect the BP in the pulmonary artery. It is generated by the right ventricle ejecting blood into the pulmonary circulation. The pulmonary vascular system acts as resistance to the output from the right ventricle. The values are used to assess for pulmonary hypertension and right heart function. Normal parameters are pulmonary

artery (PA) systolic 15 to 30 mm Hg, and PA diastolic 4 to 12 mm Hg.

This port can also be used for drawing venous oxygen saturation via a mixed venous hemoglobin saturation (SvO<sub>2</sub>). This value reflects the oxygen saturation of blood returned to the heart from both the superior and inferior vena cava therefore reflecting total body venous oxygen saturation.

The proximal port, located approximately 30 cm from the tip of the catheter in the right atrium, is used to monitor RA pressure (CVP). Central venous pressure is a reflection

of right heart preload or right ventricular end-diastolic volume. The proximal port is also used to inject the solution used to obtain a thermodilution cardiac output (CO). There is a temperature sensor built into the thermistor lumen at the tip of the PA catheter. It measures the ambient blood temperature around it continuously. To obtain a CO, a small bolus of cooler normal saline is briskly injected through the proximal injectate port. Because of the injection of cooler fluid, the temperature of the blood flowing by the sensor changes. The time it takes for the cold injectate to pass the sensor is measured in liters of blood pumped per minute. This is called the “thermodilution” method of obtaining the CO. Normal CO is 4 to 8 L/min. Typically, CO is indexed, meaning it is calculated on the basis of the patient’s body surface area (BSA). A normal **cardiac index (CI)** is 2.5 to 4 L/min/m<sup>2</sup>.

The inflation lumen leads to the balloon, located less than 1 cm from the catheter tip. The **pulmonary artery wedge pressure** or **pulmonary artery occlusive pressure** (PAWP/PAOP) is obtained by inflating the balloon with a syringe included in the PA catheter kit and specifically designed for use with the balloon (1.5 mL of air). The PAOP reflects left heart preload or left ventricular end diastolic pressure. This pressure is obtained when the balloon is inflated and floats into a wedge position in the pulmonary artery which occludes that branch of the pulmonary artery obscuring data from the right heart. In this position, the values obtained reflect pressures proximal to the balloon in the left side of the heart. Normal values are 4 to 12 mm Hg. This value assumes normal pulmonary conditions. The use of PAOP is decreasing

because its use is associated with complications. In its place, the PA diastolic pressure may be used again, assuming a normal pulmonary vasculature and mitral valve.

The PA catheter also allows for indirect measurement of *afterload* via systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR), and *contractility* via left ventricular stroke work index (LVSWI), and right ventricular stroke work index (RVSWI). Left heart afterload or the systemic vascular resistance is calculated using mean arterial pressure-central venous pressure/cardiac output (MAP-CVP/CO). Pulmonary vascular resistance is calculated as SVR, substituting pulmonary artery pressure for MAP and PAOP for CVP; PAP-PAOP/CP. The SVR and PVR can be indexed to a patient’s body size by dividing by body surface area (BSA) to yield the systemic vascular resistance index (SVRI) and pulmonary vascular resistance index (PVRI). The normal SVR value ranges from 800 to 1,200 dynes\*sec/cm<sup>5</sup>, and the PVR value is less than 250 dynes\*sec/cm<sup>5</sup>. The normal SVRI is 1,900 to 2,400 dynes\*sec/cm<sup>5</sup>/m<sup>2</sup>, and the PVRI is 200 to 400 dynes\*sec/cm<sup>5</sup>/m<sup>2</sup>. Increasing afterload in an unhealthy ventricle increases cardiac workload, thus increasing myocardial oxygen consumption. It also decreases SV and CO.

*Contractility* can be inferred by evaluating stroke work indexes of the right and left ventricles. Stroke work indexes are measurements of work done by the heart with each contraction. They are calculated via measurements obtained through the PA catheter.

Table 32.1 describes normal cardiac values, causes of abnormal values, and treatment possibilities for CO disorders.

### Nursing Implications for the Pulmonary Artery Catheter

To ensure patient safety, it is essential that the nurse understand the mechanics of the PA catheter and the proper technique for assisting in catheter insertion and obtaining data. Providers, including physicians, nurse practitioners, and physician assistants, receive education and training to insert PA catheters, measure parameters, and interpret data. Nurses receive education and training to assist with the insertion, measure parameters, and interpret data.

As with the CVP line, the patient should be placed in the Trendelenburg position before insertion. During catheter insertion, the nurse monitors the waveforms while the catheter passes through the different chambers of the heart and into the pulmonary artery (Fig. 32.7).

Once the catheter is advanced into the right atrium, and as directed by the provider, the nurse must inflate the balloon before any further catheter advancement. Balloon inflation during catheter insertion helps the PA catheter float into the pulmonary artery and prevents trauma to the cardiac structures as it moves through the heart chambers and valves. When a PAOP is obtained, the balloon must be inflated no more than 1.5 mL. After the value is obtained,

it is essential that the nurse ensure the balloon is immediately deflated. The balloon will deflate passively and should not be manually deflated or forced to deflate. A PA catheter should never be inflated and remain in the wedge position for more than 10 to 15 seconds. If the balloon remains

**FIGURE 32.7** Pressure waveforms visible on electrocardiogram during passage of the pulmonary artery line through the heart during catheter insertion.

inflated or in the wedge position there is the risk of accidental PA occlusion, hemorrhage, or PA infarction. If the waveform on the monitor indicates the catheter has remained in that wedge position, the nurse must verify that the balloon is not inflated and notify the provider for immediate intervention.

Care and risks of the PA catheter are the same as those with a central venous catheter; any handling of the line should be kept to a minimum to decrease infection risk, and an occlusive transparent dressing should be maintained and changed per hospital policy.

As with placement, the patient must be placed in a Trendelenburg position before removal. Remove any sutures holding the catheter in place, taking care not to cut the catheter. If possible, have the patient take a deep breath in and hold it during the withdrawal of the catheter. After removal, apply pressure for 3 to 5 minutes or until hemostasis is achieved. Observe the insertion site for potential bleeding. Subclavian veins are not compressible and are therefore more prone to bleeding if the coagulation studies are not within normal limits.

### Complications

The data obtained through pulmonary artery (PA) catheters can be extremely useful in the management of a complex critically ill patient, but the use of PA catheters is in question. New methods of obtaining hemodynamic data are under development (see Evidence-Based Practice) because there is a significant degree of complications and risk with a PA catheter. Complications may be related to insertion, maintenance and use, or to interpretation of data. As with any invasive intervention, there is a risk of infection and bleeding. The PA catheter also carries the risk of PA rupture, infarction, or air embolism as a result of balloon rupture during inflation to measure the wedge pressure (Box 32.6). Questions have been raised about the precise indications, cost-effectiveness, and effect on clinical outcomes. Large observational studies, small randomized studies, and meta-analyses have confirmed no benefit (survival or days in hospital) from PA catheters in any medical or surgical population of critically ill patients. The decision to use a PA catheter should be done on an individual basis, according to the specific clinical presentation, weighing the risk versus the benefit for the individual patient.

### Connection Check 32.2

The charge nurse is monitoring the care of several critically ill patients in the ICU. Which patient requires immediate intervention by the provider?

- The patient with a PA catheter remaining in the wedge position
- The patient with an SvO<sub>2</sub> of 55%
- The patient with an SVR of 1,300
- The patient with a CO of 3.2

## Evidence-Based Practice

### Newer Methods of Cardiac Output Monitoring

Noninvasive methods of measuring cardiac output are being developed because of the inherent risks associated with the pulmonary artery catheter. Several new methods include pulse contour analysis and transesophageal echocardiography (TEE). Pulse contour analysis provides information through the evaluation of the arterial pulse wave. Examples of pulse contour technologies are the FloTrac(tm)/Vigileo™ (Edwards Lifesciences, Irvine, CA) and PiCCO (PULSION medical system, Munich, Germany). Pulse contour analysis is based on the principle that stroke volume can be estimated through evaluation of the systolic portion of the arterial waveform. Cardiac output is then derived through analysis of stroke volume (SV) and heart rate. PiCCO requires an arterial line, and a central venous catheter. Similar to the PA catheter thermodilution method, cold solution is injected into the central line and is detected by a thermistor in the arterial line tip. FloTrac requires only an arterial line. Stroke volume is estimated via a calculation that evaluates the arterial waveform and specific patient demographics. Pulse contour technology has a number of limitations including inaccuracy in patients with irregular heart rhythms, right heart failure, and patients requiring low tidal volume mechanical ventilation.

Cardiac ultrasound via transesophageal echocardiography (TEE) may be used to provide real-time images of the cardiac structures and blood flow. Transthoracic echocardiography may help define pathophysiological abnormalities such as wall motion abnormalities, pericardial effusions, pulmonary hypertension, and valve abnormalities, in conjunction with other invasive or less-invasive monitoring. Although it cannot provide continuous monitoring, it can easily be repeated to quickly evaluate the response to an intervention. A TEE is obtained by placing a transducer in the esophagus next to the heart to produce images. TEE is used in the operating suites and in critical care units. There is, however, a significant learning curve for the provider, TEE is expensive, and continuous monitoring is not an option. There is a (low) risk of oropharyngeal bleeding and dislocation of the endotracheal tube.

## Box 32.6 Potential Pulmonary Artery Catheter Complications

### Insertion

- Arrhythmias
- Misplacement
- Knotting of the long flexible catheter
- Myocardial, vessel, or valve rupture
- Pneumothorax during catheter insertion

### Use and Maintenance

- Pulmonary infarction from lack of blood supply if balloon left in wedge position
- Pulmonary artery rupture from balloon inflation
- Air embolism from balloon rupture
- Thrombosis from catheter acting as a conduit for thrombus formation
- Bleeding
- Central line bloodstream infections
- Right heart/valve trauma

### Data Misinterpretation

- Improperly calibrated monitors
- Over or underestimation of PAOP
- Lung zone misplacement

## CASE STUDY: EPISODE 2

Mr. King's 12-lead ECG reveals the presence of ST-segment elevation in leads II, III, and aVF, which indicates an inferior wall myocardial infarction (MI). His troponin level is 12. The patient is diagnosed with acute inferior wall MI. After gastrointestinal bleeding is ruled out with a quick rectal examination, a heparin bolus is given IV and a heparin drip is started. His condition begins to deteriorate. Mr. King now has a BP of 75/50 mm Hg and a heart rate of 115 bpm. He is getting agitated, and his extremities are cool and pale. His ABG results, pH 7.23, PaCO<sub>2</sub> 34, PaO<sub>2</sub> 48, HCO<sub>3</sub><sup>-</sup> 20, reveal hypoxemia and metabolic acidosis. It is determined that he may be in cardiogenic shock. He is started on a norepinephrine IV drip to support his BP and a dobutamine IV drip to help improve cardiac contractility. He is intubated and immediately transported to the cardiac catheterization laboratory for coronary angiography and percutaneous coronary intervention (PCI)...

## MYOCARDIAL INFARCTION

### Epidemiology

Heart disease, which leads to MI, is the leading cause of death for men and women in the United States and not only results in serious illness and disability but also costs

hundreds of billions of dollars per year. Approximately 630,000 people die of heart disease each year—one in every four deaths. Coronary heart disease was responsible for the death of 366,000 people in 2015. Currently, more than one in three adults lives with one or more types of cardiovascular disease.

Contributing risk factors for heart disease and MI include cigarette smoking, high low-density lipoprotein (LDL), type 2 diabetes, elevated adrenaline (catecholamines), obesity, inactivity, and hypertension. These risk factors are modifiable and significant because they can accelerate the development of heart disease and lead to earlier onset of symptoms. Additional nonmodifiable risk factors include male gender, postmenopausal female, and family history of heart disease.

An MI can occur at any time of day, but the most dangerous time for all types of cardiovascular emergencies is in the early morning hours. This includes not only MI but also sudden cardiac death, rupture of an aortic aneurysm, pulmonary embolism (PE), and stroke. A group from Harvard estimates that the increased risk of MI between 6 a.m. and noon is approximately 40%. The exact cause is unknown but may be due to higher levels of circulating adrenaline released during this time. Increased adrenaline may also contribute to feelings of acute loss or stress that occur during an evolving MI.

### Pathophysiology

The term **myocardial infarction (MI)** refers to the destruction of heart muscle from lack of oxygenated blood supply. The most common cause of this obstruction is atherosclerosis. Atherosclerosis is the gradual buildup of plaque inside the wall of the artery. Rupture of this plaque results in thrombus formation and obstruction of coronary artery flow. Ischemia and death of heart muscle are the eventual outcomes. Heart muscle damaged by inadequate blood supply cannot maintain normal cardiac function, which results in decreased CO and the systemic symptoms associated with MI such as chest pain and poor tissue perfusion.

Stable angina is defined as episodes of intermittent chest pain present when the artery is narrowed 60% to 70%. It is typically associated with activity or exercise and is relieved by rest. Stable angina is not associated with damage to the heart muscle but is a warning sign for potential heart muscle damage. **Acute coronary syndrome** is an umbrella term used when there is concern for myocardial ischemia, and it encompasses unstable angina (UA), non-ST elevation MI (NSTEMI), and ST elevation MI (STEMI). Unstable angina is pain that is not associated with exercise and is not relieved by rest. It may present with ECG changes but no elevation in cardiac markers. It is an emergency requiring immediate treatment.

A NSTEMI is a partial occlusion of a major coronary vessel or complete occlusion of a minor coronary vessel causing reversible partial thickness heart muscle damage. In contrast, a STEMI is a complete occlusion of a major coronary vessel resulting in irreversible full thickness heart

muscle damage (Fig. 32.8). Table 32.2 describes the characteristics of UA, NSTEMI, and STEMI.

The extent of damage is dependent upon the location of the blockage. The heart's blood supply originates from two major vessels, the left coronary artery and the right coronary artery. Severe occlusion of the right coronary artery results in symptoms of right heart failure. In addition, the forward delivery of blood to the left ventricle may be insufficient, resulting in symptoms of left heart failure.

The left coronary artery is referred to as the *left main* (LM). This branches off into the left anterior descending (LAD) and the circumflex (CIRC) coronary arteries. In some individuals, a third branch, the ramus coronary artery, arises between the LAD and the CIRC. An occlusion of the LM coronary artery is often referred to as the *widow maker* because interruption of its extensive coverage is associated with sudden death. A left coronary artery occlusion is most likely to produce extensive cardiac injury, with impairment of heart function, pulmonary congestion, and low CO. Table 32.3 lists different locations of myocardial damage with associated implicated vessels and lead changes seen on ECG.

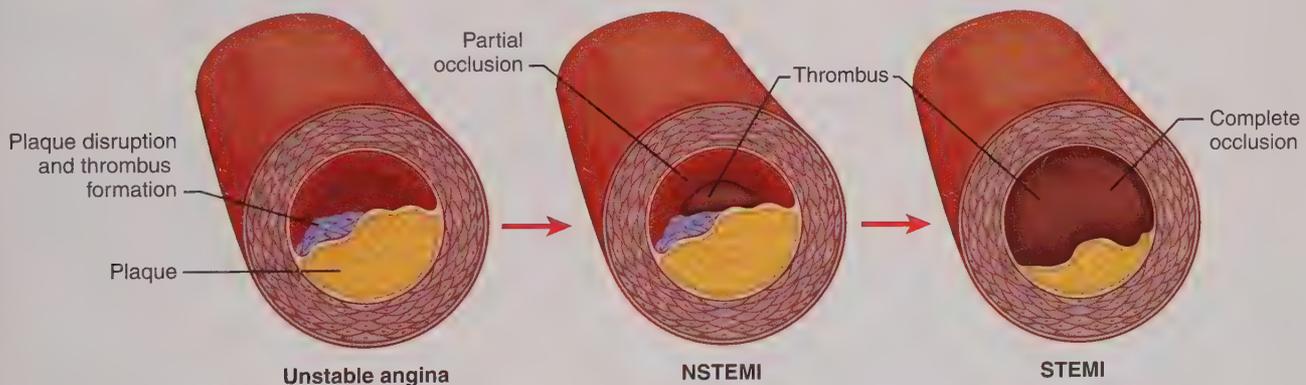

### Clinical Manifestations

The classic clinical manifestation of obstructed blood flow to the heart muscle is chest pain. As noted earlier, chest pain or angina, can be classified as stable or unstable. Stable, or exertional, angina typically occurs during activity, has a

predictable pattern, and goes away with rest. Unstable, or rest, angina (UA) is much more serious because it can occur while at rest with no specific pattern and is not relieved by change in activity. Angina is a warning sign of impending MI. Unstable angina is a medical emergency requiring immediate intervention.

Symptoms in addition to chest pain when there is a complete occlusion of the vessel resulting in an MI and significant muscle damage include shoulder and arm pain (more often on the left), jaw and tooth pain, shoulder blade pain, upper back pain, shortness of breath, nausea and vomiting, sweating, and generalized fatigue. A right coronary artery MI, or right ventricle infarction, has very distinct characteristics. The patient may present with jugular vein distention (JVD), hypotension, bradycardia; due to damage to the sinoatrial (SA) node, nausea, and vomiting. An MI that involves the left coronary artery, or left ventricle infarction, has a worse prognosis with the highest risk of sudden death and congestive heart failure. Signs of a left ventricle infarct include dyspnea, tachycardia, and hypertension. The tachycardia and hypertension result from the loss of CO because of damage to the left ventricle and subsequent stimulation of sympathetic compensatory mechanisms. Hypotension will quickly evolve.

Clinical manifestations of MI can vary significantly from person to person, with gender one prominent distinction. Women are more likely to present with atypical MI symptoms including neck, shoulder blade, and jaw pain, as well as abdominal pain. The geriatric population

**FIGURE 32.8** Acute coronary syndrome: Unstable angina, non-ST elevation myocardial infarction, and ST elevation myocardial infarction.

**Table 32.2** Characteristics of Unstable Angina, Non-ST Elevation Myocardial Infarction and ST Elevation Myocardial Infarction

Unstable Angina	Non-ST Elevation Myocardial Infarction	ST Elevation Myocardial Infarction
May present with nonspecific or transient ST segment depressions or elevations	ST depressions (0.5 mm at least) or T wave inversions (1.0 mm at least) without Q waves in 2 contiguous leads with prominent R wave or R/S ratio >1	ST elevations
No elevation in cardiac markers	Elevated cardiac markers	Elevated cardiac markers

**Table 32.3 Myocardial Infarction With Associated Electrocardiogram Leads and Coronary Artery Location**

Type of MI	Associated ECG Lead Changes	Associated Coronary Artery
Anterior wall	Leads V1–V4	LAD
Posterior wall	Possibly leads V1–V4	CIRC or RCA
Lateral wall	Leads I, aVL, V5, V6	CIRC
Inferior wall	Leads II, III, aVF	RCA

CIRC, Circumflex; ECG, electrocardiogram; LAD, left anterior descending artery; MI, myocardial infarction; RCA, right coronary artery

may not exhibit classic angina symptoms or may have coexisting conditions which mimic angina. They may experience dyspnea, syncope, weakness, or confusion. Many patients, especially patients with diabetes, never have the typical symptoms but may present with symptoms of shortness of breath or fatigue. Cardiovascular etiologies should be considered for patients exhibiting these atypical symptoms.

## Management

### Medical Management

#### Diagnosis

In 2000, the First Global MI Task Force recommended a universal definition of MI to standardize care of MI patients. This was reviewed and updated in 2007. In 2012, the Third Global MI Task Force once again reviewed and updated the definition of MI. This definition states that there must be presence of diagnostic cardiac markers, preferably troponin, with the addition of one of the following: symptoms of ischemia, ECG changes indicative of new ischemia, development of ECG Q waves, or image testing that reveals loss of viable heart muscle or new regional heart wall motion abnormalities.

#### Laboratory Testing

Laboratory tests used to diagnose an MI include troponin, creatine kinase (CK), and CK-MB. Creatine kinase is a general marker of cellular injury. It is released from cells in the brain, skeletal muscle, and cardiac tissue after muscle damage has occurred. Creatine kinase–MB is the CK isoenzyme marker specific to cardiac tissue. When myocardial damage occurs, CK-MB is released from the cells. Increased levels can be seen at 3 hours and remain elevated for up to 36 hours before returning to normal. Cardiac troponin (I and T) are proteins expressed almost exclusively in the heart and are a specific marker of cardiac muscle damage. Troponin levels can elevate within 4 hours of injury and

can stay elevated for as long as 10 days. Because it stays elevated longer than CK-MB, it is a valuable marker when attempting to diagnose injury in the recent past. Troponin is the blood test of choice to diagnose acute MI (AMI).

While infarction progresses, cardiac function decreases. End-organ compromise should be assessed and monitored with routine blood work such as:

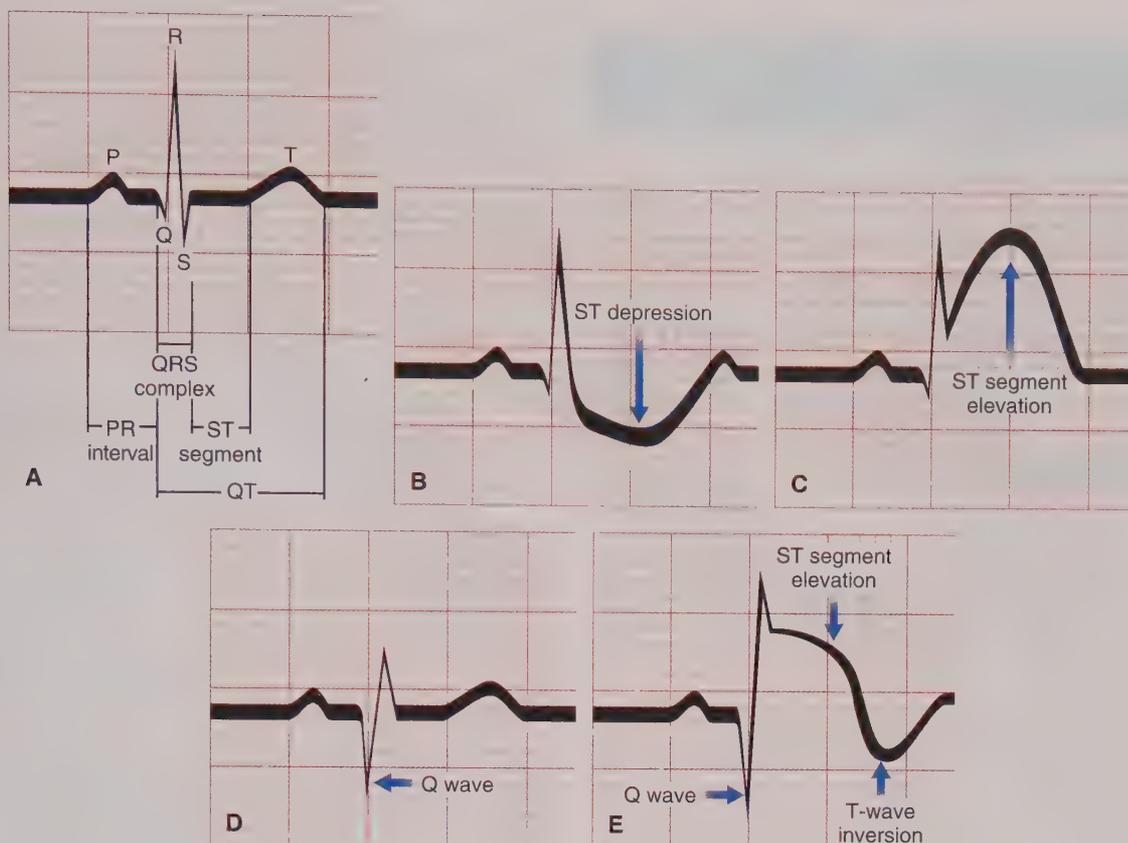

- A complete metabolic profile (CMP), which includes electrolytes and tests of organ system functioning such as renal values; BUN and creatinine
- Complete blood count (CBC), which includes hemoglobin, hematocrit, and white blood cell count
- Coagulation studies (prothrombin time, activated partial thromboplastin time, platelets)
- Arterial blood gas (ABG)

#### Diagnostic Testing

Diagnostic testing for MI can be performed through invasive and noninvasive tests. These tests include ECG, echocardiogram (echo), stress testing, and coronary angiography. An ECG has become the gold standard for diagnosis of MI. It is inexpensive, easy to perform, safe, and painless. Typical electrocardiogram changes diagnostic of AMI includes ST-segment elevation and the presence of Q waves. Electrocardiogram changes can occur in phases. The first observable ECG change is the presence of ST-segment depression indicating ischemia; NSTEMI. Although the changes may vary, typically if untreated, changes indicating the evolution from ischemia to infarction include tall narrow T waves, then ST-segment elevation, STEMI with T-wave inversion appearing. In the final phase, which can occur in the first hours, the ST-segment elevation is accompanied by development of a Q wave. Some patients do not develop a Q wave. In studies, the presence of a Q wave predicted a larger infarct and increased mortality. Other causes of Q waves may include left pneumothorax, myocarditis, cardiomyopathy, or chronic processes such as scleroderma. It is important to remember that women are less likely than men to have typical ECG changes when presenting with an MI (Fig. 32.9).

Echocardiography is used to evaluate the ventricular functions such as the ejection fraction (EF). An echo can assist in diagnosing an MI by looking for specific areas of heart muscle that are not contracting normally, referred to as *wall motion abnormalities*.

Although not done during the time an MI is evolving, stress testing is another way to evaluate heart function. Stress testing includes the exercise stress test, dobutamine/adenosine test, stress echo, and nuclear stress test. These tests are discussed in detail in Chapter 28. Testing is dependent upon the patient's needs and condition. These tests look at coronary blood flow as well as left ventricular function and wall motion abnormalities. A nuclear stress test is the best stress test for diagnosing myocardial ischemia. It reveals the amount of viable heart muscle, which helps to determine treatment.

**FIGURE 32.9** Electrocardiogram (ECG) waveforms illustrating the evolution of an MI. A, Normal ECG waveform. B, ECG waveform with ST depression indicating ischemia. C, ST elevation in acute myocardial infarction (AMI). D, Q waves after AMI. E, ECG waveform illustrating changes that occur with AMI.

### Connection Check 32.3

The nurse is reviewing the laboratory results of her patient and notes that a cardiac troponin level was drawn. This test was drawn to determine which diagnosis?

- Atrial fibrillation
- Ventricular tachycardia
- Myocardial infarction
- Congestive heart failure

Coronary angiography is the gold standard for the diagnosis of flow-limiting coronary artery disease. During coronary angiography, a catheter is inserted into the radial or femoral, and advanced up to the heart. A radiopaque dye is injected through the catheter into the coronary artery while sequences of x-rays (fluoroscopy) are obtained. This allows visualization of any obstruction or narrowing of the coronary arteries. At the same time, a ventriculogram may be obtained. This involves positioning the catheter to allow injected dye to enter the left ventricle. The ventriculogram demonstrates how efficiently the left ventricle fills and pumps blood, how well blood flows through the aortic and mitral valves, and the size of the left ventricle.

### Treatment

Once the diagnosis of MI is made, immediate patient management involves maximizing oxygenation and administering medications to control pain, dilate the coronaries, prevent clots, and decrease myocardial workload. Care then involves therapies to increase blood flow to cardiac tissue, or reperfusion therapy.

### Medications

Immediately upon arrival to the hospital, the patient should receive oxygen, sublingual (SL) nitroglycerin, aspirin, and then pain medication such as morphine sulfate if pain is not relieved by the SL nitroglycerin. Oxygen is recommended for all patients with a suspected MI and specifically for patients in respiratory distress if the arterial saturation is less than 90% or for patients with a high risk of hypoxia. Nitroglycerin dilates the coronary arteries, increasing blood flow to the heart in an attempt to limit myocardial muscle damage and control pain. One tablet may be given sublingually every 5 minutes for a maximum of three doses as long as the patient maintains an adequate BP. If pain is not controlled with three doses, IV nitroglycerin will be started. Aspirin is given to help prevent platelets from enlarging the existing clot or new clots from forming. Morphine sulfate can be given to control pain; however, in contrast to

nitroglycerin, which relieves pain and dilates the coronaries, morphine can mask pain symptoms while not improving coronary blood flow, thus potentially worsening an MI. Research has found a higher risk of death in patients who received morphine, thus as noted previously, it is recommended only when pain is not relieved by nitroglycerin. Additional medications include the initiation of beta blocker therapy to decrease the sympathetic nervous system response, thus decreasing myocardial workload and myocardial oxygen consumption. Beta blocker therapy would not be used in a patient suffering a right coronary artery MI experiencing bradycardia. Also, heparin sodium infusion (heparin) is started to help prevent new clot formation (Table 32.4).

### Reperfusion Therapy

It has been demonstrated that patients who undergo emergency revascularization by PCI or fibrinolytic therapy within 6 hours have significantly higher survival. The overall mortality when revascularization occurs in less than 6 hours is 38%. When rapid revascularization is not attempted, mortality rates approach 70%.

### Connection Check 32.4

A nurse is caring for a patient with a diagnosis of MI. The patient calls the nurse because he is experiencing chest pain. The nurse administers an SL nitroglycerin tablet as prescribed. After 5 minutes, the chest pain is unrelieved by the nitroglycerin. The next nursing action is which of the following?

- Administer another nitroglycerin tablet
- Increase the flow rate of the oxygen
- Contact the provider
- Call the charge nurse

Percutaneous coronary intervention is the most preferred method for opening blocked blood vessels that cause MI. During PCI, a catheter with a small balloon on its tip is

inserted into an artery and advanced under fluoroscopy up to the left side of the heart and coronary arteries. The balloon is inflated and deflated to open the lumen of the blocked artery. It should be done within 90 minutes of arrival to the hospital: *door to balloon—90 minutes*. Once the lumen is open, a stent may be advanced to the location to hold the artery open and maintain adequate blood flow (Fig. 32.10). The radial or femoral artery are typically used for this procedure. Any catheter placement into a blood vessel is associated with a risk of bleeding. If the femoral approach is used, the patient will need to lie flat without bending the leg for 2 to 6 hours to allow the artery to heal. In some cases, even with prolonged immobility, internal bleeding can occur and can be severe enough to require blood transfusions or surgery to repair the femoral artery. The radial artery has become the preferred site for catheterization because the risk for internal bleeding is eliminated and any external bleeding can be easily compressed. Once the catheter is removed from the radial artery, a compression device is placed around the wrist to apply pressure on the artery, and there is no requirement for the patient to remain immobile.

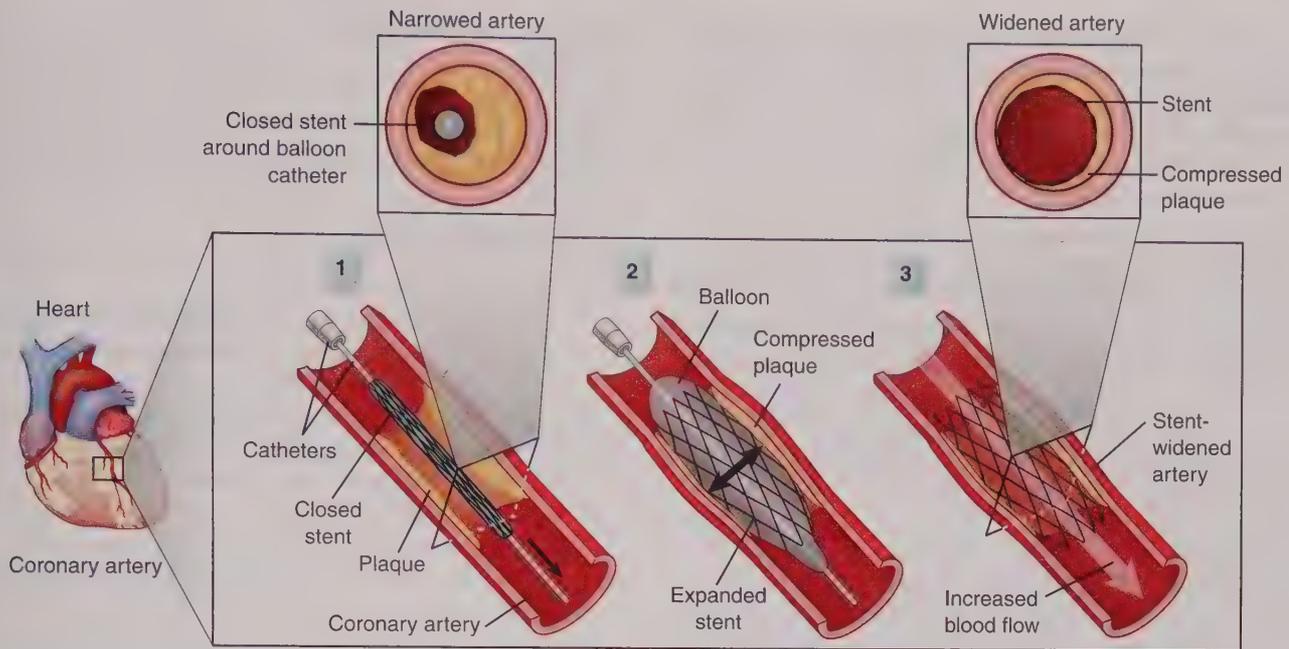

Fibrinolytics are medications that accomplish revascularization through fibrinolysis of the existing clot. They should be administered within 30 minutes of arrival to the hospital. Success of fibrinolytic therapy is defined as ECG demonstration of ST-segment reduction greater than 50% at 90 minutes. Fibrinolytics should be considered if not contraindicated and immediate PCI is not available. Contraindications include recent surgery or bleeding, presence of a peptic ulcer, uncontrolled hypertension, pregnancy, and noncompressible vascular punctures. The major complication of fibrinolytic therapy is bleeding, specifically an increased risk for intracranial hemorrhage.

### Surgical Management

Coronary artery bypass grafting (CABG) is a surgical revascularization intervention that bypasses blockages in the coronary arteries causing the myocardial muscle damage. It

**Table 32.4 Commonly Prescribed Medications for Myocardial Infarction**

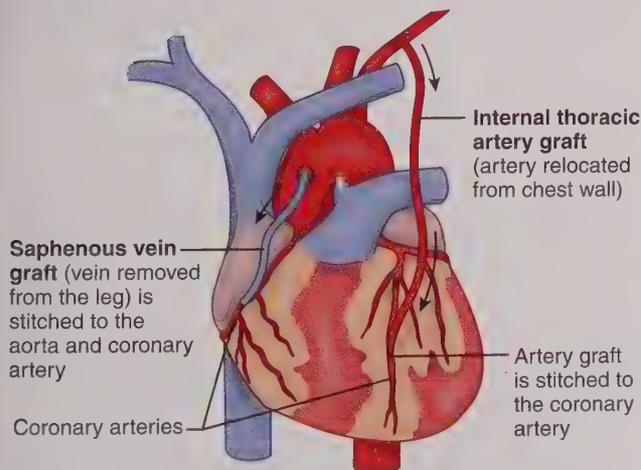

Classification	Medication	Action
Antiplatelet	Aspirin, clopidogrel (Plavix), eptifibatide (Integrilin)	Prevents platelets from forming new clots or increasing the size of the present clot
Anticoagulant	Heparin, enoxaparin (Lovenox), Factor XA inhibitors	Prevents formation of new clots
Narcotic	Morphine sulfate, hydromorphone (Dilaudid)	Relieves chest pain
Beta blocker	Metoprolol (Lopressor), Atenolol (Tenormin)	Decreases myocardial workload thus myocardial oxygen demand, limiting extension of injury
Nitrates	Nitroglycerin (Nitro-BID)	Dilate coronary arteries to increase blood flow to the heart muscle and relieve chest pain
Thrombolytics	Alteplase (Activase), reteplase (Retavase)	Revascularization of the heart muscle by dissolving clots in arteries

**FIGURE 32.10** Stent insertion to open a blocked coronary artery.

is not the first-line intervention after MI because PCI or fibrinolytics are much quicker procedures; they do not involve a long surgical procedure, thus revascularization is accomplished in a timelier fashion. Indications for CABG include unsuccessful PCI or not a candidate for PCI, failure of medical management, or critical left main or three vessel disease.

During CABG, a healthy artery or vein, typically the internal thoracic (mammary) artery or saphenous vein, is grafted to the blocked coronary artery. One end is attached to the aorta, with the other end attached to the blocked coronary distal to the occlusion, thereby bypassing the blocked portion of the artery allowing blood flow to the cardiac tissue (Fig. 32.11). The procedure is most typically done on pump or with cardiopulmonary bypass. Complications associated with CABG include bleeding, dysrhythmias,

**FIGURE 32.11** Coronary artery bypass grafting (CABG).

MI, stroke, nonunion of the sternum, sternal infection, renal failure because of decreased renal blood flow, or heart failure. Complications of bypass include induction of a systemic inflammatory response resulting in vasodilatory shock, heparin-induced thrombocytopenia, activation of platelets, and the complications associated with cross clamping the aorta during the procedure. An off pump or “beating heart” CABG procedure was developed to avoid the complications related to bypass. This option requires considerable expertise and has not demonstrated consistent improved outcomes.

### Secondary Prevention

Cardiac rehabilitation is recommended after an acute cardiovascular event such as MI, percutaneous intervention, or surgical revascularization. It is a supervised exercise program which also provides education regarding diet, weight management, medication purpose and side effects, and psychosocial support. The goals are to improve recovery from the event and improve quality of life. Patients are evaluated by their cardiologist or cardiac surgeon for participation.

### Complications

Heart failure is a complication related to MI. When an MI causes a large amount of heart muscle to die, there is decreased left ventricular function. The overall result can be heart failure and is defined as the inability to produce an adequate CO to maintain the body's metabolic demands. Heart failure is discussed in detail in Chapter 30.

Arrhythmias associated with MI include asystole, symptomatic bradycardia, heart block, and ventricular arrhythmias. Asystole, symptomatic bradycardia, and heart block are usually associated with sinoatrial (SA) node dysfunction. This is most common after an inferior wall MI because the right coronary artery supplies the SA node. A temporary pacemaker may be used to prevent asystole.

Ventricular arrhythmias after MI are not uncommon. Most ventricular arrhythmias occur in the first 48 hours. There is a sixfold increase in mortality associated with ventricular arrhythmia after MI. Immediate defibrillation is the treatment of choice for ventricular fibrillation and pulseless ventricular tachycardia.

### Connection Check 32.5

A 68-year-old male presents to the emergency department with complaints of crushing chest pain that radiates to the left shoulder. The patient is diagnosed with AMI. Admission orders include oxygen 2 L via nasal cannula, blood work, chest x-ray, 12-lead ECG, and SL nitroglycerin. What should be the nurse's first action?

- Apply oxygen
- Obtain the 12-lead ECG
- Administer the nitroglycerin
- Obtain the blood work

### Nursing Management

#### Assessment and Analysis

The clinical presentation of MI is related to lack of oxygen delivery to the heart and the resulting decrease in CO. The patient complains of chest pain, shortness of breath, nausea and vomiting, and dizziness. The patient presents with diaphoresis and pallor. Women and older adults may present differently, with women complaining of neck, shoulder blade, and jaw pain as well as abdominal pain. Older adults may present with dyspnea, syncope, weakness, or confusion. Hemodynamics are variable, but typically the patient is tachycardic with a borderline low BP.

#### Nursing Diagnoses

- **Decreased CO** related to poor cardiac contractility secondary to MI
- **Pain** related to inadequate blood supply by the heart

#### Nursing Interventions

##### Assessments

- Vital signs and pulse oximetry  
*Tachycardia with a borderline low BP and decreased oxygen saturation is a sign of inadequate CO and oxygen delivery.*
- Assess characteristics of pain including location, radiation, duration, intensity, precipitating or alleviating factors; use a 1 to 10 pain scale  
*Chest pain is an indication of MI. Continued or changing pain characteristics can be indicative of a worsening condition.*
- Assess ECG changes  
*ST-segment depression is indicative of ischemia. ST-segment elevation is indicative of injury. If present, a Q wave is diagnostic for MI.*
- Assess for restlessness  
*Restlessness may be found in the early stages, but progression to severe anxiety and sense of doom is a late-stage symptom.*

- Assess skin color and temperature, peripheral pulses, diaphoresis  
*Decreased pulses and cold, clammy, pale skin are signs of inadequate tissue perfusion and inadequate CO. Activation of the sympathetic system with low CO will stimulate diaphoresis.*

- Monitor urine output  
*Decreased or absent urine output is a sign of decreased renal perfusion related to decreased CO*
- Assess troponin and CK, CK/MB levels  
*Troponin is a protein released from damaged cardiac muscle. It elevates within 4 hours and can stay elevated for 10 days. CK/MB, the CK isoenzyme marker specific to cardiac tissue, is released from the cells with cardiac muscle damage. Increased levels can be seen at 3 hours and remain elevated for as long as 36 hours.*

#### Post-CABG

- Monitor heart rate and BP continuously with an arterial catheter at least every 15 minutes initially and then every 4 hours when the patient is stable.  
*Tachycardia, bradycardia, hypotension, and hypertension may be signs of decreased cardiac output or compensatory mechanisms.*
- Hemodynamic monitoring  
*Decreased preload (CVP, PAOP), SvO<sub>2</sub> may indicate a decreased cardiac output leading to poor tissue perfusion*
- Continuous cardiac monitoring  
*Dysrhythmias are common after CABG.*
- Assess heart tones  
*Muffled heart tones may indicate tamponade. S<sub>3</sub>, S<sub>4</sub>, and crackles may indicate heart failure.*
- Monitor breath sounds and continuous oxygen saturation monitoring  
*Decreasing saturation may indicate pulmonary complications. Diminished or unilateral absent breath sounds may indicate atelectasis, pleural effusions or pneumothorax.*
- Monitor core temperature hourly  
*Hypothermia during surgery reduces metabolic rate and risk of organ ischemia. Rewarming may produce hypotension from vasodilation. Core temperatures are most reliable.*
- Assess level of consciousness, pupils, and responsiveness  
*Assesses effectiveness of sedation and evaluates neurological function.*
- Hourly intake and output. Notify provider for output less than 30 ml/hr for 2 hours.  
*Decreased urine output may be a sign of renal damage or decreased cardiac output.*
- Assess skin color and temperature, pulses, edema, and capillary refill  
*Pale, cool skin with delayed capillary refill and weak pulses may indicate decreased cardiac output. Edema can be an expected response after CABG due to fluid resuscitation during surgery.*
- Monitor chest tube output, color, and volume hourly  
*Sudden increases in output greater than 100 to 200 ml not associated with position changes or increased bright red drainage may indicate hemorrhage and the need to return to the operating room.*

- Assess hemoglobin, hematocrit, electrolytes, creatinine and blood urea nitrogen, glucose  
*Changes may indicate bleeding, fluid shifts, and renal dysfunction. Tight glucose control is associated with improved outcomes.*
- Assess incisions for drainage, warmth, redness, swelling.  
*Redness, warmth, swelling, and purulent drainage may indicate infection.*

### ■ Actions

- Administer oxygen  
*Oxygen consumption and demand increases; therefore, oxygen supply should be increased.*
- Insert two large-bore IVs  
*IV access is essential for medication delivery and fluid resuscitation.*
- Administer medications as ordered  
*Medications are essential to be given in a timely manner:*
  - Aspirin and heparin  
*Aspirin and heparin are given to prevent new clot formation.*
  - Nitroglycerin SL  
*Nitroglycerin dilates the coronary arteries, increasing blood flow and decreasing pain.*
  - Morphine  
*Morphine is a narcotic given for pain relief if nitroglycerin is not effective.*
  - Beta blockers  
*Beta blockers decrease the sympathetic response to an MI, decreasing cardiac workload and oxygen consumption.*
  - Fibrinolytics  
*Fibrinolytics work to dissolve clots.*
- Continuous ECG monitoring  
*Electrocardiogram monitoring is essential to evaluate the evolution of the MI and the effectiveness of treatment and to monitor for dangerous dysrhythmias that can occur.*
- Bed rest  
*The patient may require bed rest as well as emotional rest to decrease oxygen and cardiac demands.*

### Post-CABG

- Maintain tight BP control  
*Hypotension may result in graft collapse; hypertension may result in bleeding.*
- Administer fluids and medications (vasodilators, vasoconstrictors, inotropes, and diuretics) as ordered  
*Maintains hemodynamic stability*
- Rewarm patient slowly with warm fluids, blankets, or air flow devices. Prevent shivering.  
*Rapid rewarming may cause dysrhythmias and/or hypotension due to vasodilation. Shivering increases oxygen needs.*
- Administer pain medication and continuous sedation medications  
*Maintains effective sedation and analgesia to decrease anxiety and pain which may potentially increase cardiac workload.*
- Pulmonary hygiene while intubated: Reposition frequently, suction as needed. Oral care every 4 hours. Pulmonary hygiene after extubation; Incentive spirometry (IS), cough and deep breathe (C&DB)

every 1 to 2 hours while awake, encourage chest splinting when coughing.

*Helps with weaning toward extubation, oral care helps prevent ventilator associated pneumonia, IS and C&BD reduces risk of hospital acquired pneumonia, improves oxygenation.*

- Plan for and initiate early mobility or ambulation  
*Reduces complications related to immobility: deep venous thrombosis, pneumonia, constipation, skin breakdown*
- Wound care: Initial dressing to be removed or changed by provider, then change daily or as needed.  
*Helps prevent wound infection and promotes healing*

### ■ Teaching

- Immediately report signs and symptoms of MI such as chest pain or chest discomfort or increased shortness of breath  
*Understanding of the signs and symptoms of MI allows the patient to have earlier intervention, thus decreasing the complications and severity of present or future MIs.*
- Purpose, dose, and side effects of medications  
*Prescribed medications are to treat the effects of MI and prevent future MIs.*
- The American Heart Association “Life’s Simple 7”:  
  1. No smoking of cigarettes or other tobacco products
  2. Maintain a normal body weight
  3. Exercise for at least 150 minutes with moderate-intensity activity, or 75 minutes of vigorous-intensity activity, or a combination of each per week
  4. Eat a healthy diet that follows the current American Heart Association recommendations
  5. Maintain total cholesterol level less than 200 mg/dL
  6. Keep BP less than 120/79 mm Hg
  7. Keep fasting blood glucose less than 100 mg/dL

### Post-CABG

- Signs of infection  
*Wound infection requires prompt intervention to promote healing.*
- Sternal precautions; do not lift weight over 10 lbs, raise arms overhead, bend at the waist, participate in vigorous activity until cleared by physician  
*These activities may interfere with sternal wound healing.*
- Participate in cardiac rehabilitation: includes a medical evaluation, exercise training and physical activity counseling, coronary risk factor reduction/secondary prevention, including nutritional counseling and weight management, psychosocial support, and education regarding diet, weight management, purpose of medications, medication side effects, effects on exercise tolerance, and reinforcement for medication adherence.  
*Changing modifiable risk factors decreases the patient’s risk of repeated MIs.*

### Evaluating Care Outcomes

A well-managed patient is free from pain and has normal vital signs with an improved SpO<sub>2</sub>. Signs of decreased perfusion from inadequate CO such as cool extremities, weak pulses, and decreased urine output are resolving. The

goals for effective care include resumption of a normal active life free from pain and feelings of anxiety and doom. Myocardial infarction survivors can reduce their risk for repeated MIs through secondary prevention measures such as Life's Simple 7.

## CARDIOMYOPATHY

### Epidemiology

Cardiomyopathy affects approximately 50,000 people in the United States. Mortality for cardiomyopathy is approximately twice as high in males as in females and nearly twice as high in blacks as in whites. Dilated cardiomyopathy occurs more often in men than women. Hypertrophic cardiomyopathy (HCM) affects women and men evenly. It typically has a familial link. Restrictive cardiomyopathy is the rarest form of cardiomyopathy and affects mostly older adults.

Risk factors for cardiomyopathy are numerous. The major risk factors include diabetes, hypertension, high cholesterol, high-fat diet, obesity, family history of heart disease, sedentary lifestyle, and smoking. Other risk factors include alcohol and cocaine use, chemotherapy medications, end-stage renal failure, genetic/congenital defects, viral infections including HIV, Lyme disease, Chagas disease, nutritional deficiencies such as selenium, thiamine, and calcium, and pregnancy. Cardiomyopathy may not be from one sole cause but may be the result of an accumulation of multiple insults to the heart muscle.

### Pathophysiology

Cardiomyopathy is a disorder in which the heart muscle becomes weak. It becomes enlarged, thick, or rigid and may develop structural changes. These changes are associated with inadequate pumping (low CO) and arrhythmias. In rare cases, the muscle tissue in the heart is replaced with scar tissue. These changes result in decreased function of the heart muscle. One measure of function is the *ejection fraction (EF)*. The EF is the percentage of blood ejected from the ventricle with each contraction. A normal EF is approximately 55% to 65%. Less than 45% usually indicates some disease process weakening the pumping strength of the heart. An EF below 30% represents a severe decrease in cardiac function and represents a patient who is at increased risk for sudden death. There are two major categories of cardiomyopathy, ischemic and nonischemic. Ischemic cardiomyopathy refers to a greatly reduced ejection fraction caused by coronary artery disease such as irreversible loss of myocardium due to MI or possibly reversible contractile ability due to the presence of viable cardiac muscle after MI. The three most common types of nonischemic cardiomyopathy are:

- Dilated cardiomyopathy
- Hypertrophic cardiomyopathy
- Restrictive cardiomyopathy

Dilated cardiomyopathy is the most common type and the third leading cause of heart failure. The disease often

starts with the dilation of the muscle in the left ventricle which causes the inside of the chamber to enlarge. The dilated chambers result in poor systolic function impairing contractility, thus decreasing CO. The impaired contractility results in a decreased ejection fraction, typically defined as less than 40%. Eventually, the heart becomes weaker, and heart failure may occur. The problem often spreads to the right ventricle and then to the atria while the disease gets worse. Most often, a specific cause for dilated cardiomyopathy is never identified; however, some factors have been linked with the disease. These include chronic, excessive alcohol consumption, viral infections, or toxins.

Hypertrophic cardiomyopathy (HCM), often referred to as *obstructive hypertrophic cardiomyopathy*, is a condition in which there is excessive myocardial hypertrophy. The heart muscle, typically the left ventricle, thickens, enlarges, and becomes stiff. Contraction is typically not weakened, but filling is impaired creating a diastolic or filling dysfunction. Ejection fraction may be normal. Hypertrophic cardiomyopathy can be the cause of sudden cardiac death (SCD) in young people as a result of life-threatening ventricular dysrhythmias. HCM is considered the most common cause of SCD in young competitive athletes.

Restrictive cardiomyopathy is characterized by stiff ventricular muscle resulting in diastolic dysfunction or impaired filling. Ejection fraction may be normal. In this disease, the normal heart muscle is replaced by fibrosis and scarring. This leads to heart failure and dangerous dysrhythmias. Restrictive cardiomyopathy typically results from another disease such as amyloidosis, sarcoidosis, or hemochromatosis.

### Clinical Manifestations

An individual with cardiomyopathy may present with symptoms of angina or heart failure. Angina symptoms include chest pain, dizziness, indigestion, nausea, vomiting, sweating, palpitations, shortness of breath, and unexplained increasing fatigue. Heart failure symptoms include rapid or irregular heart rate, shortness of breath with or without activity, shortness of breath while lying flat, and edema of the legs, feet, and abdomen. Pulmonary congestion is evident due to fluid overload. The patient with fluid overload may present with abnormal heart sounds (gallop or murmur), elevated pressures in the neck (JVD), and an enlarged liver. Other signs of cardiomyopathy include sleeplessness, cough, fatigue, fainting, and loss of appetite.

### Connection Check 32.6

The nurse understands which of the following are symptoms of HCM? (Select all that apply.)

- A. Weakened contraction
- B. Poor filling
- C. Decreased cardiac output
- D. Impaired systolic function
- E. Impaired diastolic function

## Management

### Medical Management

#### Diagnosis

##### Diagnostic Testing

Diagnosis of a patient with cardiomyopathy is done through several diagnostic tests. A chest x-ray may show an enlarged heart, as well as the presence of fluid in the lungs. An echocardiogram can estimate the size and motion of the individual chambers of the heart. The heart wall motion may be described as normal, hypokinetic, hyperkinetic, akinetic, or dyskinetic and is graded from mild to severe. An akinetic heart wall has no specific wall movement. A dyskinetic heart wall moves in the opposite direction from where it should be moving. A hypokinetic heart is not moving enough, and a hyperkinetic wall is moving too much. Motion abnormalities help to define the specific cardiomyopathy. Patients with an increased number and severity of impaired wall segments are at increased risk for adverse cardiac events. An echocardiogram can also provide information on ejection fraction.

An ECG is performed to look for electrical disturbances in the heart. The ECG can provide important information about the patient's heart rate and rhythm, as well as problems with conduction of the electrical current from one portion of the heart to another. Cardiomyopathy can lead to dangerous ventricular dysrhythmias.

Right heart catheterization is a procedure in which a catheter is threaded through the chambers of the heart in order to obtain pressure in each individual chamber. These pressures may be used to assess the heart's ability to pump blood through the heart. In addition to pressure readings, a SvO<sub>2</sub> sample and a small biopsy may be obtained.

Cardiac magnetic resonance imaging (MRI) is a technique that uses magnetic and radio waves to create images of the heart. These images may be used in adjunct with the echo to offer a more accurate picture of the size and shape of the heart.

Blood tests may be obtained to evaluate cardiac function. One important blood test is the B-type natriuretic peptide, commonly referred to as the *BNP*. The *BNP* is a protein released from overstretched ventricular tissue, a common clinical manifestation of cardiomyopathy. A variety of other blood tests are performed to assess end-organ perfusion and specific causes of cardiomyopathy, including chemistry tests to evaluate renal and liver function, thyroid function tests, iron levels, and CBCs to evaluate for anemia.

#### Treatment

##### Medications

Medication therapy is an important component in the treatment of a patient with cardiomyopathy. The overall goals for medical treatment are management of the clinical manifestations of heart failure, preventing worsening of the heart function, and reduction of the risks for complications.

Treatment will vary by individual type of cardiomyopathy and may include:

- Angiotensin-converting enzyme (ACE) inhibitors
- Angiotensin-receptor blockers (ARB)
- Beta blockers
- Diuretics

Angiotensin-converting enzyme medications are given to improve the heart's pumping capacity. They reduce afterload or SVR, making it easier for the heart to eject blood. Angiotensin receptor blockers have effects similar to those of ACE inhibitors and are given to those individuals who do not tolerate ACE inhibitors because of its side effects. Beta blockers decrease the sympathetic nervous system response to decreased CO decreasing workload and myocardial oxygen consumption. They have been shown to prevent progression of the disease and improve outcomes. For patients who cannot tolerate an ACE inhibitor and/or ARB, hydralazine and a nitrate may be an alternative. The angiotensin receptor neprilysin inhibitor (ARNI) may be used in place of an ACE inhibitor for patients who do not have improvement in function or who have worsening symptoms. Digoxin, a positive inotrope agent, is not indicated for primary therapy, but may be used to control symptoms such as fatigue, dyspnea, and exercise intolerance. Diuretics reduce fluid accumulation in the lungs that occurs because of the ineffective pumping action of the heart. One diuretic, spironolactone (Aldactone), may help prevent further scarring of heart tissue.

Hypertrophic cardiomyopathy treatment utilizes beta blockers and calcium channel blockers. Some calcium channel blockers improve the filling of the heart by reducing calcium entering the heart during the cardiac cycle, thus decreasing its stiffness. This has the effect of reducing symptoms such as chest pain, breathlessness, and palpitations because CO is improved. Restrictive cardiomyopathy uses a medication regimen aimed at symptom reduction. Diuretics are used in an attempt to control dyspnea and shortness of breath.

##### Pacemaker Intervention

A biventricular pacemaker can benefit an individual with advanced cardiomyopathy who presents with dyssynchronous ventricular heart function. A pacer wire is placed in both the right and left ventricles in an effort to coordinate the contractions of both ventricles. An implantable cardioverter defibrillator (ICD) is currently recommended for patients with reduced EF (<30%), who are at higher risk for lethal dysrhythmias. This device monitors the heart for lethal ventricular dysrhythmias and delivers a shock if needed. The pacemaker and AICD can be combined into one device, referred to as a *biventricular implantable cardioverter defibrillator*.

For patients with continued symptoms, but who are not candidates for open-heart surgery, septal ablation may be an option. Also called *septal alcohol ablation*, this is a treatment in which a small portion of the thickened heart muscle

is destroyed by injecting alcohol through a catheter into the heart muscle. The destroyed muscle is replaced with thin scar tissue, allowing the heart to fill more effectively, thus improving CO.

### Surgical Management

Surgical therapies include:

- Septal myectomy
- Surgical ventricular remodeling
- Transmyocardial revascularization (TMR)
- Mechanical circulatory support (MCS) including left ventricular assist device (LVAD)
- Heart transplantation

Septal myectomy is an open-heart surgery in which the surgeon removes part of the thickened, overgrown heart muscle wall (septum) that separates the ventricles. Removing part of this overgrown muscle improves blood flow. Myectomy is used when medications alone do not relieve symptoms. Most people who have undergone a myectomy have no further symptoms.

Surgical ventricular remodeling is an open-heart surgical procedure that reduces the size of the left ventricle to improve the function of the heart. In this procedure, the surgeon either removes a section of the heart muscle or sutures a tuck into the muscle to reduce the overall size of the ventricle. As with the septal myectomy, this procedure reshapes the heart to increase filling capacity and improve heart function.

Despite the increasing success of conventional medical and surgical interventions, many patients with cardiomyopathy have intractable angina that cannot be successfully managed. Transmyocardial revascularization is a surgical procedure that uses CO<sub>2</sub> laser ablation to create transmural channels in the heart muscle to restore myocardial perfusion. The initial premise of this procedure was these channels would offer increased blood supply to the poorly supplied myocardium. This procedure results in a reduction in angina, but research has shown no change in myocardial blood flow. The mechanism of the observed reduction in symptoms is unknown. It has been used as an adjunctive therapy with coronary artery bypass graft to achieve more complete revascularization. Its use, though, is controversial. The DIRECT trial, the only major blinded study of TMR, revealed no benefit of TMR compared with continued medical therapy in patient survival, angina classification, quality of life, duration of exercise, or nuclear imaging.

Placement of an LVAD or heart transplantation may be used for patients with dilated cardiomyopathy. An LVAD is an electrical device that is surgically attached to the patient's ventricle to augment contraction in the weakened heart. Both placement of an LVAD and heart transplantation have an extremely high degree of risk. They are considered only when other medical and surgical means have been exhausted and the patient is at risk for death. These will be discussed in more detail in the cardiogenic shock section.

### Complications

Heart failure, the inability of the heart to produce enough cardiac output (CO) to meet the body's metabolic demands, is the main complication of cardiomyopathy. This decrease in CO may be due to problems with filling or contraction. Heart failure is discussed in detail in Chapter 30.

Dysrhythmias are a common complication of cardiomyopathy. Examples include atrial fibrillation and more lethal rhythms such as ventricular tachycardia (V-tach) and ventricular fibrillation (V-fib). Atrial fibrillation decreases CO through loss of the "atrial kick"; the filling force contributed by atrial contraction immediately before ventricular systole to maximize ventricular preload. It also places the patient at risk for stroke because of the formation of clots in the quivering atria. Ventricular tachycardia and V-fib can lead to sudden death. Dysrhythmias are discussed in detail in Chapter 29.

Thrombosis, or clot formation, is a risk due to the sluggish forward flow of blood leading to stasis. Cardiomyopathy patients are at risk for pulmonary embolism (PE), MI, or stroke if clots enter the bloodstream. To reduce the risk of thrombosis, patients are typically prescribed medications such as antiplatelet agents— aspirin or clopidogrel (Plavix)—and anticoagulants such as warfarin (Coumadin) or Factor XA inhibitors such as Rivaroxaban (Xarelto).

### Connection Check 32.7

The nurse monitors for which complications in patients with cardiomyopathy? (Select all that apply.)

- A. Ventricular dysrhythmias
- B. Stroke
- C. Pericarditis
- D. Pulmonary embolism
- E. Pleural effusion

### Nursing Management

#### Assessment and Analysis

Nursing assessment is aimed toward anticipation of heart failure and recognition of the cardiovascular, cerebral, pulmonary, gastrointestinal, and renal effects that may occur as a result. Fatigue, shortness of breath, edema, dizziness, indigestion, palpitations, and loss of appetite are all common presenting symptoms. More dangerous manifestations include ventricular dysrhythmias. While the heart continues to fail to deliver adequate CO, the symptomatology may progress to signs of end-organ damage such as decreases in urine output.

#### Nursing Diagnosis

- **Decreased CO** related to ineffective cardiac pumping secondary to cardiomyopathy

## Nursing Interventions

### Assessments

- Vital signs including oxygen saturation  
*Changes in BP and heart rate may indicate worsening disease, decreasing CO or EF. A decreasing oxygen saturation may indicate worsening left heart failure.*
- Neurological status  
*Increasing fatigue that may progress to lethargy, confusion, and loss of consciousness are signs of decreased CO.*
- ECG  
*Dysrhythmias may be a sign of decreased CO and are a lethal complication of cardiomyopathy. The ECG can also provide an evaluation of ischemia.*
- Lung sounds  
*Auscultation of crackles is an indication of the development of pulmonary edema due to left heart failure.*
- Chest pain  
*Chest pain indicates that the demand for oxygen is higher than the supply, indicating insufficient CO.*
- Urine output  
*Decreased urine output can be the first sign of decreasing CO because the kidneys receive approximately 25% of the CO.*
- Laboratory tests
  - BNP  
*An increased BNP is released from overstretched tricular tissue; a sign of heart failure.*
  - Renal and liver function tests  
*Increased renal and liver function values are a sign of increasingly poor perfusion and inadequate CO.*
- Activity tolerance  
*Physical activity increases the oxygen demand. Increased fatigue and dyspnea may be signs of worsening heart failure.*

### Actions

- Administer medications as ordered:
  - Beta blockers  
*Beta blockers decrease the sympathetic nervous system response to decreased CO and decrease the workload of the heart.*
  - Diuretics  
*Diuretics reduce fluid accumulation in the lungs that occurs because of the ineffective pumping action of the left heart.*
  - Antiarrhythmics  
*Dysrhythmias are a common complication of cardiomyopathy. Bradyarrhythmias as well as tachyarrhythmias reduce CO and thus decrease tissue perfusion.*
  - ACE inhibitors/ARBs  
*Angiotensin-converting enzyme inhibitors and ARBs reduce afterload, making it easier for the heart to eject blood.*
  - Digoxin  
*Digoxin is a positive inotropic agent that can improve the heart muscle contractions, reducing associated heart failure symptoms.*

- Provide oxygen  
*Increased oxygen supply helps meet the increased oxygen demands.*
- Maintain patient positioning as prescribed for particular cardiomyopathy  
*Semi- to high-Fowler's position reduces preload and ventricular filling. It also decreases dyspnea. The supine position increases venous return and promotes diuresis.*
- Restrict activity and provide a quiet relaxed atmosphere  
*A quiet and low-stress environment reduces oxygen and cardiac demands.*

### Teaching

- Signs and symptoms of heart failure  
*Recognizing symptoms of heart failure can allow the patient to get treatment sooner, possibly preventing hospital admission.*
- Medications: purpose, dosages, and potential side effects  
*Prescribed medications are to decrease the symptoms associated with cardiomyopathy as well as improve heart function. It is important for the patient to understand the potential side effects to prevent harm.*
- Dietary restrictions of fluid and sodium  
*Maintaining fluid and sodium restrictions helps decrease volume overload, which helps avoid the development of heart failure.*
- Importance of a moderate exercise regimen and understanding the signs of overexertion  
*Exercise has been shown to improve symptoms and exercise capacity. Vigorous activity is not recommended with HCM. Patients may be referred to cardiac rehabilitation to exercise in a monitored setting.*

### Evaluating Care Outcomes

Strict adherence to the medical, dietary, and exercise regimens prescribed may help the cardiomyopathy patient remain free from symptoms of heart failure. Of great importance is the knowledge of when to seek help for worsening symptoms to avoid unnecessary hospitalizations and unwanted complications.

### Connection Check 32.8

The nurse questions which order for the patient with cardiomyopathy?

- A. ACE inhibitors
- B. Beta blockers
- C. Diuretics
- D. SL nitroglycerin

## CARDIOGENIC SHOCK

Cardiogenic shock occurs when the heart muscle is unable to pump adequate CO to meet the body's needs to maintain adequate tissue perfusion. The most common cause of cardiogenic shock is MI, but other causes include

decompensation from end-stage congestive heart failure or cardiomyopathy, mechanical complications with acute mitral regurgitation, or rupture of the ventricular wall. It is frequently noted in patients suffering ST-segment elevation MI (5%-10%) and in patients with significant comorbidities. Patients with diabetes are also at increased risk of cardiogenic shock after MI. It is the most common cause of death in patients with MI with a frequency of approximately 7% to 10%.

## Pathophysiology

In cardiogenic shock, the heart muscle cannot adequately contract, causing a decrease in cardiac output (CO). The main mechanical defect is a marked reduction in contractility evidenced by a decreased EF at normal systolic pressures. As a result of decreased contractility, left and right ventricular filling pressures are increased, but CO is low. Due to the low cardiac output there is increased oxygen extraction at the tissue level, resulting in a decreased venous oxygen saturation.

Decreased CO leads to the activation of several compensatory mechanisms. These include sympathetic stimulation, which increases the heart rate and cardiac contractility and causes renal fluid retention, augmenting the left ventricular preload. The increased heart rate and contractility increase the myocardial workload and thus the myocardial oxygen demand, worsening myocardial ischemia. Sympathetic stimulation also causes vasoconstriction to maintain systemic BP to increase CO, which also increases SVR. The increased afterload additionally increases cardiac workload. The renin-angiotensin-aldosterone (RAAS) is also stimulated due to decreased renal perfusion, resulting in vasoconstriction and fluid retention increasing filling pressures. The increased left ventricular volumes combined with poor contractile function contribute to the development of pulmonary edema and hypoxia. This cycle of excessive myocardial oxygen demand combined with inadequate myocardial perfusion worsens myocardial ischemia, ultimately ending in death if the cycle is uninterrupted. Autopsy typically reveals necrosis of more than 40% of the left ventricular cardiac tissue in patients with cardiogenic shock.

## Clinical Manifestations

Cardiogenic shock is frequently caused by MI; therefore, the patient may present with clinical symptoms of MI including chest pain, diaphoresis, nausea, and vomiting. These symptoms are the consequence of oxygen-deprived tissue and the compensatory mechanisms that occur as a result of the low CO. Without intervention, clinical symptoms occur including shortness of breath, auscultation of crackles, decreased peripheral pulses, cool pale skin, decreased bowel sounds, decreased urine output, restlessness, and confusion. The initiation of compensatory mechanisms leads to increased heart rate. If a PA line is in place, increased SVR,

increased right and left ventricular end-diastolic volume or pressure, CVP or PAOP respectively, and decreased mixed venous oxygen level are demonstrated. Oxygen deprivation leads to excessive production of lactic acid. Arterial blood gases reveal a metabolic acidosis with an accompanying increase in serum lactate level.

Compensatory mechanisms eventually fail to maintain adequate CO, worsening inadequate organ perfusion. At this time, clinical manifestations include hypotension; tachycardia with weak pulses; tachypnea; cold, cyanotic, and mottled skin; decreased or absent urine output; severely decreased level of consciousness; and severely decreased or absent bowel sounds. Over time, without intervention, multiple organ systems begin to fail. This is evidenced by severe hypotension, bradycardia, hypoxia, liver and pancreas failure leading to hypoglycemia, and hematological changes resulting in emboli, diffuse intravascular clotting (DIC), and severe coagulopathy.

## Management

### Medical Management

#### Diagnosis

#### Laboratory and Diagnostic Testing

Cardiogenic shock is diagnosed after exclusion of other causes of hypotension and shock such as hypovolemia, sepsis, aortic dissection, PE, tension pneumothorax, or cardiac tamponade. Laboratory testing includes cardiac enzymes in conjunction with ECG changes to confirm an AMI. An ABG analysis will assist with the assessment of hypoxia and the presence of metabolic acidosis, which indicates decreased tissue perfusion. Venous oxygen saturation can assist with the evaluation of the adequacy of oxygen supply in relation to tissue oxygen demands. A lactate level may be obtained to assess tissue perfusion. An increased lactate level is an indication of anaerobic metabolism producing increased lactic acid. A metabolic profile including liver function and renal function tests helps assess organ function.

#### Medications

Treatment priorities include stabilizing oxygenation and initiating medication therapy to increase BP and cardiac output. The focus of medication therapy is to increase BP and CO and decrease cardiac workload. The presence of an arterial line is essential in monitoring the patient's response to medication. A PA catheter can also help to guide management through evaluation of CO, preload, afterload, stroke work indices, and SvO<sub>2</sub>. As soon as possible, inotropic medications such as dobutamine hydrochloride (Dobutamine) and epinephrine should be initiated to improve CO. Vasopressor support such as dopamine hydrochloride, norepinephrine (Levophed), or phenylephrine (Neo-Synephrine) should be started to support BP and help maintain an adequate MAP.

Nitroglycerin may be added to decrease preload and afterload. It decreases preload through venous dilation and

decreases afterload through arterial dilation. It will also decrease BP, so it should be used with extreme caution. Nitroprusside may also be used with extreme caution to decrease afterload. Diuretics may also be used, again, with caution to decrease filling volumes. Morphine sulfate may also be administered. It may relieve pain due to a myocardial infarction and decrease venous return and preload through its action as a venous dilator.

### Treatment

If providing 100% oxygen via a non-rebreather face mask does not adequately improve oxygenation, ventilatory support through endotracheal intubation and mechanical ventilation may be required to decrease the work of breathing and improve oxygenation. Early revascularization through percutaneous coronary intervention has been shown to increase short-term and long-term survival in most patients in cardiogenic shock.

Intra-aortic balloon pump (IABP) therapy may be necessary when the initial medical management does not improve CO enough to maintain adequate tissue perfusion. The primary goal of IABP therapy is to increase myocardial oxygen supply and decrease myocardial oxygen demand. The IABP catheter is inserted into the aorta usually via the femoral artery. Upon placement, the catheter with a balloon at the tip should sit just below the aortic arch, approximately 2 cm from the left SC artery. The IABP moves helium gas in and out of the balloon. It is timed to inflate at the start of diastole and deflate just before systole. As the balloon inflates, it displaces the blood toward the systemic and coronary circulation, which improves coronary and systemic perfusion. While the balloon deflates, it decreases afterload, thus decreasing the workload of the left ventricle (Fig. 32.12). The most common complications from IABP include limb ischemia from clot formation, aortic dissection, bleeding, balloon rupture, infection, thrombocytopenia, and catheter migration.

### Safety Intra-aortic Balloon Pump

#### Alert

It is critical to not allow the IABP to remain dormant for longer than a few minutes to reduce risk of clot formation and embolization. The catheter should be monitored regularly for signs of balloon rupture, including brown flecks of blood in the catheter, poor augmentation, or gas leak alarms. Balloon rupture is an emergency and needs immediate intervention. The pump should immediately be placed in standby mode and plans made for immediate removal.

### Connection Check 32.9

What action of IABP therapy supports cardiac function?

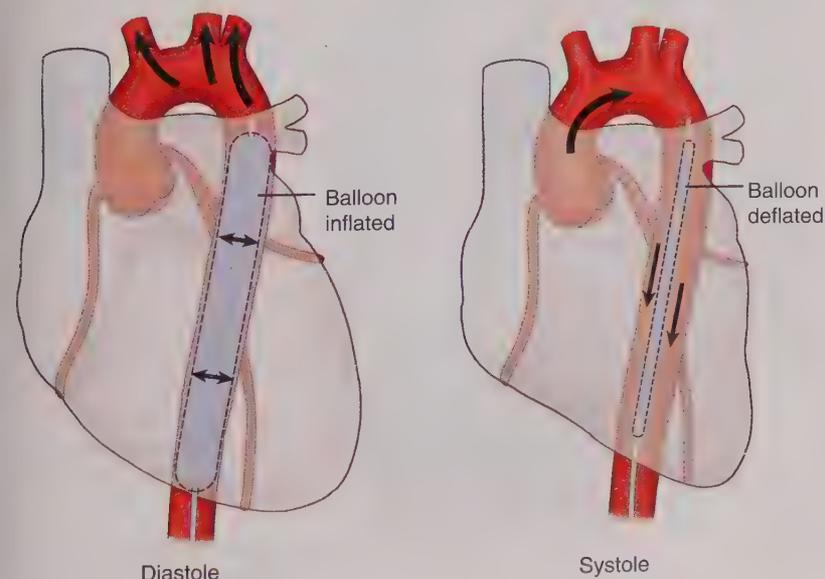

- Inflating the balloon during systole, increasing CO
- Inflating the balloon during diastole, improving coronary circulation
- Deflating the balloon during diastole, decreasing SVR
- Deflating the balloon during systole, improving coronary circulation

### Surgical Management

The patient in end-stage heart failure or cardiogenic shock who has not improved with inotropic and/or IABP support may be referred for placement of a mechanical circulatory support (MCS) or for heart transplant.

### Mechanical Circulatory Support Devices

Mechanical circulatory support devices are mechanical pumps used to assist the ventricles and decrease the workload of the heart. In heart failure or cardiogenic shock, a patient may require an MCS device as a bridge to recovery or to transplantation. **Most MCS devices are typically used**

**FIGURE 32.12** Intra-aortic balloon pump; balloon inflated during diastole to push blood into the coronaries, deflated during systole to decrease systemic vascular resistance.

in the left ventricle (LVAD). An LVAD works by pulling blood from the left ventricle into the pump (Fig. 32.13). The pump then ejects the blood into the aorta. A right ventricular assist device (RVAD) works by pulling blood from the right ventricle, then ejecting the blood into the pulmonary artery.

Ventricular assist devices include percutaneous left atrial-to-femoral arterial ventricular assist device (Tandem Heart), a type of ventricular assist device in which a pump returns blood to the femoral artery from the left atrium decreasing the workload of the left ventricle. Another type of ventricular assist device is a percutaneous transvalvular left ventricular assist device (Impella LP 2.5 or Impella CP). This catheter is placed via the femoral artery, retrograde across the aortic valve into the left ventricle to replace the work done by left ventricle. A right ventricular assist device; Impella RP System (Abiomed, United States) provides similar support to patients with refractory right ventricle shock. If the patient is ineligible for a heart transplant, an MCS can be used as long-term or destination therapy.

Extracorporeal membrane oxygenation (ECMO) offers an alternative form of mechanical circulatory support therapy for patients with severe acute respiratory and/or cardiac failure who have a high mortality risk despite optimal conventional treatment. ECMO may be described as a bedside heart-lung intervention. With ECMO, deoxygenated blood is diverted from the vascular system via a central vein and returned to the circulation after being oxygenated outside

the body. Indications include respiratory failure and/or cardiogenic shock. Extracorporeal membrane oxygenation is a complex procedure that allows complete support of the patient's respiratory and/or cardiac function at the bedside to allow for recovery and treatment of the underlying process or as a bridge to a more durable device.

Venovenous (VV) ECMO provides respiratory support only. Blood is extracted from cannula placed in the vena cava or right atrium and returned via cannula to the right atrium and provides gas exchange and respiratory support only.

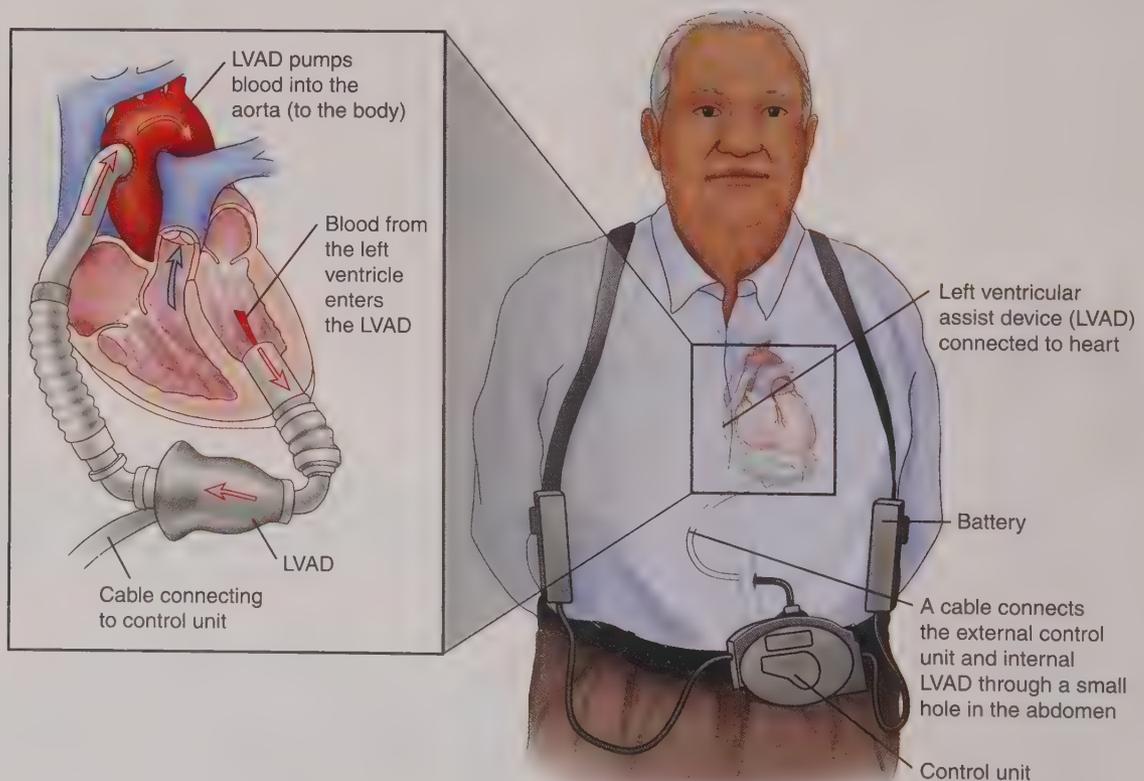

Venoarterial (VA) ECMO provides both respiratory and hemodynamic support. Blood is extracted from a cannula placed in the right atrium and returned via cannula placed in the arterial system, bypassing the heart and lungs.

### Total Artificial Hearts

The total artificial heart may be considered a form of heart assist device but is actually a heart replacement device. Many patients in end-stage heart failure have only a few options—immediate heart transplant, two VADs (RVAD and LVAD), or total artificial heart implantation. Criteria for recipients of an artificial heart include end-stage heart failure, life expectancy of less than 30 days, not eligible for a natural heart transplant, and have no other viable treatment options.

### Heart Transplantation

Urgent heart transplantation is another option for the patient in cardiogenic shock. This is an option only when all

**FIGURE 32.13** Left ventricular assist device.

other medical and surgical therapies have been exhausted. Unlike an MCS device, a heart transplant replaces the patient's failing heart with a healthy heart received from a donor.

### Connection Check 32.10

The nurse understands that a/an \_\_\_\_\_ is used in the evaluation of cardiogenic shock.

- A. PA catheter
- B. LVAD
- C. RVAD
- D. IABP

### Nursing Management

#### Assessment and Analysis

The clinical manifestations in cardiogenic shock are related to the decrease in CO and impaired blood flow to all vital organs: hypotension; tachycardia with weak pulses; tachypnea; cold, cyanotic, and mottled skin; decreased or absent urine output; severely decreased level of consciousness; and severely decreased or absent bowel sounds. Without successful intervention, multiple organ systems begin to fail. Severe hypotension, bradycardia, hypoxia, hypoglycemia, DIC, and severe coagulopathy are possible.

#### Nursing Diagnosis

- **Altered tissue perfusion** related to inadequate CO

#### Nursing Interventions

##### Assessments

- Vital signs and hemodynamic readings  
*Hypotension, decreased CO, and increased left ventricular filling volumes are present because of the ineffective contractile ability of the heart. Increased SVR and tachycardia occur as a compensatory mechanism to increase BP and CO. RR is increased to improve oxygenation.*
- BP readings in both arms  
*BP may have contralateral differences if the patient has the presence of arterial dissection or IABP migration.*
- Breath sounds and oxygen saturation  
*Decreasing O<sub>2</sub> saturation and/or auscultation of crackles indicate the presence of left heart weakening and pulmonary edema.*
- Neurological status  
*Decreased level of consciousness occurs as a result of decreased CO.*
- Skin color and temperature  
*Cold and clammy skin may be a sign of progressing shock.*
- Labs to include:
  - ABGs  
*Arterial blood gases may reflect a metabolic acidosis due to anaerobic metabolism.*
  - Hemoglobin and hematocrit  
*Adequate hemoglobin and hematocrit are essential to support oxygenation.*

- Metabolic profile  
*Metabolic profile data can track organ function through liver function and renal function tests.*
- Lactate  
*Increasing lactate levels are an indicator of anaerobic metabolism.*
- SvO<sub>2</sub>  
*Decreasing SvO<sub>2</sub> indicates increased oxygen utilization at the tissue level due to low CO.*

##### Actions

- Apply 100% non-rebreather oxygen mask  
*Maximizing oxygenation is essential*
- Anticipate intubation and mechanical ventilation  
*Intubation with mechanical ventilation may be required to decrease myocardial workload and improve oxygenation.*
- Prepare for invasive hemodynamic monitoring such as arterial, central, and PA catheters  
*Invasive monitoring allows more precise evaluation and adjustment of medications.*
- Administer inotropic and vasoactive medications as prescribed  
*Inotropic medications increase contractility. Vasoactive medications increase BP. Both are done to improve stroke volume and systemic tissue perfusion.*
- Administer fluid replacement as prescribed  
*Fluid is administered to improve CO and preload only if filling pressures are low.*
- Administer diuretics as prescribed  
*Diuretics may be administered with caution if left ventricular filling volumes are greatly increased.*
- Restrict activity and allow rest periods; treat pain and anxiety  
*Restricting activity and decreasing pain and anxiety decrease cardiac workload and oxygen consumption. Morphine for pain also decreases preload with its action as a venous dilator.*
- Anticipate the potential placement of an IABP  
*IABP helps increase coronary circulation (balloon inflation during diastole) and decrease SVR (balloon deflation during systole)*
- If an IABP is in place:
  - Assure the IABP catheter is secured, the head of bed is elevated no more than 30 degrees, and the affected leg is kept straight at all times  
*Helps avoid catheter migration*
  - Assess catheter tubing for brown flecks or blood  
*The presence of brown flecks may indicate balloon rupture.*
  - Assess lower-extremity perfusion such as color, temperature, and pulses  
*An IABP catheter may cause decreased perfusion to the affected extremity.*

##### Teaching

- Instruct patient on the importance of rest periods  
*Increased activity or stress levels cause increased myocardial oxygen consumption and can worsen a shock state.*

## Box 32.7 Healthy People 2020: Cardiovascular Dysfunction and the Goals for 2020

Our nursing care plans and the *Healthy People 2020* goals are intricately linked to promote health and reduce cardiovascular dysfunction. Atherosclerosis is the major cause of the cardiovascular disease discussed in this chapter. The objectives of *Healthy People 2020* put a major focus on decreasing the risk factors for this disease and early identification and treatment of issues. *Healthy People 2020* guidelines also reflect the strong scientific background that supports the benefits associated with eating a healthy diet, maintaining a healthy body weight, smoking cessation, maintaining daily physical activity, and diabetic control. This is essential for myocardial infarction, cardiomyopathy, and ultimately cardiogenic shock.

- Allow family member visitation  
*Family visitation can help to decrease a patient's anxiety and stress levels.*
- Teach the patient to maintain fluid and sodium restrictions as prescribed  
*Maintaining fluid and sodium restrictions decreases the risk of heart failure, which exacerbates the presence of shock.*
- Patient will state understanding of symptoms of heart failure to report to his or her provider  
*Early treatment of heart failure prevents the progression to shock.*

### Evaluating Care Outcomes

Quick and effective intervention with inotropic and vasoactive support is essential to return the patient to hemodynamic stability. Careful monitoring of clinical manifestations and hemodynamic status helps evaluate therapeutic interventions. Successful treatment is demonstrated by a satisfactory BP level and cardiac output and adequate tissue perfusion. With strict adherence to dietary and lifestyle changes, the patient may return to activities of daily living, freed from abnormal findings on physical examination, sleeping comfortably, and articulating feelings of control (Box 32.7).

## Making Connections

### CASE STUDY: WRAP-UP

Post-PCI, an IABP is inserted, and Mr. King is transported to the coronary care unit. A PA catheter and arterial line are placed. The PA line reveals a greatly reduced CO of 2, increased occlusive pressure of 24, increased SVR of 1,800, and decreased SvO<sub>2</sub> of 50%. His

BP remains low at 80/50 mm Hg with a heart rate of 108 bpm. He remains on a norepinephrine and dobutamine drip. He remains intubated and on assist/control on the ventilator with a fraction of inspired oxygen of 60%.

Mr. King requires continuous and extensive monitoring. He remains on the balloon pump and slowly begins to improve. His BP increases to 105/65, and the dose of norepinephrine is decreased. His SVR decreases slightly, and his CO improves to 4. His occlusive pressure decreases to 16 after a 40-mg dose of IV Lasix. After 2 days in the coronary care unit on the balloon pump after PCI, Mr. King begins to turn the corner. His BP is stabilizing, and his CO is within normal limits. His ABGs, pH 7.37, PaCO<sub>2</sub> 38, PaO<sub>2</sub> 85, and HCO<sub>3</sub><sup>-</sup> 24, reveal improved oxygenation and resolution of metabolic acidosis, demonstrating improved systemic blood flow.

### Case Study Questions

1. The nurse monitors for which clinical manifestations in the patient diagnosed with MI? (*Select all that apply.*)
  - A. Chest pain
  - B. Nausea
  - C. Diaphoresis
  - D. Hypertension
  - E. Bounding pulses
2. On arrival to the emergency department, the nurse caring for Mr. King receives several orders from the provider. Which order should the nurse implement first?
  - A. Morphine sulfate, 2 mg IV
  - B. Nitroglycerin tab SL
  - C. Oxygen, 2 L via nasal cannula
  - D. Aspirin, 325 mg chewed
3. A treatment goal for Mr. King is to decrease myocardial workload. What order should the nurse anticipate to accomplish this goal?
  - A. Norepinephrine IV drip
  - B. Dobutamine IV drip
  - C. Metoprolol IV push
  - D. Aspirin 325 mg PO
4. The nurse caring for the patient with cardiogenic shock incorporates which nursing diagnosis into the plan of care?
  - A. Impaired tissue perfusion related to decreased circulating volume secondary to hypovolemia
  - B. Impaired tissue perfusion related to decreased circulating volume secondary to peripheral vasodilation
  - C. Impaired tissue perfusion related to decreased circulating volume secondary to poor contractile function of myocardial muscle
  - D. Impaired tissue perfusion related to decreased circulating volume secondary to interrupted response of the sympathetic nervous system

5. What is the main purpose of the IABP? (Select all that apply.)
- Deflate during diastole to facilitate myocardial oxygen delivery
  - Inflate during diastole to facilitate myocardial oxygen delivery
  - Deflate during systole to decrease SVR
  - Inflate during systole to increase BP
  - Deflate during systole to facilitate myocardial oxygen delivery

## CHAPTER SUMMARY

Invasive hemodynamic monitoring is important to allow early identification and treatment of the complex medical problems of the critically ill patient. With the use of central venous or PA catheters, the nurse can evaluate the patient's immediate response to treatments including inotropic medications and mechanical support. Invasive monitoring may also be used for transvenous pacemaker insertion, central venous and pulmonary pressure monitoring, volume resuscitation, frequent blood draws, long-term IV antibiotics, medications known to be caustic to peripheral administration, and parenteral nutrition administration. These catheters may also be used when IV therapy is needed, and peripheral veins are not accessible. It is important to remember that IV medications may never be infused through the arterial line for risk of loss of limb.

Pulmonary artery catheters use is decreasing because of questions that have been raised about their precise indications, cost-effectiveness, effect on clinical outcomes, and the extensive training required to accurately interpret the hemodynamic data they provide. The use of a PA catheter needs to be individualized based on patient needs.

Myocardial infarction (MI), cardiomyopathy, and cardiogenic shock are different disease processes that result from destruction of normal heart muscle. Complications arise when the heart is not able to supply enough blood to the

other organs of the body. Myocardial infarction refers to the destruction of heart muscle from the lack of oxygenated blood supply. Many patients who develop MI have early warning signs such as fatigue and pain, but these symptoms are frequently ignored or misdiagnosed. Pain is caused by insufficient blood supply to the heart. The gold standard to determine diagnosis of MI is cardiac troponin level elevation. Routine MI admission orders include initial application of oxygen via nasal cannula, blood work, chest x-ray, and 12-lead ECG. Once the diagnosis of MI is made, early patient management involves control of ischemic pain, increasing blood flow to the heart muscle, prevention of clots, decreasing myocardial workload, and maintenance of hemodynamics. Emergency revascularization after MI by angioplasty within 6 hours has been found to have significant survivor benefits. The consequences of MI may include cardiomyopathy and cardiogenic shock.

Cardiomyopathy is a disorder in which the heart muscle becomes weak and may develop structural changes. An individual with cardiomyopathy may present with symptoms of angina or heart failure. Jugular vein distention is a common presenting symptom. Medication therapy is an important component in the treatment and management of a patient with cardiomyopathy. The overall goals for medical therapy are management of symptoms, preventing worsening of heart function, and reduction of risks for complications.

Any disorder that results in the acute deterioration of cardiac function can lead to cardiogenic shock. Cardiogenic shock is a medical emergency; immediate treatment aimed at improving delivery of oxygenated blood, preventing further ischemia, and progression of shock is necessary for any chance of survival.

The most common cause of cardiogenic shock is MI, but other causes include decompensation from end-stage congestive heart failure or cardiomyopathy. Invasive monitoring with arterial and PA catheters can assist in properly managing therapy for the patient in cardiogenic shock. Patient management is a combination of ventilator support and medications. Emergency revascularization helps improve survival. When medical management does not improve cardiac output, adjunct therapy needs to be initiated. Adjunct therapy includes intra-aortic balloon pump or LVAD.

## Promoting Health in Patients With Hematological Disorders

### Chapter 33

## Assessment of Hematological Function

*Kristy Gorman*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the hematological system
2. Discussing the oxygenation function of the hematological system
3. Explaining the role of the clotting cascade in maintaining homeostasis
4. Describing the procedure for completing a history and physical assessment of the hematological system
5. Correlating relevant diagnostic examinations to hematological function
6. Explaining nursing considerations for diagnostic studies relevant to the hematological system
7. Discussing changes in hematological function associated with aging

#### CONCEPTS

- Assessment
- Clotting
- Hematologic Regulation
- Infection
- Medication
- Nursing Roles
- Nutrition
- Oxygenation

#### ESSENTIAL TERMS

Agranulocytes	Leukocytes
Albumin	Lymphatic
Anemia	Lymphocytes
Basophils	Lymphoid
Cytopoiesis	Macrophages
Eosinophils	Monocytes
Erythrocytes	Myeloid
Erythropoiesis	Neutrophil
Extrinsic factors	Partial
Ferritin	thromboplastin
Fibrin	time (PTT)
Fibrinogen	Phagocytosis
Globulin	Plasma
Granules	Plasma cells
Granulocytes	Platelets
Hematocrit	Pluripotent
Hematopoiesis	Polycythemia
Hemoglobin	Prothrombin

Immunoglobulins	Reticulocytes
International	Stem cells
Normalized Ratio	Thalassemia
(INR)	Thrombocytes
Intrinsic factors	Thrombocytopenia
Left shift	Transferrin

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Marge Starr is a 25-year-old female who presents to the hematology clinic with complaints of generalized fatigue and increased shortness of breath. Ms. Starr is a high school physical education teacher who has noticed that she is having increasing difficulty performing her teaching responsibilities. During the last 2 weeks, she has had to take an afternoon nap after school hours. Ms. Starr schedules an appointment with her nurse practitioner for evaluation of these symptoms...

## INTRODUCTION

The hematological system includes the blood, blood cells, lymph, and organs involved with blood formation or blood storage. Blood is a specialized connective tissue that acts as a transport vehicle of materials between the external environment and the body's cells. Blood consists of **plasma** (a clear yellow, protein-rich fluid); solutes (proteins, electrolytes, and organic elements); red blood cells (RBCs), white blood cells (WBCs); and **platelets** (which are fragments of cells). Blood accounts for approximately 7% to 10% of total body weight. The total volume of blood in the average adult is approximately 5 to 6 L, and it circulates throughout the body within the circulatory system.

The hematological system is important in helping the body by circulating oxygen, nutrients, hormones, and metabolic wastes; protecting against invasion of pathogens; maintaining blood coagulation; and regulating fluids, electrolytes, acids, bases, and body temperature. This chapter reviews the physiology of the hematological system and the assessment of hematological status.

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

### Bone Marrow

Bone marrow is the primary site for blood formation and maturation (**hematopoiesis**). It is involved in the body's immune responses and is one of the largest organs of the body, making up 4% to 5% of total body weight. The bone marrow is a network of flexible connective tissue that produces stem cells (also called pluripotent or *precursor stem cells*). The stem cells are immature, undifferentiated cells that have the ability to become any one of several types of blood cells. Depending on the body's needs, stem cells can begin multilineage differentiation into mature **myeloid** or **lymphoid** stem cells. Lymphoid stem cells produce either T or B **lymphocytes**, which are the main functional cells

of the immune system. Myeloid stem cells differentiate into three cell types: RBCs (**erythrocytes**), WBCs (**leukocytes**), and platelets (**thrombocytes**).

At sites where the bone marrow is hematopoietically active, numerous erythrocytes are produced that make it red, hence the name *red bone marrow*. Red marrow regresses after birth until late adolescence (during active skeletal growth), after which it is located in the lower skull, vertebrae, shoulder and pelvic girdles, ribs, and sternum. Red marrow is gradually replaced by yellow marrow (fat cells) in most of the long bones, including the hands, feet, legs, and arms. Fat occupies approximately 50% of the space of red marrow in the adult. When the demand for red cell replacement increases, as in chronic hemolytic **anemia** (low RBC count), substitution of red marrow for yellow marrow can occur. Self-renewal and differentiation of stem cells are highly regulated processes to ensure homeostasis. Disruption of these processes inevitably leads to abnormal cell growth in the marrow or bone marrow failure.

### Connection Check 33.1

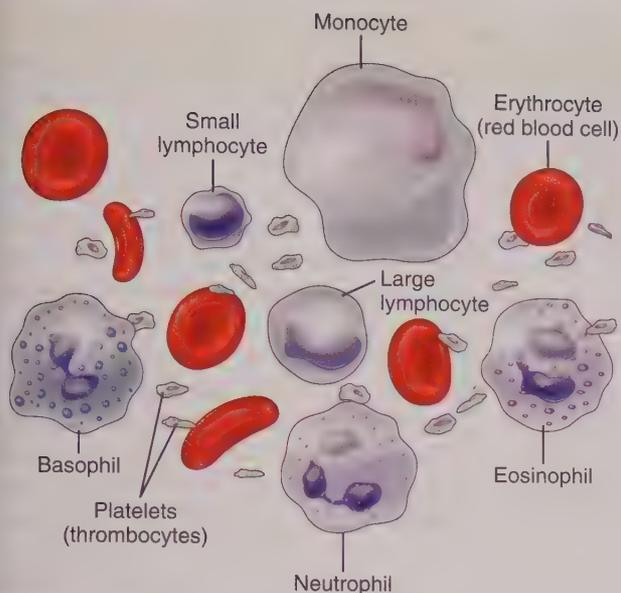

The nurse recognizes which statement as correct about blood cell formation?

- It occurs mostly in the marrow found in flat bones such as the sternum, ribs, and pelvis
- It occurs mostly in the marrow found in the shaft of long bones
- It occurs outside the marrow, once it enters the circulatory system
- It occurs after birth until late adolescence

### Blood Cells

Hematopoiesis is defined as the process of formation, development, and differentiation of the formed elements of blood. As previously discussed, all blood cells originate from cells in the bone marrow called pluripotential **stem cells**. Regulatory mechanisms cause stem cells to differentiate into families of parent cells, each of which gives rise to one of the mature, formed elements that are released into the circulation: RBCs (erythrocytes), platelets (thrombocytes), or WBCs (leukocytes) (Fig. 33.1).

The blood cells, or formed elements, are not all true cells because they lack many characteristics and structures of most cells. Platelets, or thrombocytes, are circulating cell fragments that have a cell membrane but no nucleus for cell division. The erythrocyte has no mitochondria available for oxidative metabolism and cellular energy conversion, no ribosomes for regeneration of lost or damaged proteins, and no nucleus to direct cell function and division. Because most blood cells do not divide, they must be constantly renewed by cell division in the bone marrow.

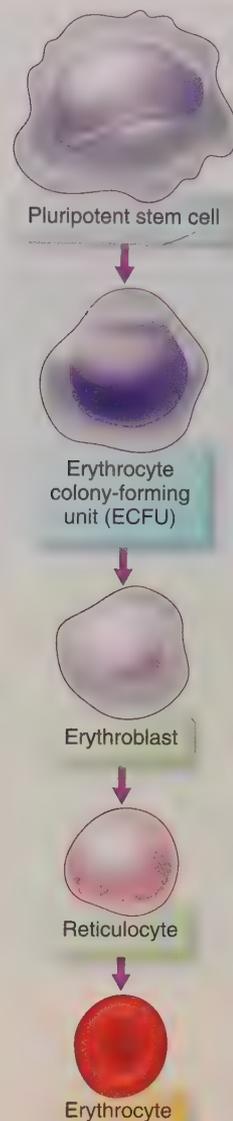

**FIGURE 33.1** Formed elements of blood: red blood cells (erythrocytes), platelets (thrombocytes), and white blood cells (leukocytes). Types of white blood cells are lymphocytes, monocytes, neutrophils, eosinophils, and basophils.

### Red Blood Cells

Erythrocytes (red blood cells, RBCs) are the most abundant of the formed elements. The erythrocyte is a small, biconcave disk with no nucleus. It has a large surface area and is so flexible that it can move through small capillaries of the circulatory system. The membrane of the red cell is very thin so that oxygen and carbon dioxide gases easily diffuse across. Erythrocytes have two principal functions: (1) to pick up oxygen from the lungs and transport it to systemic tissues and (2) to pick up carbon dioxide from the tissues and deliver it in the lungs. Shifts in the amount, size, shape, or composition of erythrocytes affect their ability to successfully carry out these functions.

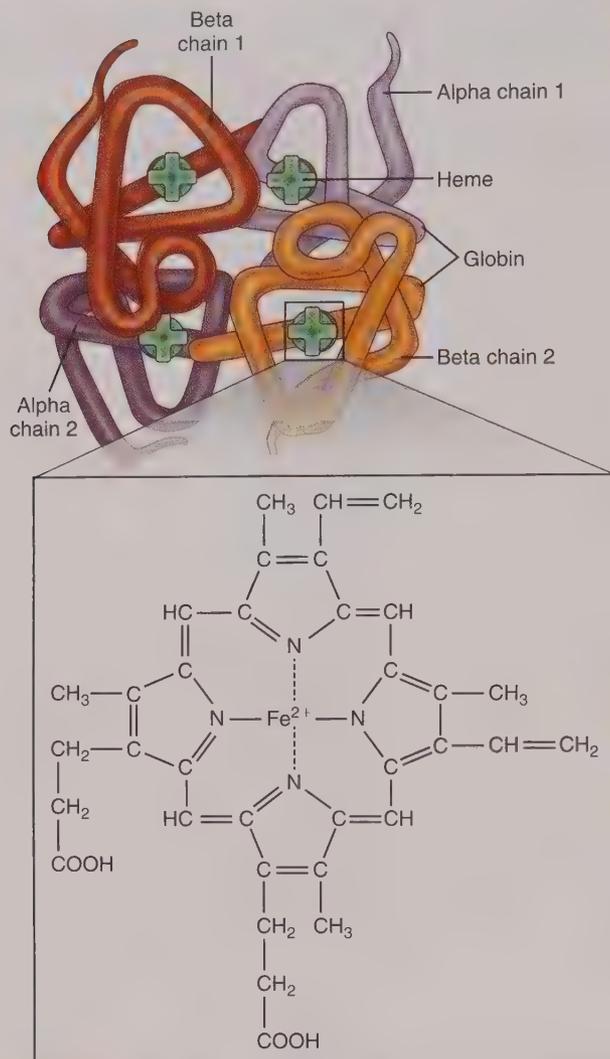

The erythrocytes, which are formed in the bone marrow, live approximately 120 days in the circulatory system. The number of RBCs in a human varies with gender, age, and general health, but the normal range is from 3.61 to 5.81 million/mm<sup>3</sup> (3.61–5.11 million cells/mm<sup>3</sup> in females and 4.21–5.81 million cells/mm<sup>3</sup> in males). The number of erythrocytes is controlled through **erythropoiesis** (the selective maturation of stem cells into mature erythrocytes). Differentiation into an erythrocyte begins when the pluripotent stem cell of the marrow becomes an erythrocyte colony-forming unit (ECFU), which has receptors for the hormone erythropoietin (EPO). An ECFU then transforms into an erythroblast when stimulated by EPO. The cell is called a **reticulocyte** when the nucleus shrinks and is discharged from the cell. **Reticulocytes** (a temporary network composed of ribosome clusters) leave the bone marrow and enter the circulating blood. In approximately 2 days, the last of the ribosome clusters disappear, and the cell is a mature erythrocyte (Fig. 33.2). For normal erythrocyte production, the bone marrow also requires iron, vitamin B<sub>12</sub>, folic acid,

**FIGURE 33.2** Erythropoiesis. Steps in the formation of an erythrocyte.

vitamin B<sub>6</sub> (pyridoxine), protein, and other factors. The volume of blood composed of erythrocytes is measured as **haematocrit**, with normal values being 36% to 48% in females and 42% to 52% in males.

The RBCs produce **hemoglobin** (Hgb; the oxygen-carrying component of an RBC), and each normal mature RBC contains thousands of Hgb molecules. Hemoglobin is composed of a pigment (heme) that contains iron (Fe<sup>2+</sup>) and a protein (globin). The Hgb molecule is made up of four globins with a heme molecule attached to each globin. The heme molecule has iron at its center, which binds with oxygen. This makes Hgb capable of transporting up to four molecules of oxygen; therefore, iron is a significant component of Hgb (Fig. 33.3). Erythrocytes are critical to survival, and a severe deficiency of erythrocytes in the case of major trauma or hemorrhage, can be fatal within a few minutes because of the lack of oxygen.

**FIGURE 33.3** Structure of hemoglobin. Hemoglobin is composed of a pigment (heme) that contains iron ( $\text{Fe}^{2+}$ ) and a protein (globin). The Hgb molecule is made up of four globins with a heme molecule attached to each globin. The heme molecule has iron at its center, which binds with oxygen.

### Connection Check 33.2

What is the role of erythropoietin in the regulation of red blood cells?

- To make Hgb capable of transporting oxygen
- To pick up carbon dioxide from the tissues and deliver it to the lungs
- To decrease RBC production
- To stimulate RBC production

### White Blood Cells

White blood cells, also called *leukocytes*, are components of the body's defense system against infection and disease. Leukocytes are the least abundant formed elements, yet they are required for life to provide protection against infectious microorganisms and other pathogens. On average,

there are 4,500 to 11,000 WBCs per cubic millimeter of blood, which constitutes only 1% of the total blood volume. Leukocytes are essential to the body's defense against disease. Unlike RBCs, which remain within blood vessels, WBCs travel through the circulatory system and can migrate out of blood vessels into other tissues. Leukocytes are responsible for the immune responses that protect against harmful microorganisms, including identification and destruction of cancer cells and involvement in the inflammatory response and wound healing.

Leukocytes differ from erythrocytes in that they retain their organelles for protein synthesis throughout life, including the nucleus, rough endoplasmic reticulum, ribosomes, and Golgi complex. Protein is essential for leukocytes to carry out their functions, and some of these proteins appear as noticeable **granules** in the cytoplasm that distinguish one WBC type from another. There are two major types of WBCs, granulocytes and agranular leukocytes, based on the presence or absence of specific cytoplasmic granules (Fig. 33.4). Those containing specific granules (neutrophils, eosinophils, basophils) are classified as **granulocytes**, and those that lack granules (lymphocytes and monocytes) are classified as **agranulocytes**.

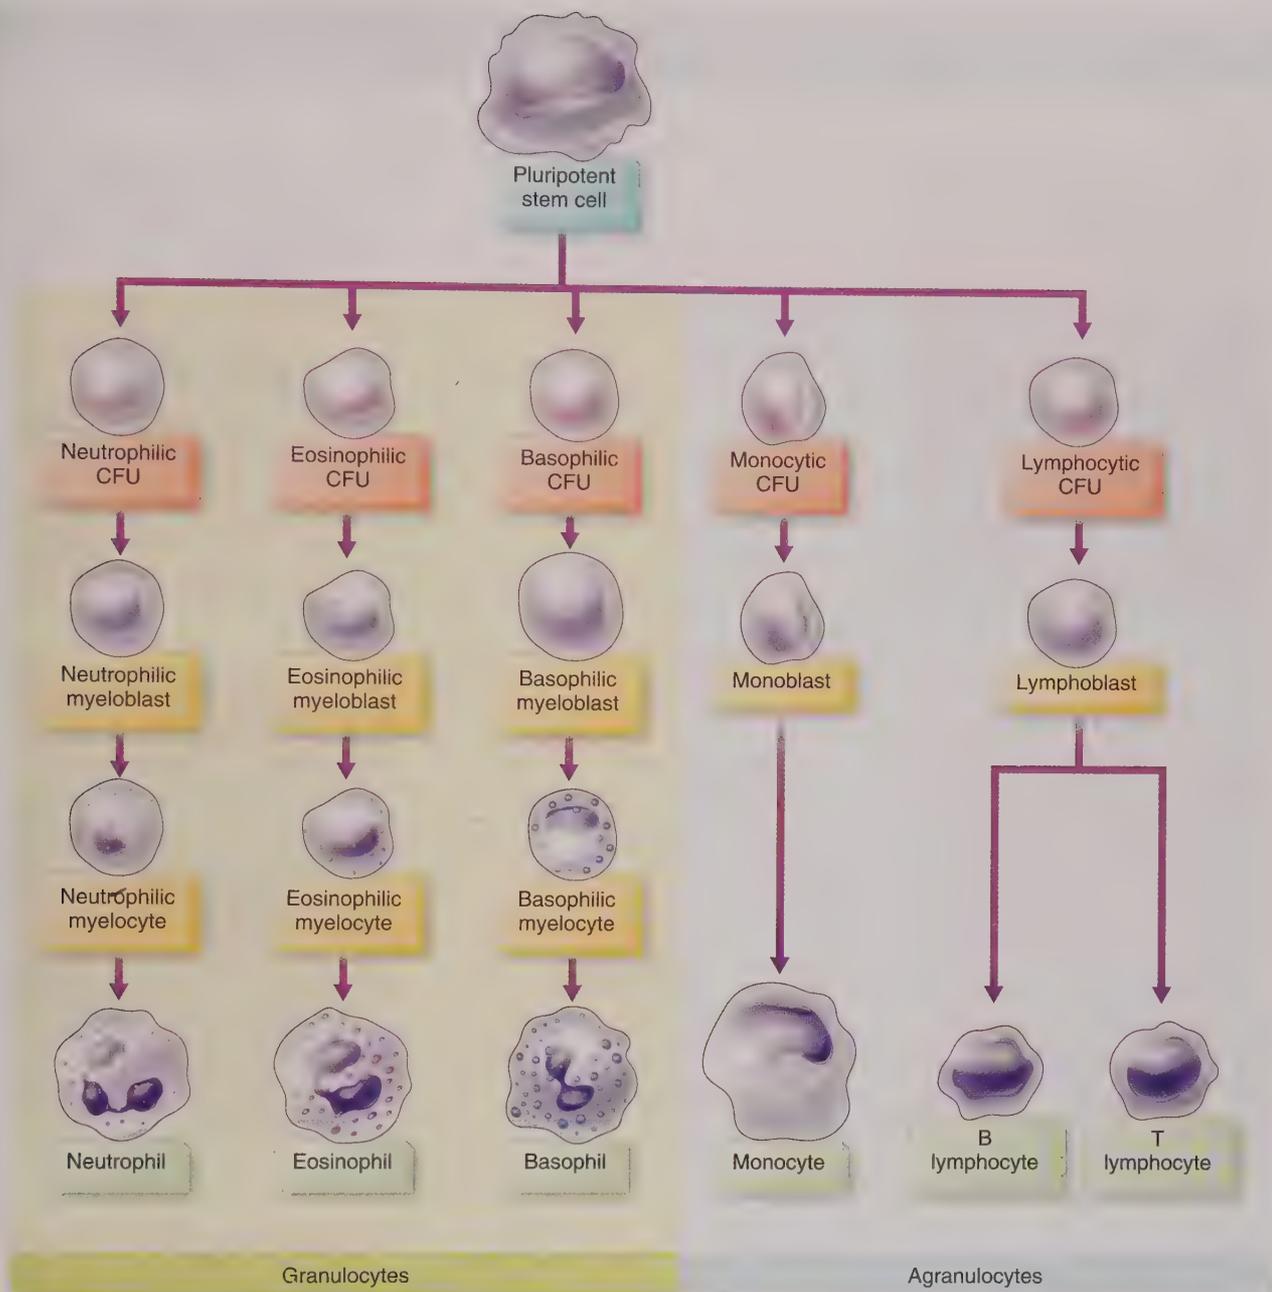

### Granulocytes

Granulocytes (neutrophils, eosinophils, and basophils) are spherical and have distinctive multilobar nuclei. They are also distinguished from each other by their relative size and abundance, the size and shape of their nuclei, and the staining properties of their individual granules (Table 33.1). Eosinophils have bright-red granules in their cytoplasm, and basophil granules stain deep blue. Neutrophils have granules that stain a pink to violet hue. Granulocytes play a key role in protecting the body from harmful microorganisms during acute inflammation and infection by means of their individual functions.

### Neutrophils

The **neutrophils** comprise 50% to 70% of circulating WBCs. Because they have nuclei that are divided into three to five lobes, they are often called *polymorphonuclear leukocytes* or PMNs. Immature (young) neutrophils are called "bands," which have an undivided, horseshoe-shaped nucleus. Mature neutrophils are referred to as "segs" because of their segmented nucleus. An increased need for neutrophils causes an increase in both the segs and the bands. Once the neutrophil matures (segmentation), it is released into the circulation from the marrow to perform its function of **phagocytosis** (engulfing and digesting bacteria). Bands generally account for a small percentage (3%–5%) of circulating granulocytes. An increase in band level is called a **left shift**, which occurs with acute infection, inflammation, or some other significant physical stress (Fig. 33.5). Because they are immature, the bands are not very effective in combating infection.

The neutrophils are primarily responsible for sustaining normal host defenses against invading bacteria and fungi, cell debris, and foreign substances. Neutrophils are phagocytic

**FIGURE 33.4** Leukopoiesis. Stages in the development of white blood cells. The pluripotent stem cell also is the ultimate source of red blood cells and platelet-producing cells (CFU = colony-forming unit).

and are responsible for engulfing and destroying foreign matter and are the first cells to arrive at a site of invasion. Once released from the marrow, neutrophils remain in the circulation for approximately 6 hours before migrating to the invaded tissues.

**Safety Alert** Decreased neutrophil counts significantly increase the risk of infection because of a decreased immune response. Protect the patient by using and teaching proper hand hygiene, performing frequent oral care, and limiting visitors.

### Eosinophils

**Eosinophils** constitute 1% to 3% of the total WBCs and have a life span of approximately 3 to 8 hours. Although scarce in the circulating blood, eosinophils are abundant in the mucous membranes of the respiratory, digestive, and urinary systems. The exact functions of eosinophils are unknown, but they do have granules that contain vasoactive amines that may be used to destroy foreign cells invading the body. Eosinophils are involved in hypersensitivity reactions, inactivating some of the inflammatory chemicals released during the inflammatory response. The number of eosinophils increases and migrates to the site of inflammation during allergic reactions, parasitic infections, collagen

**Table 33.1 White Blood Cells****Granulocytes****Neutrophils**

Percentage of circulating WBCs:	50% – 70%
Cell count:	3,000–7,000 cells/ $\mu$ L
Cell size:	10–16 $\mu$ m

**Appearance**

- 3–5 distinct nuclear lobes
- Fine pink to violet granules in cytoplasm

**Count Variations**

- Increase: bacterial infections, inflammation
- Decrease: radiation, chemotherapy for cancer

**Functions**

- Destroy bacteria through phagocytosis
- Release antimicrobial chemicals

Neutrophils

**Eosinophils**

Percentage of circulating WBCs:	1% to 3%
Cell count:	100–400 cells/ $\mu$ L
Cell size:	10–16 $\mu$ m

**Appearance**

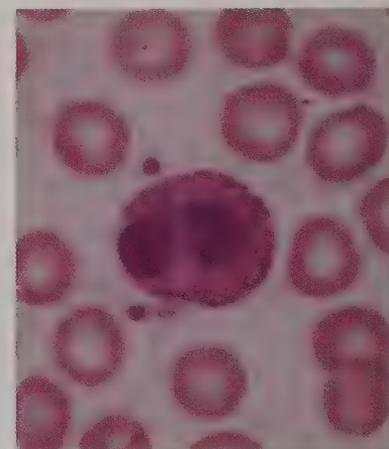

- 2 distinct nuclear lobes connected by thin strand
- Uniform red granules in cytoplasm

**Count Variations**

- Increase: allergies, parasitic infections, collagen diseases, diseases of spleen and central nervous system
- Decrease: aplastic anemia, corticosteroid excess

**Functions**

- Combat effects of histamine in allergic reactions
- Phagocytize antigen-antibody complexes and inflammatory chemicals
- Destroy parasitic worms through release of enzymes

Eosinophil

**Basophils**

Percentage of circulating WBCs:	0.4% to 1%
Cell count:	20–50 cells/ $\mu$ L
Cell size:	8–10 $\mu$ m

**Appearance**

- Two nuclear lobes
- Coarse, abundant blue granules in cytoplasm

**Count Variations**

- Increase: allergies, inflammatory disorders, infection
- Decrease: alcoholism, anemias, malnutrition, viral infections

**Functions**

- Release histamine, heparin, and other mediators in inflammation response

Basophil

**Table 33.1 White Blood Cells—cont'd****Agranulocytes****Lymphocytes**

Percentage of circulating WBCs:	20% to 35%
Cell count:	1,500–3,000 cells/ $\mu$ L
Cell size:	5–17 $\mu$ m

**Appearance**

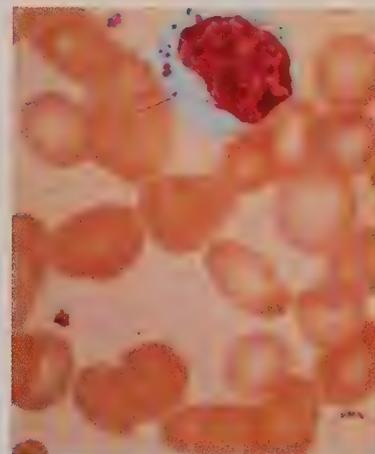

- Nucleus is round or indented
- Cytoplasm forms sky-blue rim around nucleus

**Count Variations**

- Increase: diverse infections and immune responses
- Decrease: HIV/AIDS, severe burns, cancer, radiation

**Functions**

- Mediate immune responses by direct cell attack or through antibodies
- Destroy tumor, virus-infected, and foreign cells
- Reject transplants of foreign tissue

Lymphocyte

**Monocytes**

Percentage of circulating WBCs:	3% to 8%
Cell count:	100–700 cells/ $\mu$ L
Cell size:	12–18 $\mu$ m

**Appearance**

- Kidney or horseshoe-shaped nucleus
- Cytoplasm is abundant and appears blue-gray

**Count Variations**

- Increase: many viral diseases, chronic inflammation
- Decrease: corticosteroid excess

**Functions**

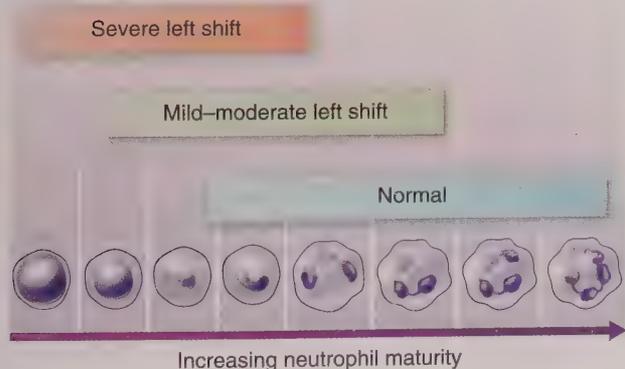

- Develop into macrophages in tissues
- Phagocytize bacteria and debris in tissues

Monocyte

**FIGURE 33.5** Diagram of left shift. A shift to the left indicates that more immature cells are present in the blood than normal.

diseases, and diseases of the spleen and central nervous system. Containing proteolytic substances that protect the body from parasitic worms in parasitic infections, eosinophils use surface markers to attach themselves to the parasite and then release toxic hydrolytic enzymes that kill the invading organism. Eosinophil counts can increase to more than 30% of baseline in parasitic infections.

Eosinophil counts decrease in conditions such as aplastic anemia (because of bone marrow failure) and infections (because of a significant production of neutrophils). When the body experiences stress, there are changes in adrenal hormones such as cortisol and aldosterone. These increased levels of adrenal steroids suppress the number of eosinophils.

### Basophils

**Basophils** are the least numerous of the WBCs, making up 0.4% to 1% of total WBCs, and have a life span of approximately 7 to 12 hours. Basophils are not phagocytic. Their cytoplasmic granules contain heparin, an anticoagulant; histamine, a vasodilator; and other mediators of inflammation. These chemicals aid in defense mechanisms by making the blood vessels more permeable for neutrophils and clotting proteins to enter the injured site more quickly and efficiently. The basophils are believed to be an integral part of both hypersensitivity and stress responses. Basophils increase in circulation because of pathologic conditions such as inflammatory disorders, all types of infections, and anemias. They also increase as a result of normal physiological and environmental conditions such as exposure to extreme heat or cold, acute stress, and strenuous exercise. Basophils decrease in conditions such as alcoholism, anemias, malnutrition, and viral infections.

### Agranulocytes

#### Lymphocytes

**Lymphocytes** are essential elements in the immune response and function to produce substances that aid in attacking foreign material. After birth, some lymphocytes are produced in the bone marrow. Differentiation and maturation of lymphocytes occur primarily in the lymph nodes and in the lymphoid tissue of the intestine and spleen after exposure to a specific antigen (see Chapter 18). The ability of lymphocytes to produce antibodies (in the case of B lymphocytes), or cell-surface receptors (in the case of T lymphocytes) that are specific for one of the many millions of foreign entities that may invade the body is essential to acquired immunity. B lymphocytes have the ability to differentiate into **plasma cells**. Plasma cells then produce antibodies, called **immunoglobulins (Igs)** that attack and neutralize antigens produced by bacterial infections. T lymphocytes kill foreign cells directly or release a variety of substances that enhance the activity of phagocytosis by other cells. T lymphocytes are responsible for delayed allergic reactions, rejection of transplants of foreign tissue (e.g., transplanted organs), and destruction of tumor cells.

#### Monocytes

**Monocytes** (also called *mononuclear leukocytes*) are leukocytes with a single-lobed nucleus with no granules in the cytoplasm; they are the largest of the leukocytes and account for 3% to 8% of the total leukocytes in the circulating blood. Monocytes enter the blood from the bone marrow and circulate for a short time before they enter the tissues and become tissue **macrophages**. Active in the spleen, liver, peritoneum, and alveoli, macrophages are activated by cytokines released from T lymphocytes and migrate in response to stimuli from bacterial cells. Macrophages remove debris and phagocytize bacteria within the tissues.

### Platelets

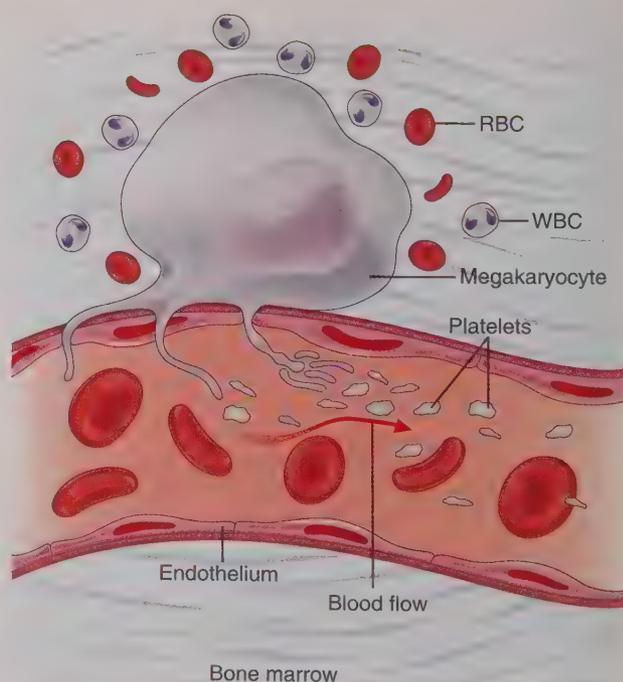

Thrombocytes, or platelets, are circulating cell fragments of the cytoplasm of large cells in the bone marrow called

*megakaryocytes* (Fig. 33.6). The production of platelets is a division of hematopoiesis called *thrombopoiesis* (Fig. 33.7). Regulated by the hormone thrombopoietin, some pluripotent stem cells become megakaryoblasts, cells committed to the platelet-producing line. Platelets circulate freely in the blood in an inactive state. After a vascular injury occurs, platelets play an essential part in the control of bleeding. Platelets collect at the damaged site and are activated to begin adhesion and formation of a temporary plug. Their cytoplasmic granules release mediators to activate coagulation factors in the blood plasma and initiate the formation of a stable clot composed of **fibrin** (a fibrous protein).

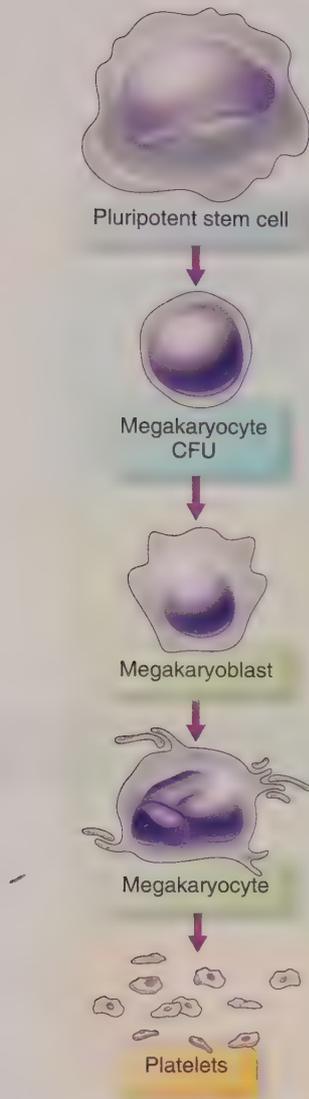

Platelets have a membrane but no nucleus and cannot replicate. Approximately 25% to 40% of the platelets are stored in the spleen and are released as needed. If not consumed in a clotting reaction, platelets are normally removed by the spleen and live for approximately 7 to 10 days.

### Plasma

Blood is made up of plasma (a clear yellow, protein-rich fluid), and the cells and cell fragments suspended in it are RBCs, WBCs, and platelets. Plasma is a complex mixture of water, proteins, nutrients, electrolytes, nitrogenous wastes, hormones, and gases. Plasma is part of the body's extracellular fluid and contains approximately 90% water, 6.5% to 8% proteins, and 2% other small molecular substances. Plasma serves as a transport vehicle for materials carried in the blood (Fig. 33.8).

**FIGURE 33.6** Platelet production. Thrombocytes, or platelets, are circulating cell fragments of the cytoplasm of large cells in the bone marrow called megakaryocytes.

**FIGURE 33.7** Thrombopoiesis. The production of platelets is a division of hematopoiesis called thrombopoiesis and is regulated by the hormone thrombopoietin. Some pluripotent stem cells become megakaryoblasts, cells committed to the platelet-producing line.

Protein, the most abundant plasma solute, plays a variety of roles including clotting, immune defense, and transport of other solutes that contribute to the osmotic regulation of body fluids. There are three major types of proteins in plasma: albumin, globulin, and fibrinogen (Table 33.2). **Albumin**, synthesized in the liver, serves to transport various solutes and buffer the pH of the plasma, and is important in fluid balance by increasing the osmotic pressure of the blood, which prevents the plasma from leaking into the tissues. Low levels of albumin may be the result of inadequate intake (i.e., malnutrition), inadequate production (i.e., liver disease), or excessive loss (i.e., burns, hemorrhage).

**Globulins** play various roles in solute transport, clotting, and immunity as they are the main proteins of antibodies. There are three main types of globulins, each with different functions: alpha, beta, and gamma. Alpha and beta globulins are made in the liver and are important in transport and

clotting, and gamma globulins are important in immune defense. **Fibrinogen** is an inactive protein that is activated by thrombin (a vitamin K–dependent enzyme) to form fibrin (a sticky protein that forms the framework of a blood clot).

## Spleen

The spleen is a coffee bean–shaped, encapsulated organ composed of vascular and lymphoid tissues located in the left upper quadrant of the abdomen (Fig. 33.9). Splenic functions include filtration, host defense, storage, and **cytopoiesis** (formation of cells). The splenic cellular tissue (parenchyma) is composed of two main elements: the red pulp, where filtration occurs, and the white pulp, where immune functions are generated (Fig. 33.10).

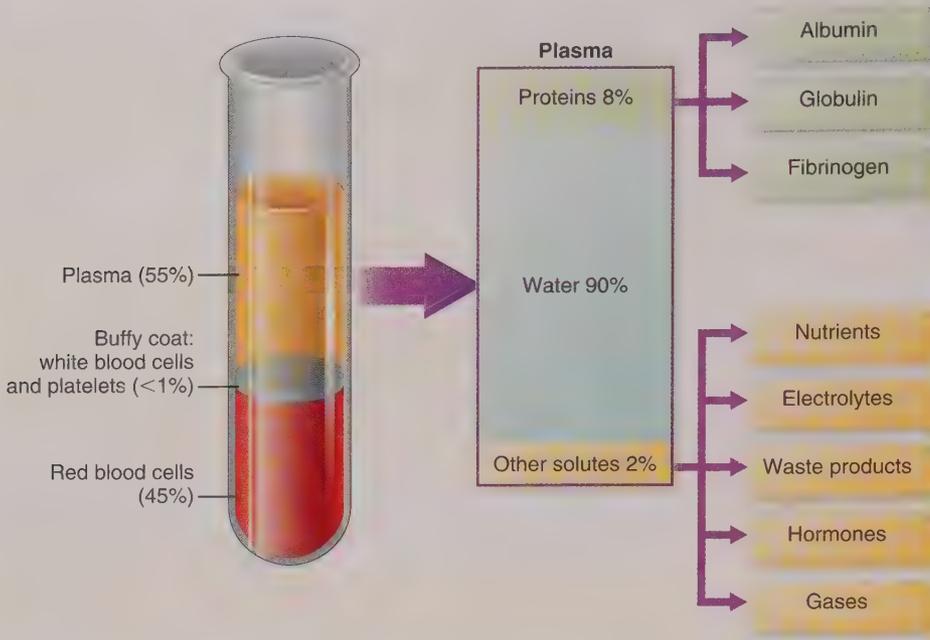

The spleen serves as a large filter by removing aged erythrocytes (Fig. 33.11) and plays a part in the removal of abnormal WBCs and platelets. Splenic blood flow is approximately 250 to 300 mL/min. Because the average life span of a normal circulating RBC is 120 days, each red cell averages 1,000 passes through the spleen every day. Normal blood cells pass through the spleen without incident, whereas damaged and aged cells are slowed and trapped. The spleen acts as the major site for clearance from the blood of damaged or aged RBCs, removing approximately 20 mL of senescent (old or dying) RBCs per day. This is facilitated by a group of large phagocytic cells located in the spleen, which ingest and destroy old and defective red cells in a series of enzymatic reactions. The degradation products of RBCs, including iron and amino acids, are recycled.

The spleen also has immunological functions similar to those of other lymphoid organs (e.g., lymph nodes, thymus). Blood passing through the spleen is exposed to all the essential cellular components necessary for both humoral and cellular immune responses. There are follicles within the spleen that aid in antigen production and initiation of T- and B-lymphocyte activities involved in humoral and cellular immune responses. In summary, the spleen filters the blood, produces lymphocytes, and stores blood and platelets.

## OVERVIEW OF HEMATOLOGY FUNCTION

### Oxygen Delivery

All body tissues rely on oxygen that is transported in the blood to meet metabolic needs. Respiration is a primary function of erythrocytes (RBCs) because they are responsible for producing hemoglobin (Hgb), an oxygen-carrying protein. A Hgb molecule combines loosely with oxygen in the lungs, which allows the transfer of oxygen from Hgb to the tissues (oxygen dissociation). This transfer is important in meeting the body tissues' need for oxygen. The ability of the circulating blood to carry oxygen is dependent on both Hgb levels and the capability of the lungs to oxygenate the Hgb. The number of circulating RBCs is balanced to ensure sufficient RBCs are available for oxygenation. Excessive increases in RBCs raise the blood viscosity, slowing its flow and therefore reducing oxygen transport.

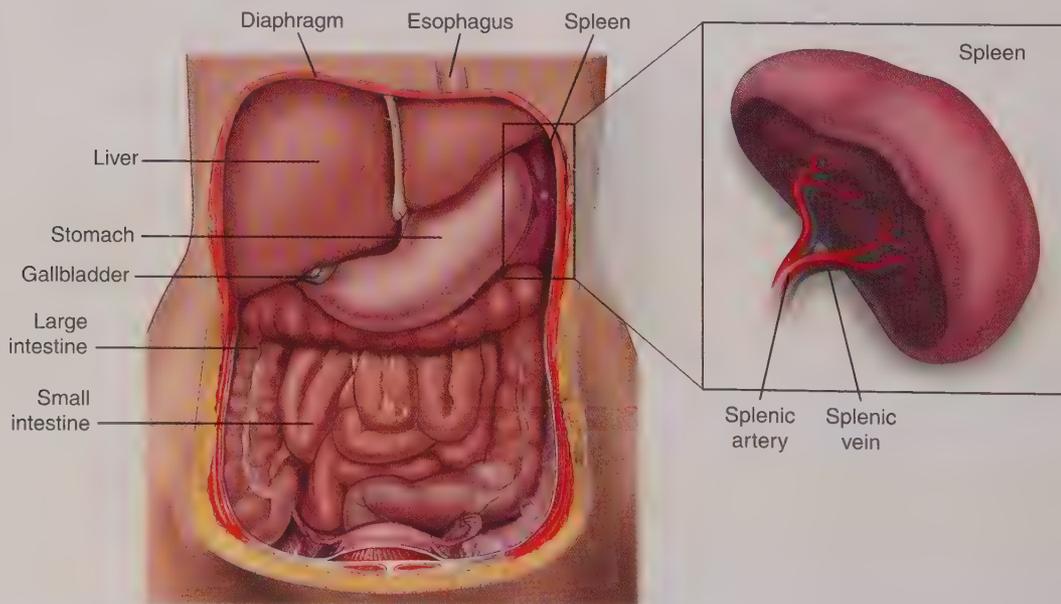

**FIGURE 33.8** Components of blood. Centrifuging a sample of blood separates the erythrocytes from the white cells and platelets (buffy coat) and plasma. The hematocrit is the percentage of the volume composed of erythrocytes. Plasma contains approximately 90% water, 6.5% to 8% proteins (albumin, globulin, fibrinogen), and 2% other small molecular substances (nutrients, electrolytes, waste products, hormones and gases).

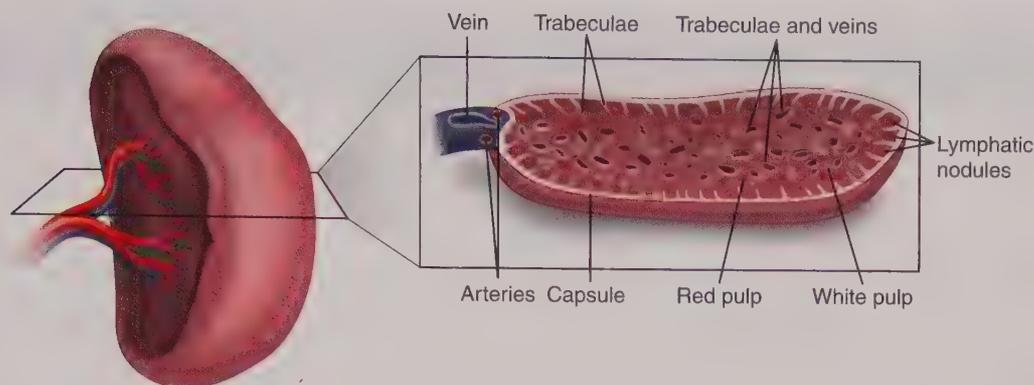

**Table 33.2 Blood Plasma Proteins**

Proteins	Functions
<b>Albumin (60%)*</b>	Maintains osmotic pressure; transports various solutes; buffers plasma pH
<b>Globulins (36%)*</b> <i>Alpha (α) globulins, Beta (β) globulins</i> <i>Gamma (γ) globulins</i>	Transport hemoglobin, metal ions, lipids, and fat-soluble vitamins; promote blood clotting Antibodies
<b>Fibrinogen (4%)*</b>	Activated by thrombin, becomes fibrin; major component of blood clots

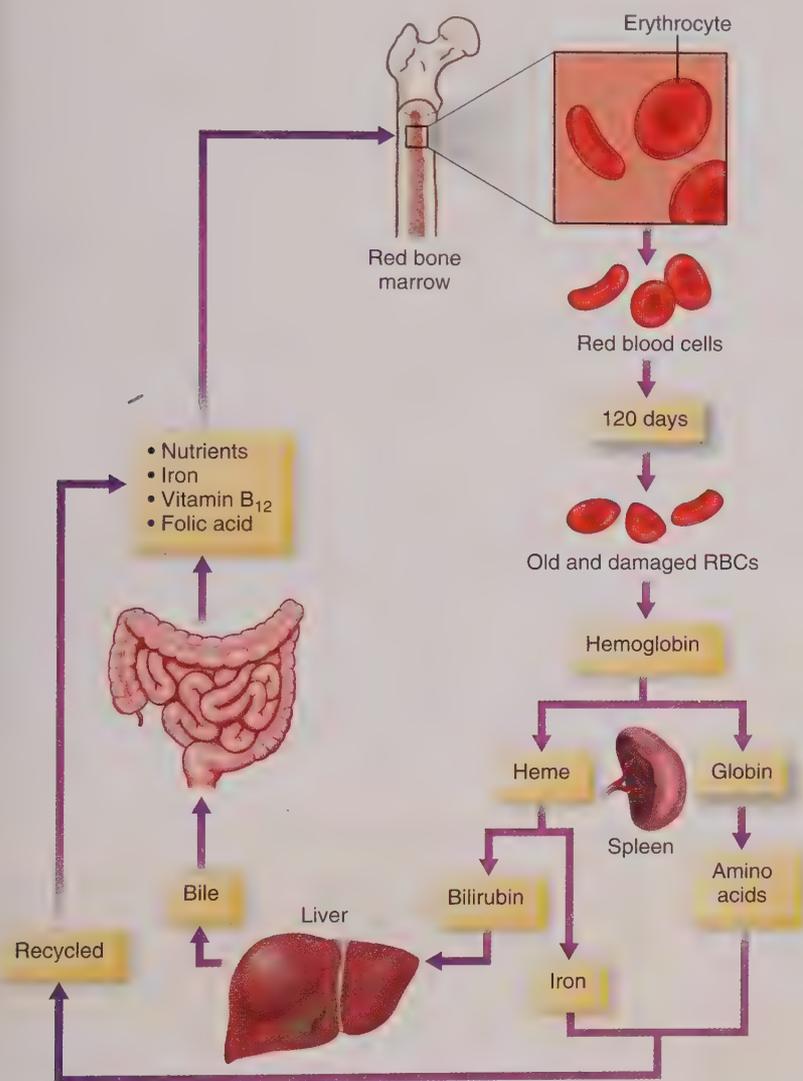

\*Mean percentage of the total plasma protein by weight

**FIGURE 33.9** Spleen location inside the abdomen. The spleen is a coffee bean-shaped, encapsulated organ composed of vascular and lymphoid tissues located in the left upper quadrant of the abdomen.

**FIGURE 33.10** Splenic architecture. The splenic parenchyma is composed of two main elements: the red pulp, where filtration occurs, and the white pulp, where immune functions are generated.

**FIGURE 33.11** Life and death of erythrocytes. The average life span of a normal circulating RBC is 120 days. Each red cell averages 1,000 passes through the spleen every day. Normal blood cells pass through the spleen without incident, whereas damaged and aged cells are slowed and entrapped. This is facilitated by a group of large phagocytic cells located in the spleen, which ingest and destroy old and defective red cells in a series of enzymatic reactions. The degradation products of RBCs, such as iron and amino acids, are recycled.

### Connection Check 33.3

What is a probable initial assessment finding for a patient with a low hemoglobin count?

- Increased and bounding peripheral pulses
- Hypertension
- Pallor and fatigue
- Moist mucus membranes

### Clotting Cascade

**Hemostasis**, or blood clotting, is a complex process that stops bleeding. It is also the orderly process (Table 33.3) that balances the production and dissolution of clotting factors and involves (1) vasospasm, (2) formation of a platelet plug, (3) development of a fibrin clot, (4) clot retraction, and (5) fibrinolysis. Hemostasis is normal when it seals a blood vessel to prevent blood loss and hemorrhage.

**Table 33.3 Stages of Hemostasis**

Stage	Process	Description
1	Vasospasm	Damage to a blood vessel causes it to spasm. This spasm, which lasts more than a minute, constricts the vessel and reduces blood flow.
2	Formation of the platelet plug	Platelets adhere to the damaged vessel wall and to one another, forming a platelet plug. Von Willebrand's factor (an adhesive protein that is synthesized by the endothelium and megakaryocytes) is necessary for platelets to adhere to one another. The platelet plug is stabilized by fibrin, which binds the platelets and other blood cells.
3	Clot formation	Coagulation occurs as fibrin forms a meshwork that cements blood components together into an insoluble clot. The process involves two different clotting pathways. The intrinsic pathway is activated by vessel injury; the extrinsic pathway is activated by blood leaking out of the vessel into the tissues. The final outcome is fibrin clot formation. Each clotting factor is activated in sequence; activation of one clotting factor activates another in turn. A deficiency of one or more factors interrupts blood clotting.
4	Clot retraction	After approximately 30 minutes, platelets trapped within the clot begin to contract. This pulls the broken portions of the ruptured blood vessel closer together. At the same time, platelets release growth factors that stimulate cell division and tissue repair in the damaged vessel.
5	Clot dissolution	A process called <i>fibrinolysis</i> removes the clot after tissue has been repaired. Fibrinolysis begins within a few days of clot formation and continues until the clot is dissolved.

The blood-clotting cascade is triggered by the formation of a platelet plug, where platelets clump together. It is a stepwise process resulting in the conversion of the soluble plasma protein, fibrinogen, into fibrin. The insoluble fibrin strands create a sticky meshwork that cements platelets and other blood components together to form the temporary clot. The steps of the cascade between the formation of a platelet plug and the formation of a fibrin clot depend on the presence of specific clotting factors. Clotting factors (Table 33.4) are inactive enzymes that become activated in succession.

The coagulation process can be initiated by two pathways: the intrinsic pathway and the extrinsic pathway. **Intrinsic factors** are substances located directly within the blood that first makes platelets clump and then trigger the coagulation cascade (Fig. 33.12). The intrinsic pathway is initiated when the blood is exposed to a stimulus (i.e., damaged subendothelium) and activates factor XII (Hageman factor). The process continues in a chainlike reaction, activating factors IX and XI, in combination with calcium, generating factor Xa. The clotting cascade then continues by converting prothrombin to thrombin, which acts on fibrinogen to produce fibrin, leading to final clot formation.

**Extrinsic factors** are elements outside the cell that can also stimulate platelet plug formation. They usually result from changes in blood vessels, such as tissue trauma, rather than inside the blood. These changes begin a complex series of chemical reactions that are activated by factor III (tissue thromboplastin) and, in the presence of calcium, are catalysed by factor VII (proconvertin). The binding of calcium causes factor X (thrombokinase) to convert to factor Xa. Just as in the intrinsic pathway, prothrombin is converted to thrombin, then fibrinogen and, ultimately, fibrin. The extrinsic pathway causes clotting to occur more quickly because some of the steps in the intrinsic pathway are bypassed.

### Connection Check 33.4

The nurse recognizes that a deficiency in a clotting factor may cause which finding(s)? (*Select all that apply.*)

- Easy bruising and cutaneous hematoma formation with minor trauma (e.g., an injection)
- Bleeding from the gums and prolonged bleeding following minor injuries or cuts
- Enhanced platelet aggregation and increased clumping of RBCs
- Fibrin molecules form fibrin threads to increase wound healing
- Yellowish skin color

### Inflammation and Immunity

The blood plays several roles in inflammation and immunity by providing a defense mechanism for limiting the spread of infection and promoting the healing of damaged tissue. Inflammation is a protective response that aims to eliminate the initial cause of cell injury, remove the damaged tissue, and generate new tissue. In an acute inflammatory response, immediate vascular changes such as vasodilation and increased capillary permeability occur. This allows the influx of inflammatory cells such as neutrophils and the broad effects of inflammatory mediators (derived from platelets, neutrophils, and macrophages), which produce fever and other systemic clinical manifestations.

### HEMATOLOGICAL ASSESSMENT

Nurses play an important role in identifying hematological disorders. Assessment of this system is generally conducted as part of the general survey of the patient's health or

**Table 33.4 Clotting Factors**

Factor	Function	Pathway
<b>I. Fibrinogen</b>	Converted to fibrin, clot formation	Common
<b>II. Prothrombin</b>	Converted to thrombin, activates fibrinogen (factor I)	Common
<b>III. Tissue thromboplastin, tissue factor</b>	Activates factor VII	Extrinsic
<b>IV. Calcium ions (Ca<sup>++</sup>)</b>	Intrinsic: Combines with factor IX to activate factor X Extrinsic: Combines with factor III to activate factor VII Common: Combines with factor X to activate prothrombin (factor II)	Intrinsic, extrinsic, and common
<b>V. Proaccelerin, labile factor</b>	Combines with factor X to activate prothrombin (factor II)	Common
<b>VII.* Proconvertin, stable factor</b>	Activates factor X in extrinsic pathway	Extrinsic
<b>VIII. Antihemophilic factor</b>	Activates factor X in intrinsic pathway	Intrinsic
<b>IX. Plasma thromboplastin component, Christmas factor</b>	Activates factor VIII	Intrinsic
<b>X. Stuart-Prower factor</b>	Combines with factor V to activate prothrombin (factor II)	Common
<b>XI. Plasma thromboplastin antecedent</b>	Activates factor IX	Intrinsic
<b>XII. Hageman factor</b>	Activates factor XI	Intrinsic
<b>XIII. Fibrin-stabilizing factor</b>	Cross-links fibrin	Common

\*Factor VI designation is no longer used; it was found to be the same substance as activated factor V.

concurrently with focused cardiovascular system assessment. However, unless the nurse specifically focuses on this system, early manifestations of hematological disorders can be missed or attributed to dysfunction of a different body system. Age and gender are important variables when assessing the patient's hematological status because bone marrow and immune activity diminish with age.

## History

### Nutrition

Dietary pattern can alter cell quality and affect blood clotting. Ask the patient about usual diet, including protein, vitamin, and mineral intake. Diets high in vitamin K, such as raw leafy green vegetables, may increase the rate of blood coagulation. Diets high in fat and carbohydrates and low in protein, iron, and vitamins can decrease the function of all blood cells and potentially lead to different types of anemia (Table 33.5).

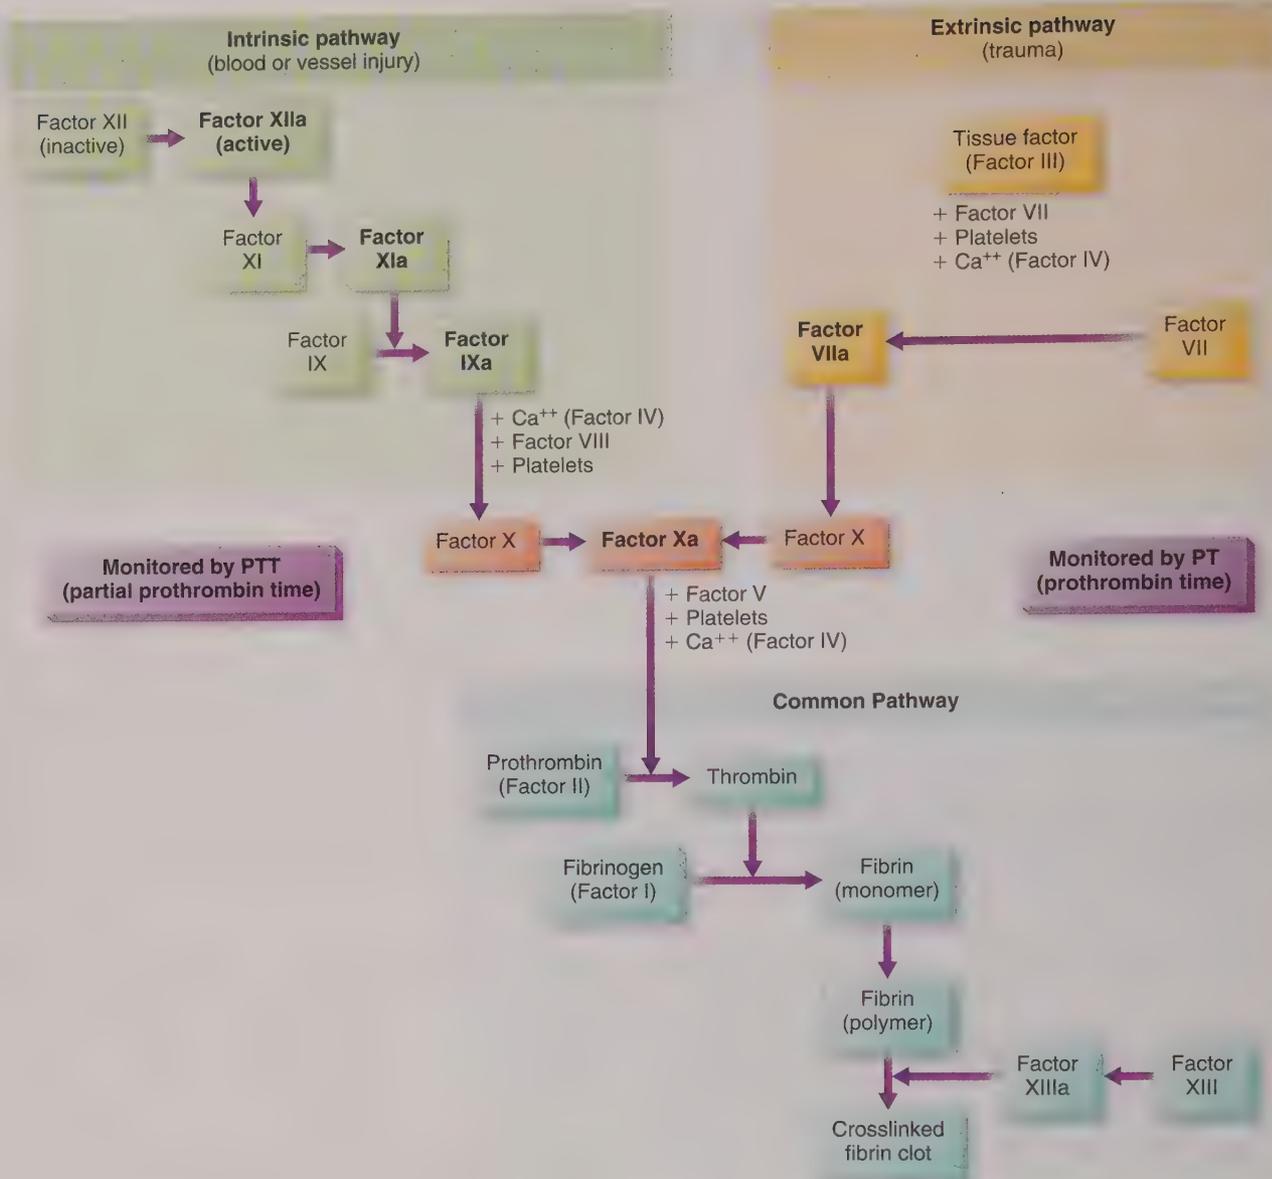

Ask about the use of tobacco, alcohol, and other recreational drugs. Chronic alcohol use is associated with nutritional deficiencies and liver impairment, both of which can decrease the ability of the blood to clot. Alcohol (ethyl alcohol, or ethanol) is absorbed readily from the gastrointestinal (GI) tract but cannot be broken down or stored as protein, fat, or carbohydrate. Approximately 90% of the alcohol a person drinks is metabolized by the liver. During metabolism, an excess of an ethanol by product is thought to contribute to the liver damage that

often accompanies increased alcohol consumption. This damage interrupts the synthesis of clotting factors and plasma proteins. A concise patient history can focus on changes related to hematological function, and the nurse should pose the following questions to the patient:

- Have you had any recent changes in energy level?
- Do you have any difficulties maintaining usual daily activities, including recreational activities and sports?
- Have you been experiencing any pain, burning, or tingling sensations? Any changes in skin color or temperature? Any swelling (edema)?
- Have you experienced any bleeding or easy bruising, dizziness, fatigue, or changes in lymph nodes (swelling, pain or tenderness, warmth)?

### Past Medical History

Obtain the patient's medical history, being sure to ask about any chronic diseases. Because the liver synthesizes most of the clotting factors, diseases such as hepatitis, cirrhosis, and cancer that alter liver function may result in clotting factor deficiencies. Also, the synthesis of clotting factors II, VII, IX, and X requires vitamin K. The absorption of vitamin K from the diet requires bile, a liver secretion. Cholelithiasis (gallstones) can lead to a clotting deficiency by obstructing the bile duct and, in turn, interfering with bile secretion and vitamin K absorption. Ask about pregnancy because the incidence of gestational thrombocytopenia is observed in 5% to 11% of all pregnancies.

**FIGURE 33.12** Clotting pathways. Both the slower intrinsic pathway (on the left) and the more rapid extrinsic pathway (on the right) are necessary to form a stable blood clot. Both pathways come together at factor X activation, which then activates prothrombin (factor II) to thrombin, the final enzyme of the clotting cascade. The intrinsic pathway is measured by PTT (partial thromboplastin time). The extrinsic pathway is measured by PT (prothrombin time).

### Medication History

Inquire about current medications, including anticoagulants, aspirin and other salicylates, herbs, nutritional supplements, and nutraceuticals. Some dietary supplements may interact with prescribed medication therapy. For example, goldenseal and green tea may reduce the effect of certain anticoagulants, thus increasing the risk of thromboembolism. Ask about the use of anticoagulants or “blood thinners” such as sodium warfarin (Coumadin), aspirin, or other NSAIDs. If a patient is prescribed any of these medications, there may be a clotting disorder or a health problem that requires further assessment and treatment (Table 33.6). Aspirin can irreversibly inhibit platelet aggregation by inactivation of a

crucial cyclooxygenase (COX) enzyme. A 325-mg dose of the medication results in approximately 90% inhibition of COX in circulating platelets. This effect lasts for the life span of platelets (4–7 days). During prolonged aspirin therapy, periodic assessments of Hct, Hgb level, **prothrombin time** (PT), International Normalized Ratio (INR), and renal function are recommended. Also ask the patient about antibiotic use because prolonged antibiotic therapy can lead to coagulopathies, bone marrow depression, or other undesired effects. For example, neutropenia may occur during therapy with penicillins, cephalosporins, or vancomycin. Box 33.1 summarizes selected medications that may predispose the patient to bleeding.

**Table 33.5 Sources and Functions of Vitamins and Minerals**

<b>Vitamin and Minerals</b>	<b>Food Source</b>	<b>Recommended Dietary Allowance (RDA)</b>	<b>Blood Cell Functions</b>
<b>Vitamins</b>			
Vitamin C (ascorbic acid)	Asparagus, broccoli, sweet and hot peppers, collards, Brussels sprouts, kale, potatoes, spinach, tomatoes, citrus fruits, strawberries	Children: 15 to 75 mg per day depending upon age and gender Adult men aged 19 and older: 90 mg per day Adult women aged 19 and older: 75 mg per day	Facilitates calcium and nonheme (vegetable) iron absorption by increasing the solubility of nonheme iron; synthesizes leukocytes and other immune cell components
Folacin (folic acid)	Liver, legumes, green leafy vegetables	Children: 150 to 300 mcg per day depending upon age Adult men and women: 400 mcg per day	Promotes red cell formation; classified as a hematopoietic vitamin
Vitamin B <sub>6</sub> (pyridoxine)	Meat, poultry, fish, shellfish, green and leafy vegetables, whole-grain products, legumes	Children: 0.5 to 1.0 mg per day depending upon age Adult men aged 14–50: 1.3 mg per day Men over age 50: 1.7 mg per day Adult women aged 14–50: 1.2 to 1.3 mg per day Women older than age 50: 1.5 mg per day	Required for normal development and function of red blood cells; needed for normal synthesis of hemoglobin; classified as a hematopoietic vitamin
Vitamin B <sub>12</sub> (cobalamin)	Meat, poultry, fish, shellfish, eggs, dairy products	Children: 0.9 to 1.8 mcg per day depending upon age Adult men and women: 2.4 mcg per day	Assists in division and maturity of red blood cells
Vitamin K	Cabbage, cauliflower, cereals, dark green vegetables (broccoli, Brussels sprouts, asparagus), dark leafy vegetables (spinach, kale, collards, turnip greens), fish, liver, beef, eggs	Children: 30 to 75 mcg per day, depending upon age Adult women: 90 mcg per day Adult men: 120 mcg per day	Necessary for formation of prothrombin and other clotting factors in the liver
<b>Minerals</b>			
Calcium	Milk and milk products, fish with bones, greens	1,000 mg before age 50; 1,200 mg after age 50	Bone formation and maintenance; vitamin B absorption; blood clotting
Cobalt	Organ meats, meats	Required in small amounts as a component of vitamin B <sub>12</sub>	Aids in maturation of red blood cells (as part of B <sub>12</sub> molecule)
Copper	Cereals, nuts, legumes, liver, shellfish, grapes, meats	Adult men and women: 900 mcg	Catalyst for hemoglobin formation
Iron	Meats, heart, liver, clams, oysters, lima beans, spinach, dates, dried nuts, enriched and whole-grain cereals	Men and postmenopausal women: 8 mg Premenopausal women: 18 mg Pregnant women: 27 mg	Hemoglobin synthesis; cellular energy release (cytochrome pathway); killing bacteria (myeloperoxidase)

**Table 33.6 Medications to Treat Clotting Disorders**

Medication	Actions
<p><b>Anticoagulants</b> <i>Thrombin inhibitors, Vitamin K agonists, indirect factor X inhibitors</i></p> <ul style="list-style-type: none"> <li>● Warfarin sodium (Coumadin) derivatives</li> <li>● Heparin sodium</li> <li>● Trental (pentoxifylline)</li> <li>● Argatroban (Novastan)</li> <li>● Fondaparinux (Arixtra)</li> <li>● Dalteparin (Fragmin)</li> <li>● Enoxaparin (Lovenox)</li> <li>● Dabigatran (Pradaxa)</li> </ul>	<ul style="list-style-type: none"> <li>● Alter the synthesis of blood coagulation factors II (prothrombin), VII (proconvertin), IX (Christmas factor or plasma thromboplastin component), and X (Stuart-Prower factor) in the liver by interfering with the action of vitamin K</li> <li>● Treatment or secondary prevention for deep-vein thrombosis and pulmonary embolism</li> <li>● Prevent new clots from forming; limit or prevent clot extension</li> <li>● Cannot break down existing clot</li> </ul>
<p><b>Fibrinolytics</b> <i>Thrombolytics – a biosynthetic (recombinant DNA origin) form of the enzyme human tissue-type plasminogen activator (tPA)</i></p> <ul style="list-style-type: none"> <li>● Alteplase</li> <li>● Reteplase</li> <li>● Tenecteplase</li> <li>● Streptokinase</li> </ul>	<ul style="list-style-type: none"> <li>● Break down formed fibrin clots</li> <li>● Give within first 12 hours after onset of ischemic symptoms (e.g., myocardial infarction, thrombotic strokes)</li> </ul>
<p><b>Platelet inhibitors</b> <i>Platelet glycoprotein (GP IIb/IIIa)-receptor inhibitor</i></p> <ul style="list-style-type: none"> <li>● Clopidogrel bisulfate (Plavix)</li> <li>● Abciximab</li> <li>● Eptifibatide</li> <li>● Tirofiban</li> </ul>	<ul style="list-style-type: none"> <li>● Prevent platelets from becoming active or prevent activated platelets from clumping together</li> <li>● Change platelet membrane, preventing activators from binding to platelet receptor sites</li> <li>● Used for acute ischemic complications of percutaneous coronary intervention, unstable angina, and non-ST-segment elevation myocardial infarction</li> </ul>

## Physical Assessment

Typically, the physical examination follows a systematic head-to-toe approach. Patient preparation includes clearly explaining the examination as well as proper positioning and draping before and during the examination. During the physical assessment, the nurse is aware and respectful of the patient's feelings (particularly embarrassment and anxiety) as well as providing comfort measures and following appropriate safety precautions. Assess the whole body because blood disorders may cause oxygen delivery to be less than what is needed for normal oxygenation and tissue perfusion in all systems.

### Skin, Head, and Neck Assessment

- Inspect the color of the skin and mucous membranes, including observing for pallor or cyanosis or fissures at the corners of the mouth (indicating nutritional deficiencies and/or chronic anemia).
- Palpate for skin temperature, capillary refill, and edema of the extremities.
- Palpate lymph nodes for swelling and tenderness.
- Inspect oral mucous membranes and the skin of the trunk and extremities for erythema, red streaks,

petechiae (pinpoint hemorrhagic lesions in the skin), bruising, or purpura (purple rashes caused by blood leaking into the skin).

- A red, swollen, smooth, shiny, and tender tongue (glossitis) may indicate iron deficiency anemia or pernicious anemia.

### Respiratory Assessment

- When hematological disorders reduce oxygen delivery, the lungs work harder to increase oxygen delivery.
- Four measures of respiration—rate, rhythm, depth, and sound—reflect the body's metabolic state, diaphragm and chest muscle condition, and airway patency. Knowing a patient's baseline respiratory rate allows detection of changes in the patient's condition.
- Respiratory rates of less than 12 or more than 20 breaths per minute usually are considered abnormal. Report the sudden onset of such rates promptly.
- Many anemias can cause fatigue and shortness of breath at rest or on exertion.

### Cardiovascular Assessment

- Obtain the vital signs, including blood pressure (BP), temperature, and apical pulse.

## Box 33.1 Medications That May Predispose to Bleeding

### Interference With Platelet Production or Function

- Acetazolamide
- Antimetabolite and anticancer medications
- Antibiotics such as penicillin and the cephalosporins
- Aspirin and salicylates
- Carbamazepine
- Clofibrate
- Clopidogrel
- Colchicine
- Dipyridamole
- Thiazide diuretics
- Gold compounds
- Heparin, low molecular weight heparins
- NSAIDs (Acetylsalicylic acid [ASA], ibuprofen, indomethacin, naproxen)
- Quinine derivatives (quinidine and hydroxychloroquine)
- Sulfonamides

### Interference With Coagulation Factors

- Amiodarone
- Anabolic steroids
- Warfarin (Coumadin)
- Novel oral anticoagulants such as dabigatran and rivaroxaban
- Heparin, low molecular weight heparins

### Decrease in Vitamin K Levels

- Antibiotics
- Clofibrate

- When blood problems reduce oxygen delivery, the heart works harder to facilitate adequate tissue perfusion.
- Use a stethoscope to listen for murmurs, gallops, irregular rhythms, and abnormal BP.
- Systolic BP tends to be lower than normal in patients with anemia.
- Blood pressure may be higher than normal if the patient has too many RBCs.

### Renal and Urinary Assessment

- Check the urinary meatus for bleeding or other abnormalities.
- Obtain a clean-catch or catheterized urine specimen for testing as ordered.
- Hematuria is the abnormal presence of gross or microscopic blood in urine. Red blood cells commonly do not appear in the urine without clinical symptoms; however, strenuous exercise can also cause hematuria.

### Musculoskeletal Assessment

- Abdominal or bone pain may occur in patients with hyper- or hypoproliferative disorders (i.e., sickle cell anemia, leukemia) or infection.

- Leukemia is a malignant proliferation of white blood cell precursors, or blasts, in bone marrow or lymph tissue, which increases the pressure in the bones.
- Sickle cell anemia causes RBCs to become sickle shaped. The abnormal cells accumulate in capillaries and smaller blood vessels, making the blood more viscous, impairing normal circulation, and causing pain, tissue infarctions, and swelling.
- Assess the range of joint motion and observe for swelling, joint pain, or motion limitation.

### Abdominal Assessment

- Advise the patient to empty his or her bladder before the examination to facilitate an abdominal assessment.
- There should be no visible masses. If the abdomen is distended, inquire about changes in bowel patterns and urination.
- Lightly palpate the upper left quadrant of the abdomen for tenderness. The adult spleen is not usually palpable. An enlarged spleen occurs with many hematological problems such as anemia, neutropenia, **thrombocytopenia** (low platelet count), or polycythemia vera (excessive RBC's). Splenomegaly may also occur in conditions such as cirrhosis, hepatitis, mononucleosis, and splenic rupture.
- Palpate gently, as an enlarged spleen may be tender and may rupture easily (Fig. 33.13).

### CASE STUDY: EPISODE 2

Ms. Starr's physical examination reveals heart rate 118 beats per minute, BP 90/72 mm Hg, and respiratory rate 26 breaths per minute. Her skin and nailbeds are pale, and her tongue is red and swollen. She is scheduled to have blood samples obtained for complete blood cell count (CBC) with differential. The nurse practitioner also completes a nutritional assessment to determine any possible deficits...

**FIGURE 33.13** Palpating for splenomegaly. Palpation of the spleen is best performed with the patient in a supine position with abdomen relaxed. The upper left quadrant is lightly palpated for tenderness. If splenomegaly is noted, palpate gently because the enlarged spleen may rupture with deep palpation.

### Connection Check 33.5

When completing a history and physical examination on a patient with a hematological disorder, which action is appropriate?

- Deeply palpate the spleen to determine the extent of splenomegaly
- Perform a respiratory assessment after moderate exercise for accurate measurement of depth and rhythm
- Inspect oral mucous membranes and the tongue for lesions, swelling, and pain
- Suggest a bone marrow biopsy if the patient reports decreased energy levels

## DIAGNOSTIC STUDIES

### Laboratory Profile

Table 33.7 presents an overview of the most common diagnostic studies used to assess hematological function.

### Complete Blood Count

The most common test used for routine screening of hematological function is the complete blood count (CBC). This diagnostic test provides a highly informative profile of data on multiple blood values, identifying the total number of blood cells (leukocytes, erythrocytes, and platelets) as well as the Hgb, Hct, and RBC indices (mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], and mean

**Table 33.7 Laboratory Profile**

Test	Normal Range for Adults	Significance of Abnormal Findings
<b>Red blood cell (RBC) count</b>	Women: 3.61 – 5.11 million/mm <sup>3</sup> Men: 4.21 – 5.81 million/mm <sup>3</sup>	Increased RBCs (polycythemia or erythrocytosis) can result from: <ul style="list-style-type: none"> <li>● High altitude or after increased physical training</li> <li>● Chronic anoxia</li> <li>● Polycythemia or erythrocytosis</li> </ul> Decreased RBCs can result from: <ul style="list-style-type: none"> <li>● Anemia or blood loss</li> <li>● Abnormal loss of erythrocytes</li> <li>● Abnormal destruction of erythrocytes</li> <li>● Lack of needed elements or hormones for erythrocyte production</li> <li>● Bone marrow suppression</li> </ul>
<b>Hematocrit</b>	Women: 36%–48% Men: 42%–52%	Same as for RBC
<b>Hemoglobin</b>	Women: 11.7–15.5 g/dL Men: 14–17.3 g/dL	Same as for RBC
<b>Mean corpuscular volume (MCV)</b>	Women: 78–102 μm <sup>3</sup> Men: 78–100 μm <sup>3</sup>	Increased levels: ( <i>macrocytic</i> , or larger than normal) pernicious anemia and folic acid deficiencies Decreased levels: ( <i>microcytic</i> , or smaller than normal) iron-deficiency anemia and lead poisoning
<b>Mean corpuscular hemoglobin (MCH)</b>	25–35 pg/cell	Same as for MCV
<b>Mean corpuscular hemoglobin concentration (MCHC)</b>	31%–37%	Increased levels: (rare) spherocytosis or anemia Decreased levels: iron-deficiency anemia or a hemoglobinopathy
<b>White blood cell (WBC) count</b>	4.50–11.1 10 <sup>3</sup> /mm <sup>3</sup>	Increased levels: infection, inflammation, autoimmune disorders, and leukemia Decreased levels: prolonged infection or bone marrow depression
<b>Reticulocyte count</b>	0.5%–2.5% of the total RBC count	Increased levels: hemolysis or blood loss; therapeutic response Decreased levels: possible inadequate RBC production (i.e., pernicious anemia) or hypoproliferative bone marrow (hypoplastic anemia)

**Table 33.7 Laboratory Profile—cont'd**

Test	Normal Range for Adults	Significance of Abnormal Findings
<b>Serum iron (Fe)</b>	30–160 mcg/dL (higher in men)	Increased levels: excess iron; hemochromatosis; liver disorders; megaloblastic anemia Decreased levels: iron-deficiency anemia; hemorrhage
<b>Serum ferritin</b>	20–400 ng/mL (lower in premenopausal women)	Same as for iron
<b>Total iron-binding capacity</b>	250–410 mcg/dL	Increased levels: iron-deficiency anemia Decreased levels: anemia, hemorrhage, hemolysis; hemochromatosis
<b>Transferrin saturation</b>	20%–50%	Decreased levels: iron-deficiency anemia; hemochromatosis
<b>Platelets</b>	150,000–450,000/ $\mu$ L	Increased levels: thrombocytosis; may indicate polycythemia vera or malignancy; splenectomy (temporary increase) Decreased levels: thrombocytopenia; suppressed bone marrow function, autoimmune disease, hypersplenism, or splenomegaly
<b>Hemoglobin electrophoresis</b>	Hgb A: 95%–100% (normal) Hgb A2: 1.5%–3% (normal) Hgb F: Under 1% (normal)	Variations indicate hemoglobinopathies 4%–5.8% = beta-thalassemia minor Under 1.5% = Hgb H disease 2%–5%: beta-thalassemia minor 10%–90%: beta-thalassemia major 5%–15%: beta-thalassemia minor Homozygous Hgb S: 70%–98% = sickle cell disease Homozygous Hgb C: 90%–98% = Hgb C disease Heterozygous Hgb C: 24%–44% = Hgb C trait
<b>Direct Coombs' and indirect Coombs' test</b>	Negative	Positive findings indicate antibodies to RBCs
<b>Prothrombin time (PT)</b>	10–13 seconds	Prolonged PT may indicate possible deficiencies in clotting factors V and VII; response to oral anticoagulant therapy Decreased time may indicate vitamin K excess
<b>Bleeding time</b>	3–8 minutes	Prolonged bleeding time may indicate a platelet function disorder or deficiency of clotting factors
<b>Platelet aggregation</b>	Factor VIII (antihemophilic globulin) 50%–200%	Diminished aggregation may indicate von Willebrand's disease

1 Cubic millimeter ( $\text{mm}^3$ ) = 1 microliter ( $\mu\text{l}$ ).

corpuscular hemoglobin concentration [MCHC]). These laboratory tests, their normal values, and nursing implications are summarized in Table 33.7, as well as other laboratory tests that may be done to evaluate hematological and lymphatic functions.

The RBC count measures circulating RBCs in  $1 \text{ mm}^3$  of blood and is calculated as the percentage of RBCs in the

total blood volume. A low Hct suggests anemia, hemodilution, or massive blood loss. A high Hct indicates polycythemia or hemoconcentration caused by blood loss or dehydration. The Hgb level is the total amount of hemoglobin in the blood, and assessment of Hgb levels measures the severity of anemia or polycythemia and monitors the patient's response to therapy. A low Hgb level may indicate

anemia, recent hemorrhage, or fluid retention, causing hemodilution. A high Hgb level suggests hemoconcentration from polycythemia or dehydration.

The CBC can measure other features of the RBCs, including MCV, MCH, and MCHC. Mean corpuscular volume (MCV) expresses the average size of the erythrocytes and indicates whether they are undersized (microcytic), oversized (macrocytic), or normal (normocytic) and is useful in classifying anemias. An elevated MCV indicates the cell is larger than normal (macrocytic) and can be seen in megaloblastic anemias. A decreased MCV indicates the cell is smaller than normal (microcytic) and can be seen in iron-deficiency anemia. Mean corpuscular hemoglobin (MCH), the Hgb-to-RBC count ratio, gives the weight of Hgb in an average RBC. Mean corpuscular hemoglobin concentration (MCHC), the Hgb weight-to-Hct ratio, defines the concentration of Hgb in 100 mL of packed RBCs. It helps to distinguish normally colored (normochromic) RBCs from paler (hypochromic) RBCs.

The platelet count evaluates the function of platelets, or thrombocytes, which promote coagulation and formation of a hemostatic plug in vascular injury. The platelet count also determines the ability of the patient's blood to clot normally. A count lower than 50,000/ $\mu\text{L}$  may result in spontaneous bleeding; when the count is lower than 5,000/ $\mu\text{L}$ , fatal central nervous system bleeding or massive GI hemorrhage is possible. A decreased count (thrombocytopenia, 80–100/ $\mu\text{L}$ ) can indicate aplastic or hypoplastic bone marrow, infiltrative bone marrow disease such as leukemia or disseminated infection, or ineffective thrombopoiesis caused by folic acid or vitamin B<sub>12</sub> deficiency. An increased platelet count (thrombocytosis) can result from hemorrhage, infectious disorders, iron-deficiency anemia, recent surgery, pregnancy, splenectomy, or inflammatory disorders. Whenever the platelet count is abnormal, diagnosis usually requires a CBC, bone marrow biopsy, direct Coombs' test, and serum protein electrophoresis for confirmation.

The WBC count measures all leukocytes present in 1 mm<sup>3</sup> of blood, and a WBC count with differential determines the percentages of different types of leukocytes circulating in the blood. The WBC count may increase or decrease significantly in certain diseases but is diagnostically useful when the patient's differential and condition are considered. The purpose of the WBC count is to determine infection or inflammation, to detect and identify various types of leukemia, to determine the need for further tests, such as the WBC differential or bone marrow biopsy, and to monitor responses to antibiotic therapy, chemotherapy, or radiation therapy. An increased WBC count (*leukocytosis*) commonly indicates infection such as an abscess, meningitis, appendicitis, or tonsillitis, or it may result from leukemia and tissue necrosis caused by burns, myocardial infarction, or gangrene. A decreased count (*leukopenia*) signals bone marrow depression that may result from viral infections or from toxic reactions such as those following treatment with antineoplastics (medications that destroy cancer cells), ingestion of mercury

or other heavy metals, or exposure to benzene or arsenicals. It may also indicate influenza, typhoid fever, infectious hepatitis, mononucleosis, measles, or rubella.

### Patient Preparation and Nursing Implications

Explain to the patient that the complete blood count (CBC) is used to assess for changes in RBC, WBC, Hct, and Hgb. Inform the patient that there are no dietary restrictions required for the test, and describe that the test requires a blood sample and that slight discomfort may be experienced from the tourniquet and needle puncture. It is important to notify the laboratory and practitioner of medications the patient is taking that may affect test results; it may be necessary to restrict them. Confirm the patient's identity using two patient identifiers according to facility policy. Perform a venipuncture (Box 33.2). A lavender-topped ethylenediaminetetraacetic acid (EDTA) tube is used to collect the blood sample. (Ethylenediaminetetraacetic acid is an anticoagulant that prevents the sample from clotting). The tube is filled and then gently inverted several times to mix the sample and the anticoagulant in the tube. The accuracy of CBC results can be impacted if the specimen collection technique is not correct. For example, the RBC, CBC, Hgb,

## Box 33.2 Patient Preparation for Venipuncture

### Key Steps

1. Verify the order.
2. Confirm the patient's identity using two patient identifiers according to facility policy.
3. Perform hand hygiene and put on gloves. If the patient has a history of a latex allergy, avoid the use of latex gloves.
4. Explain the procedure to ease anxiety and ensure cooperation.
5. Clean the venipuncture site with an alcohol pad in a back-and-forth motion. Allow the skin to dry before performing venipuncture and then insert the needle into the vein at a 30-degree angle. Continue to fill the required tubes and gently rotate each tube as you remove it to help mix the additive with the sample.
6. Remove the tourniquet as soon as blood flows adequately to prevent stasis and hemolysis, which can impair test results.

### Postprocedure Care

1. After gently removing the needle, apply gauze and direct pressure to the venipuncture site until the bleeding stops.
2. Inform the practitioner of abnormal results.

### Precautions

1. Handle the sample gently to prevent hemolysis.
2. Send the sample to the laboratory immediately.

### Complications

1. May include hematoma at the venipuncture site.
2. Infection may result from poor technique.

and Hct levels may be falsely elevated secondary to venous stasis if the tourniquet is left in place for longer than one minute.

### Connection Check 33.6

The nurse is asked to obtain a differential after the results of the CBC reveal an elevated WBC count. Which statement is true about a differential?

- Determines the percentage of platelets in the circulating blood
- Determines the proportion of each type of WBC in a blood sample
- If the infection is bacterial, then the neutrophil count will be decreased.
- If the basophils are elevated, then the patient has a viral infection.

### Connection Check 33.7

The nurse is assigned to a patient with thrombocytopenia. What is the priority goal of nursing care?

- Prevention of infection
- Prevention of injury
- Prevention of dehydration
- Prevention of nutritional deficit

### Reticulocyte Count

Reticulocytes are usually larger than mature RBCs because they still contain the network composed of ribosome clusters from the erythroblast precursor cell. Reticulocytes are non-nucleated, immature RBCs that remain in the peripheral blood for 24 to 48 hours while maturing. The reticulocyte count is useful for evaluating anemia, specifically to help distinguish between hypoproliferative and hyperproliferative anemias. The reticulocyte count may also help assess blood loss, evaluate bone marrow response to anemia, and evaluate treatments for anemia. The test involves counting the number of reticulocytes in a whole blood sample, where the value is expressed as a percentage of the total RBC count. A low reticulocyte count indicates hypoproliferative bone marrow (hypoplastic anemia) or ineffective erythropoiesis (pernicious anemia). Pernicious anemia occurs when the body cannot properly absorb vitamin B<sub>12</sub> from the gastrointestinal tract because vitamin B<sub>12</sub> is necessary for the proper development of RBCs. To absorb vitamin B<sub>12</sub>, the body uses a special protein called *intrinsic factor*, which is released by cells in the stomach. When the stomach does not make enough intrinsic factor, the intestine cannot properly absorb vitamin B<sub>12</sub>; hence, erythropoiesis is disrupted.

An increase in the percentage of reticulocytes indicates that the release of RBCs into the bloodstream is occurring more rapidly than usual. A high reticulocyte count may

indicate a bone marrow response to anemia caused by hemolysis or blood loss. The increase in the reticulocyte count is a physiological response to the need for more RBCs.

### Patient Preparation and Nursing Implications

Explain to the patient that the reticulocyte count is used to detect anemia or to monitor its treatment. Inform the patient that there are no dietary restrictions required for the test and describe that the test requires a blood sample and that slight discomfort may be experienced from the tourniquet and needle puncture. If the patient is an infant or child, the parents are told that a small amount of blood will be taken from the child's finger or earlobe. It is important to notify the laboratory and practitioner of medications the patient is taking that may affect test results; it may be necessary to restrict them. Confirm the patient's identity using two patient identifiers according to facility policy. Perform a venipuncture. The collection tube is filled completely and then gently inverted several times to mix the sample and the anticoagulant in the tube.

### Hemoglobin Electrophoresis

Hemoglobin electrophoresis is the most useful laboratory method for separating and measuring normal and abnormal hemoglobin. The purpose of this test is to help diagnose **thalassemias**, which are a group of inherited autosomal recessive genetic disorders characterized by defective synthesis in one or more of the polypeptide chains needed for Hgb production. They most commonly occur as a result of reduced or absent production of the Hgb alpha or beta chains. This affects Hgb production and impairs RBC synthesis. Hemoglobin electrophoresis may show elevated or normal Hgb A<sub>2</sub> levels (beta-thalassemia trait) or elevated Hgb A<sub>2</sub> and F levels with reduced or absent Hgb A<sub>1</sub> levels (beta-thalassemia major).

### Patient Preparation and Nursing Implications

Describe to the patient that hemoglobin electrophoresis evaluates Hgb and explain that no dietary restrictions are required. If the patient is an infant or child, explain to the parents that a small amount of blood will be taken from the child's finger. Confirm the patient's identity using two patient identifiers according to agency policy. Ask whether a blood transfusion has been received within the past 4 months. Perform a venipuncture and collect the sample in a 3- or 4.5-mL EDTA tube (lavender top) that includes an anticoagulant in the tube.

### Leukocyte Alkaline Phosphatase

Leukocyte alkaline phosphatase (LAP) is an enzyme produced by normal mature neutrophils. Elevated LAP levels may result from infection, stress, inflammation, pregnancy, steroid use, and leukemia. An elevated neutrophil count without an accompanying elevation in LAP level is associated with chronic myelogenous leukemia. Inform the patient that this test can assist in evaluating for blood disorders. Venipuncture is performed and 1 mL of blood is collected in an EDTA tube.

### Coombs Test

A direct Coombs test detects the presence of immunoglobulins (antibodies) on the surface of RBCs that develop through sensitization to antigens (such as Rh factor). This test is performed to diagnose hemolytic disease of the newborn, to investigate hemolytic transfusion reactions, and to aid in the differential diagnosis of hemolytic anemias. Medications such as quinidine, methyl dopa, cephalosporins, sulfonamides, hydralazine, levodopa, melphalan, penicillin, rifampin, streptomycin, and isoniazid may cause a false-positive Coombs test result. A positive Coombs test in the neonate indicates that maternal antibodies have crossed the placental barrier and coated the fetal RBCs, causing hemolytic disease of the neonate. In other patients, a positive test result may indicate hemolytic anemia and may help differentiate between autoimmune and secondary hemolytic anemias. A positive test may also indicate sepsis. A weakly positive test may indicate a transfusion reaction in which the patient's antibodies reacted with transfused RBCs that contained the corresponding antigen.

### Patient Preparation and Nursing Implications

Describe the purpose of the test and how it is performed. Inform the patient that this test is used in assessing for disorders that break down RBCs. Explain to the patient that no dietary restrictions are needed. Perform the venipuncture and collect the specimen in two 5-mL EDTA tubes.

### Iron: Serum Ferritin, Transferrin, Total Iron-Binding Capacity

Serum iron (Fe) levels are measured directly, and blood levels should be drawn in the morning because of a diurnal variation in serum iron, with lower evening values. The patient is instructed to avoid taking any iron supplements for at least 24 hours before the test is performed.

**Ferritin** is a protein that stores iron in the body. A ferritin level provides information about the body's ability to store iron for later use and is usually performed with iron testing and total iron-binding capacity (TIBC). Low ferritin levels may indicate iron deficiency, chronic GI bleeding, or heavy menstrual bleeding. High levels may indicate alcoholic liver disease, hemochromatosis (excessive iron absorption), hemolytic anemia, Hodgkin's lymphoma, or megaloblastic anemia. Illnesses such as infections, inflammations, and malignant diseases cause increased levels and therefore may make ferritin levels unreliable as an indicator of iron stores.

**Transferrin**, a plasma protein, transports circulating iron obtained from dietary sources or from the breakdown of RBCs for use in Hgb synthesis or to the liver, spleen, and bone marrow for storage. The purpose of the transferrin level test is to determine the iron-transporting capacity of the blood and evaluate iron metabolism in iron-deficiency anemia. Inadequate transferrin levels may lead to impaired Hgb synthesis and, possibly, anemia. Low serum levels may indicate inadequate transferrin production caused by hepatic damage or excessive protein loss from renal disease. Decreased transferrin levels may also result from acute or

chronic infection and cancer. Increased serum transferrin levels may indicate severe iron deficiency.

Total iron-binding capacity measures the amount of iron that appears in plasma if all transferrin is saturated with iron. The TIBC is used with the serum iron to calculate transferrin saturation. As previously discussed, iron is essential to the formation and function of Hgb. In iron deficiency, serum iron levels decrease and TIBC increases, decreasing saturation. In chronic inflammation, serum iron may be low despite adequate body stores, but TIBC may be unchanged or decreased to preserve normal saturation. Iron overload may not alter serum levels until later, but serum iron increases and TIBC remain the same, increasing saturation.

### Patient Preparation and Nursing Implications

Blood specimens for serum iron and TIBC are collected in iron-free tubes. Specimens for serum ferritin may be placed in either green- or lavender-top tubes. Check with the laboratory for the total amount needed. Iron must be drawn in the morning, and an overnight fast is recommended. For the transferrin level test, an interfering factor may be hormonal contraceptives and late pregnancy, possibly causing an increase in level.

### Clotting Studies: Prothrombin Time, Bleeding Time, International Normalized Ratio, Partial Thromboplastin Time, Platelet Aggregation

#### Prothrombin Time

**Prothrombin time (PT)** measures the time required for a fibrin clot to form in a citrated plasma sample after addition of calcium ions and tissue thromboplastin (factor III). The purpose of this test is to evaluate the extrinsic coagulation system (factors V, VII, and X, and prothrombin and fibrinogen) and to monitor response to oral anticoagulant therapy. A prolonged PT may indicate deficiencies in fibrinogen; prothrombin; factors V, VII, or XI; or vitamin K. It may also result as a therapeutic response from ongoing oral anticoagulant therapy (warfarin, Coumadin; tinzaparin sodium, Innohep). A prolonged PT that exceeds two and one-half times the control value usually indicates abnormal bleeding. More than 1 g per day of salicylates may interfere with the PT value by increasing the value and increasing the risk of bleeding.

### Patient Preparation and Nursing Implications

Explain to the patient that the PT test determines whether the blood clots normally. When appropriate, explain that this test monitors the effects of oral anticoagulants; the test will occur daily when therapy begins and will be repeated at longer intervals as the medication results in the desired PT levels. Inform the patient that no dietary restrictions are required. Notify the laboratory and practitioner of medications the patient is taking that may affect test results; they may be restricted. Perform a venipuncture and collect the sample in a 3- or 4.5-mL sodium citrate tube. Gently invert the tube several times to thoroughly mix the sample and the anticoagulant. Remove the needle and apply direct pressure

with dry gauze to stop bleeding. Ensure that subdermal bleeding has stopped before removing pressure. If a large hematoma develops at the venipuncture site, monitor pulses distal to the site. Inform the practitioner of abnormal results.

### Bleeding Time

The purpose of the bleeding time test is to assess overall hemostatic (clotting) function and to detect platelet function disorders. It is most commonly performed in the patient with a personal or family history of bleeding disorders but is also useful for preoperative screening.

**Safety Alert** A bleeding time test is usually not recommended for a patient with a platelet count of less than 75,000  $\mu\text{L}$  because of an increased risk for massive bleeding and ineffective clotting.

Bleeding time measures the duration of bleeding after a measured skin incision. There are three methods of measuring bleeding: template, Ivy, and Duke. The template bleeding time procedure is performed with lancet devices that make two reproducible skin incisions 1-mm deep and several millimeters long. A blood pressure cuff is wrapped around the upper arm and inflated to 40 mm Hg. The drops of blood are blotted with filter paper every 30 seconds until the bleeding stops in both cuts. The average bleeding times of the two cuts is recorded.

Because of these small wounds, the primary hemostatic mechanisms involving platelets and blood vessels can stop the bleeding independently of coagulation reactions. Prolonged bleeding time may indicate disorders associated with thrombocytopenia, such as Hodgkin's disease, acute leukemia, disseminated intravascular coagulation (DIC), hemolytic disease of the newborn, severe hepatic disease (i.e., cirrhosis), or severe deficiency of factors I, II, V, VII, VIII, IX, and XI. Thrombasthenia is a bleeding disorder caused by abnormal platelet function characterized by abnormal clot retraction, prolonged bleeding time, and lack of aggregation of the platelets. Prolonged bleeding time in a patient with a normal platelet count suggests a platelet function disorder (thrombasthenia) and requires additional analysis with clot retraction, prothrombin consumption, and platelet aggregation tests.

**Safety Alert** WARNING! If the bleeding does not stop in 15 minutes after the cuts are made, stop the test and maintain a pressure bandage over the incision or puncture sites for 24 to 48 hours to prevent further bleeding. Anticoagulants, NSAIDs, aspirin, and aspirin compounds (prolonged bleeding time) can interfere with this test.

### International Normalized Ratio

The **International Normalized Ratio (INR)**, also known as the *INR system*, is performed to measure PT (prothrombin time) and to evaluate the effectiveness of oral anticoagulant therapy (warfarin sodium, Coumadin). Laboratories convert their PT values into an INR, and this test is not used to screen for coagulopathies. For patients receiving warfarin therapy, the therapeutic INR is 2 to 3. For those who are receiving warfarin therapy and have mechanical prosthetic heart valves, the therapeutic INR is 2.5 to 3.5. Increased INR values may be a sign of disseminated intravascular coagulation (DIC), cirrhosis, hepatitis, vitamin K deficiency, salicylate intoxication, uncontrolled oral anticoagulation, or massive blood transfusion. Perform a venipuncture and collect the sample in a 4.5-mL tube with sodium citrate added. Gently invert the tube several times to thoroughly mix the sample and the anticoagulant. Remove the needle and apply direct pressure to the venipuncture site with dry gauze until bleedings stops.

### Partial Thromboplastin Time

The purpose of the **partial thromboplastin time (PTT)** or activated partial thromboplastin time (aPTT) is to screen for deficiencies of the clotting factors in the intrinsic pathways and to monitor response to thrombin inhibitor therapy (heparin, argatroban). It is used to evaluate all the clotting factors of the intrinsic pathway (with the exception of platelets) by mixing decalcified plasma (collected in citrate) and a phospholipid substitute (thromboplastin), adding calcium, and determining the time for visible clot formation using an automated system. The reference range of the PTT is 60 to 70 seconds and aPTT is 30 to 40 seconds after adding an activator (that speeds up the clotting time and results in a narrower reference range). For a patient receiving an anticoagulant, the practitioner needs to specify the reference values for the therapy being delivered. A prolonged PTT may indicate an insufficiency of certain clotting factors, the presence of heparin, the presence of fibrin split products, fibrinolysis, or circulating anticoagulants that are antibodies to specific clotting factors.

Inform the patient that this test can assist in evaluating the effectiveness of blood clotting. A venipuncture is performed, and a blood sample is collected in a 7-mL sodium citrate tube. The tube must be filled completely and then inverted several times to mix with contents of the tube. Direct pressure is applied to the venipuncture site until bleeding stops. If a patient is on anticoagulant therapy, additional pressure at the venipuncture site to control bleeding may be needed.

### Platelet Aggregation

Platelet aggregation studies are performed in patients who are suspected of having abnormal platelet function, i.e., those who have a prolonged bleeding time and a normal or near-normal platelet count. Platelet aggregation, or the ability of platelets to clump, can be tested by mixing the patient's plasma with a substance called *ristocetin*, and then

the degree of aggregation is noted. Aggregation can be impaired with von Willebrand's disease (see Genetic Connections) and with the use of medications such as aspirin, NSAIDs, antineoplastics, and psychotropic agents. Venous blood (4.5 mL) is collected in a sodium citrate tube. The collection tube is completely filled and then gently inverted several times to mix the sample with the sodium citrate. It is important that pressure is applied directly to the venipuncture site until bleeding stops.

## Genetic Connections

### Von Willebrand's Disease

Von Willebrand's disease (vWD) is a common hereditary platelet disorder caused by a deficiency or dysfunction of von Willebrand factor (vWF). Von Willebrand's disease affects the normal interaction with platelets and impairs primary hemostasis, causing prolonged bleeding (like nosebleeds) and easy bruising. vWD is classified into three major types (types 1, 2, and 3). The disorder is caused by a gene located on chromosome 12 inherited as an autosomal dominant trait (types 1 and 2) or autosomal recessive trait (type 3).

Patients with vWF generally have a normal PT, abnormal platelet function screening test, and prolonged partial thromboplastin time (PTT). A vWF antigen testing helps establish the type of vWD. For most affected patients, vWD is a mild, manageable bleeding disorder in which clinically severe hemorrhage occurs only in the event of trauma or invasive procedures.

The main treatment options for patients with vWD are desmopressin (DDAVP), recombinant vWF, and vWF/factor VIII (vWF/FVIII) concentrates. In addition, antifibrinolytic medications (i.e., aminocaproic acid, tranexamic acid) can be used orally or intravenously to treat mild mucocutaneous bleeding. Patients with possible vWD should be asked about any family or personal history of bleeding problems. Patients should also be asked about the use of medications that might affect coagulation.

## Examination of the Bone Marrow

### Bone Marrow Aspiration and Biopsy

The purpose of a bone marrow aspiration and biopsy is to diagnose thrombocytopenia, leukemias, granulomas, anemias, and primary and metastatic tumors. This diagnostic study is also performed to determine causes of infection, to help stage diseases such as Hodgkin's disease, to evaluate chemotherapy, and to monitor myelosuppression (Table 33.8).

**Table 33.8 Interpretation of Bone Marrow Results**

Normal Results	Abnormal Results
<ul style="list-style-type: none"> <li>● Yellow bone marrow contains fat cells and connective tissue.</li> <li>● Red bone marrow contains hematopoietic cells, fat cells, and connective tissue.</li> <li>● The iron stain, which measures hemosiderin (storage iron), has a +2 level.</li> <li>● Negative Sudan black B stain, which shows granulocytes.</li> <li>● The periodic acid–Schiff (PAS) stain, which detects glycogen reactions, is negative.</li> </ul>	<ul style="list-style-type: none"> <li>● Decreased hemosiderin levels in an iron stain may indicate a true iron deficiency.</li> <li>● A positive iron stain can differentiate acute myelogenous leukemia from acute lymphoblastic leukemia (negative stain).</li> <li>● A positive iron stain may also suggest granulation in myeloblasts.</li> <li>● Increased hemosiderin levels may suggest other types of anemias or blood disorders.</li> <li>● A positive PAS stain may suggest acute or chronic lymphocytic leukemia, amyloidosis, thalassemia, lymphoma, infectious mononucleosis, iron-deficiency anemia, or sideroblastic anemia.</li> </ul>

Bone marrow biopsy and aspiration (Fig. 33.14) involve the collection of a soft tissue specimen from the medullary canals of the long bone and interstices of cancellous bone for histological and hematological examination. The procedure is performed by aspiration or needle biopsy under local anesthesia.

- Aspiration biopsy: removal of a fluid specimen from the bone marrow
- Needle biopsy: removal of a core of marrow cells

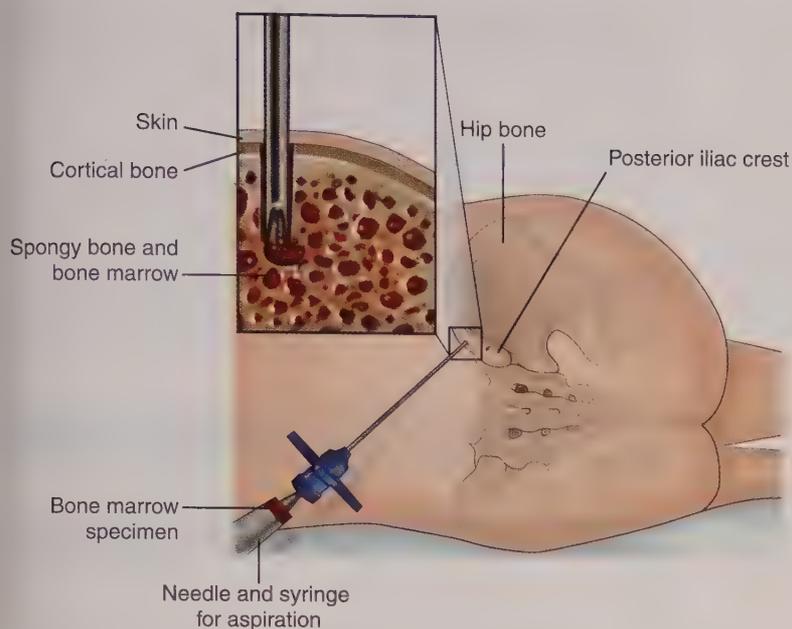

It is common to perform both methods at the same time to obtain the best possible specimens.

When leukemic cells are identified on bone marrow aspirate smears, special stains are used to explore the interpretation of the abnormal cell population. These stains include the iron stain, which measures hemosiderin (storage iron), the Sudan black B stain, which shows the number of granulocytes, and the periodic acid–Schiff (PAS) stain, which detects glycogen reactions. This microscopic evaluation can be used to distinguish acute myelogenous from acute lymphoblastic leukemias or to subtype myelogenous leukemias.

### Patient Preparation and Nursing Implications

#### Before the Test

- Ensure that the patient has received teaching from the provider performing the procedure, has given informed consent, and that all allergies are documented.

**FIGURE 33.14** Bone marrow biopsy and aspiration. The patient is positioned into the prone or lateral decubitus position for biopsy of the posterior iliac crest. The patient may experience feelings of pressure upon insertion of the biopsy needle and a brief, pulling pain will be experienced on removal of the marrow. Some patients can hear a crunching sound or feel a scraping sensation as the needle punctures the bone.

- Assess for bleeding risk, such as medical history, coagulation laboratory results, platelet count, anticoagulant therapy, and other medications or supplements that may interfere with clotting.
- Explain the purpose of the test and the procedure.
- Explain that a blood sample (aspiration) is required before the biopsy for laboratory testing (cells and fluids from marrow).
- Explain which bone site (sternum, anterior or posterior iliac crest, vertebral spinous process, rib, or tibia) will be used. The most common biopsy site is the back of the hip (*posterior superior iliac crest*).
- Explain to the patient that pressure will be felt upon insertion of the biopsy needle and a brief, pulling pain may be experienced on removal of the marrow, caused by the mild suction of the syringe. Some patients can hear a crunching sound or feel a scraping sensation as the needle punctures the bone.
- Tell the patient that the actual test takes only 5 to 10 minutes. If the patient is anxious, use relaxation techniques, or administer a mild sedative, if prescribed, 1 hour before the test.
- Assist the patient to the appropriate position and help maintain a comfortable patient position. If the insertion site is the posterior iliac crest, assist the patient into the prone or lateral decubitus position. If the sample is taken from the sternum or anterior iliac crest, the patient will be supine.
- Encourage deep breaths and relaxation techniques during the procedure.

#### After the Test

- After aspiration, apply direct pressure over the puncture site according to agency policy for 5 to 10 minutes until bleeding stops. Cover the site with a sterile dressing.

- Instruct the patient to rest for several hours. Report bleeding that completely soaks the dressing or continues for more than 24 hours. Reinforce the dressing, if needed, but do not remove it for at least 24 hours.
- Properly label and promptly transport all specimens to the laboratory.
- Assess for postprocedural pain and provide analgesia as ordered.
- Teach the patient to watch for signs of infection.

### AGE-RELATED CHANGES TO THE HEMATOLOGICAL SYSTEM

While the human body ages, the number of cells of the body is gradually reduced. Lean body mass decreases, but fat tissue increases until approximately age 60 years. Bone mass and intracellular fluids also tend to decrease, and normal aging causes a decrease in total body water. With the decrease in total body water, there is less fluid in the bloodstream, so blood volume decreases, with lower levels of plasma proteins. The lower plasma protein level may be related to a low dietary intake of proteins and reduced protein production by the older liver (see Evidence-Based Practice).

#### Evidence-Based Practice

##### Older Adults and Anemia

The prevalence of anemia increases with age, with the frequency of anemia doubling in individuals aged 85 years and older compared with individuals aged 65 to 84 years. Additionally, the prevalence of anemia in older people is considerably greater in nursing homes than in other settings. In nursing homes, anemia is present in 48% to 63% of

residents. Various causes that contribute to anemia include iron deficiency, chronic inflammation, renal insufficiency, folate deficiency, and vitamin B<sub>12</sub> deficiency.

According to a systematic review (Tay & Soiza, 2015), many studies suggest oral iron improves hemoglobin and that this will lead to tangible benefits, such as improved quality of life and lower morbidity and mortality of older adults. The meta-analysis found that oral iron therapy increases hemoglobin levels more than placebo or no treatment. However, intravenous iron may be necessary to treat iron deficiency anemia in patients who have poor iron absorption in the gastrointestinal tract, patients with severe iron deficiency or chronic blood loss, patients who are having treatment with erythropoietin, or patients who cannot tolerate oral iron due to the side effects.

Tay, H. S., & Soiza, R. L. (2015). Systematic review and meta-analysis: what is the evidence for oral iron supplementation in treating anaemia in elderly people? *Drugs & Aging*, 32(2), 149-158. <https://doi.org/10.1007/s40266-015-0241-5>

While bone marrow ages, it produces fewer blood cells (Table 33.9). The bone marrow's ability to produce RBCs and WBCs may be decreased. The number of circulating RBCs, along with Hgb and Hct levels, are reduced, and this may contribute to fatigue. Lymphocytes decrease in their number and ability to defend against bacteria, which reduces the ability to fight infection.

**Table 33.9 Age-Related Changes in Hematology Results**

Test	Age-related Changes
Hematocrit	No normal decline with age
Hemoglobin (Hgb)	No normal decline with age
Reticulocyte count	Slight decrease
Lymphocytes	Both T- and B-cell levels decrease
Albumin	Declines because of a decrease in liver size and enzymes
Serum iron (Fe)	Slight decrease
Iron binding	Decrease
Platelets	No change with age
Sedimentation rate (ESR)	Increase
Vitamin B <sub>12</sub>	Slight decrease

### Connection Check 33.8

Age-related changes that affect the hematological system include which findings? (Select all that apply.)

- Iron binding decreases.
- The number of stem cells in the marrow increases.
- Lymphocyte function, especially cellular immunity, decreases.
- Platelet adhesiveness decreases.
- Hematocrit decreases.

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Starr's laboratory results include RBC count 3 million/mm<sup>3</sup>, Hct 31%, Hgb 9 g/dL, and a decrease in serum ferritin levels. The laboratory results for RBCs, Hct, and Hgb show a decrease in all three values. Combining the laboratory values with vital signs and reported symptoms identifies her disorder. Low Hct and Hgb and low ferritin level combined with her complaints of generalized fatigue and increased shortness of breath and her pale skin and nailbeds, along with red, swollen tongue, suggest iron-deficiency anemia. The decrease in serum ferritin level further supports the differentiation of this anemia. Ms. Starr is prescribed iron supplements and referred to a hematologist for further evaluation.

#### Case Study Questions

- The nurse correlates which clinical manifestations with Ms. Starr's diagnosis of iron-deficiency anemia? (Select all that apply.)
  - Decreased temperature
  - Decreased heart rate
  - Increased blood pressure
  - Increased heart rate
  - Increased respiratory rate
- Which diagnostic result confirms Ms. Starr's diagnosis of iron-deficiency anemia?
  - Decreased transferrin saturation
  - Decreased mean corpuscular volume
  - Increased total iron-binding capacity
  - Increased ferritin levels
- The nurse assesses for which clinical manifestation as a compensatory mechanism for iron-deficiency anemia?
  - Increased respiratory rate
  - Increased blood pressure
  - Decreased temperature
  - Decreased pulse rate

4. During an assessment of Ms. Starr's mouth, which finding does the nurse correlate with iron-deficiency anemia?
  - A. Red, beefy gums
  - B. Loss of teeth
  - C. Red, swollen, tender tongue
  - D. Xerostomia
5. Ms. Starr is scheduled to have a serum iron level in 1 month. The nurse includes which instructions about this test?
  - A. "You will need to fast for 12 hours before the test."
  - B. "This sample needs to be drawn in the morning."
  - C. "Continue to take your iron supplements."
  - D. "This test will require three different samples taken at hourly intervals."

nutrients, and other substances in the body. The primary function of RBCs is to transport oxygen to the cells. The primary function of WBCs is to fight infection, destroy foreign matter, and eliminate damaged or abnormal cells in the body. White blood cells are an integral part of the immune system and are necessary for its functioning. Platelets and clotting factors work together in the process of blood clotting and the control of bleeding. The lymphatic system also is involved in the immune response. Blood tests to evaluate the number and types of cells present, their size and shape, and the ability of the blood to clot are the primary diagnostic tests used to evaluate the hematological system. Aspiration of bone marrow may be necessary to provide additional information about blood formation. Nursing care of the patient undergoing diagnostic testing for a possible hematological disorder is both educational, explaining the purpose of the test and any special preparation or expected sensations during the test, and supportive.

## CHAPTER SUMMARY

The hematological system is composed of the blood, blood cells, lymph, and organs involved with blood formation or blood storage. Blood is the transport medium for oxygen,

## Coordinating Care for Patients With Hematological Disorders

*Margaret McCormick*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of disorders of the hematological system
2. Correlating clinical manifestations to pathophysiological processes of nonmalignant and malignant hematological disorders:
  - a. Iron-deficiency anemia
  - b. Vitamin B<sub>12</sub> and pernicious anemia
  - c. Folic acid deficiency anemia
  - d. Sickle cell anemia
  - e. Aplastic anemia
  - f. Glucose-6-phosphate dehydrogenase (G6PD) deficiency
  - g. Polycythemia vera
  - h. Idiopathic (immune) thrombocytopenia purpura
  - i. Leukemia
  - j. Malignant lymphoma
  - k. Multiple myeloma
3. Describing the diagnostic results used to confirm disorders of the hematological system
4. Discussing the medical management of identified hematological disorders
5. Developing a comprehensive plan of nursing care for patients with nonmalignant and malignant hematological disorders
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with nonmalignant and malignant hematological disorders
7. Coordinating the interprofessional plan of care for the patient with hematological disorders

### CONCEPTS

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. William Owens is a 62-year-old male who presents to his healthcare provider with complaints of fatigue, weakness, and shortness of breath on climbing stairs. He also states that he has noticed some bleeding of his gums sometimes when he brushes his teeth but otherwise has been in relatively good health. Mr. Owens has worked in the oil refinery business since he was a teenager. He has a history of smoking one-half to one pack of cigarettes daily for 40+ years, likes to drink beer “with the guys,” and has no history of substance use...

## INTRODUCTION

**Hematology** is the study of the blood and the lymphatic system. Blood is composed of plasma (the liquid transporting medium), blood cells, oxygen, nutrients, carbon dioxide, antibodies, and other proteins. **Hematopoiesis** is the production of blood cells in the bone marrow located in flat and irregular bones. The blood cells are red blood cells (RBCs), white blood cells (WBCs), and platelets.

Red blood cells, or **erythrocytes**, are normally round in shape and are without nuclei. The lack of a nucleus makes them malleable and able to squeeze through the small blood capillaries. Red blood cells contain the hemoglobin (Hb) molecule, which bonds with oxygen and becomes oxyhemoglobin in the pulmonary capillaries of the lungs. **Anemia** occurs when there is a reduction in the oxygen-carrying capacity through either fewer RBCs or a reduction in hemoglobin.

There are five different types of WBCs or **leukocytes**: **basophils**, **eosinophils**, **neutrophils**, **monocytes**, and **lymphocytes**. Neutrophils, eosinophils, and basophils are produced in the bone marrow. Neutrophils **phagocytize**, or destroy, pathogens to fight infection, eosinophils respond during an allergic reaction to detoxify the foreign proteins or antibodies, and basophils release histamine in inflammatory reactions. Lymphocytes and monocytes are produced in the lymphatic tissue. Pathogens and dead tissue are phagocytized by monocytes. There are three types of lymphocytes: B cells (produce antibodies to foreign substances), T cells (helper, suppressor, memory, amplifier, delayed hypersensitivity, cytotoxic), and natural killer cells.

The lymphatic system is composed of lymphatic tissue (called **nodes** or **nodules**), lymph (the liquid transporting medium), lymph vessels, the spleen, and the **thymus**. The thymus is a gland located behind the upper sternum that produces T lymphocytes (T cells) and hormones, which

mature the immune system. The thymus is larger in infancy and childhood but shrinks with age, and its function is to assist in removing phagocytized pathogens and foreign materials, protect the body from infection, and return fluid to blood vessels to maintain blood pressure. **Lymph** is formed from plasma that is filtered by the blood capillaries and flows through the lymph vessels and lymph nodes. There are three major pairs of lymph nodes: cervical (located in the neck), axillary (located in the underarms), and inguinal (located in the groin). Lymph flows from the left upper quadrant and lower body, through the thoracic duct (in front of the spine), and drains into the left subclavian vein. Lymph from the right upper quadrant enters the right lymphatic duct and drains into the right subclavian vein. The function of the spleen is to produce lymphocytes, monocytes, and certain antibodies. The spleen also phagocytizes old RBCs to form bilirubin.

**Platelets** or **thrombocytes** are involved with hemostasis, the arresting of the escape of blood from a damaged blood vessel. When a blood vessel is damaged, platelets release serotonin to produce vasoconstriction, becoming sticky and adhering to capillary walls and to one another and forming a platelet plug to stop the initial bleeding. In a series of three stages, platelets release chemicals, or clotting factors, that catalyze the prothrombinase complex to convert prothrombin into thrombin to form a clot. **Thrombocytopenia** is a reduction in the number of platelets, whereas **thrombocytosis** is an increase in platelet production. For normal ranges of blood cells, see Table 34.1.

## RED BLOOD CELL DISORDERS

### Iron-Deficiency Anemia

#### Epidemiology

Iron-deficiency anemia (IDA) is considered the most prevalent nutritional deficiency in the world and is highest among non-Caucasian Americans of lower socioeconomic status, especially infants, children, and pregnant women. In the United States, it is highly prevalent among African American and Mexican American women, presumably because of the large numbers of this population with low incomes. It is greater in females than males, especially premenopausal women because of the monthly blood loss with menses. There is an approximate 10% increase of anemia in adults over the age of 65, and this increased incidence of IDA in this population is often a result of the aging process and the increased frequency of chronic diseases. This condition is often referred to as anemia of chronic disease when the specific etiology of the anemia cannot be definitively determined.

Inadequate iron in the diet is often a contributing factor to IDA. Globally, iron intake through food is well below the estimated daily requirement of 8 mg in men aged 19 to 50 years and 18 mg in women, increasing to 22 mg in pregnant females. During periods of blood loss or growth, iron intake may be inadequate to meet the increased demands

**Table 34.1 Review of Normal Ranges for Complete Blood Cell Counts (Adult)**

Blood Cell	Normal Ranges
<b>Red blood cells (mature, circulating)</b>	Male: 4.21–5.81 million/mm <sup>3</sup> Female: 3.61–5.11 million/mm <sup>3</sup>
<b>Hemoglobin</b>	Adult (15–64 yr) Male 14–17.3 g/dL Female 11.7–15.5 g/dL
<b>Hematocrit</b>	42–52% in males 36–48% in females
<b>Reticulocytes</b>	0.5%–2.5% of total RBC count
<b>White blood cells (total)</b>	4.5–11.1 10 <sup>3</sup> cells/mm <sup>3</sup> 4,500–11,000 cells/mm <sup>3</sup>
<b>Neutrophils</b>	59% Bands—3% Segs—56%
<b>Eosinophils</b>	2.7%
<b>Basophils</b>	0.5%
<b>Lymphocytes</b>	34%
<b>Monocytes</b>	4%
<b>Platelets</b>	150,000–450,000 mm <sup>3</sup>

One cubic millimeter (mm<sup>3</sup>) = 1 microliter (μl).

of the body, resulting in a higher incidence of IDA in infants, children, and pregnant women. In lower-socioeconomic areas where lead paint is still present in some buildings, lead poisoning, causing cognitive impairment and developmental abnormalities in children, becomes a concern. Iron-deficiency anemia can result in a condition known as **pica**, causing the iron-depleted individual to ingest nonnutritive substances such as paint, dirt, clay, ice, or laundry starch. Iron replacement resolves this compulsion to eat nonfood items. It is unknown why pica occurs mostly in children and pregnant females.

Iron-deficiency anemia often occurs as a result of hemorrhage and chronic blood loss, for example, heavy menstrual bleeding, certain types of cancer (esophageal, colon, stomach), and ulcerative gastrointestinal problems such as peptic ulcer disease. Poor absorption of iron may be due to celiac disease, Crohn's disease, and the chronic use of medications such as H<sub>2</sub> inhibitors, proton-pump inhibitors, antacids, aspirin, and NSAIDs. Gastrointestinal surgeries such as gastric bypass surgery and partial and total gastrectomy can lead to poor absorption of iron and IDA. In older adults with multiple comorbidities, anemia is frequently a cause for hospitalization and exacerbates many chronic conditions, such as congestive heart failure (CHF) and chronic kidney disease.

## Pathophysiology

Every living cell contains iron, and it is essential to the formation of the hemoglobin molecules on RBCs. With an iron deficiency, the body has insufficient hemoglobin to carry adequate oxygen to meet body requirements. Iron also plays a part in adenosine triphosphate production, necessary for glucose metabolism, and DNA synthesis, the basic gene component. The body is able to store iron in the liver as ferritin, and it is transferred to the rest of the body in times of increased demand via the protein transferrin, manufactured in the liver. Simply, IDA occurs when the body has exhausted its iron stores. The sequela of IDA is initiated with the release of cytokines as a response to the acute loss or inflammation that results in a diminished response from the kidneys for production of erythropoietin, increased resistance of the bone marrow to erythropoietin stimulation, and shorter RBC life span.

Greater iron demands occur primarily in periods of growth and development and secondary to pathologic causes. Except in the case of hemorrhage, IDA slowly progresses through several stages from a negative iron balance to iron depletion, deficient erythropoiesis, and finally IDA. Anemia is a late manifestation of iron deficiency.

## Clinical Manifestations

As the body's iron stores are depleted, the decreased hemoglobin levels lead to inadequate oxygenation of the body's tissues, or hypoxia. This oxygen deficiency manifests itself as fatigue and pallor, with the onset of tachycardia and tachypnea resulting from the heart and lungs attempting to compensate for the hypoxemia (oxygen deficiency of the blood). As hypoxia increases, the patient may become increasingly short of breath. Iron-deficiency anemia may also affect the rapidly regenerating cells of mucous membranes and the gastrointestinal tract, causing fissures in the corners of the mouth and/or **glossitis**, painful swelling of the tongue, which appears smooth and shiny because of the flattening of the lingual papillae (Fig. 34.1). Spoon-shaped fingernails, or **koilonychia**, are a result of severe, prolonged iron deficiency, which renders the cells of the fingernail soft and malleable. The pressure exerted by ordinary functions such as writing causes the nails to become deformed (Fig. 34.2). Koilonychia is currently an uncommon finding in industrialized countries.

**FIGURE 34.1** Glossitis in a patient with iron-deficiency anemia. Note the bright red color, the swelling, and the shiny appearance due to the flattening of the papillae on the tongue.

**FIGURE 34.2** Koilonychias in a patient with iron-deficiency anemia. Note the spoon shape and thinness of the nail.

## Management

### Diagnosis

The diagnosis of IDA is confirmed by specific blood tests. A complete blood count (CBC) demonstrates decreased hemoglobin and hematocrit levels. Low serum ferritin levels, which reflect the body's iron stores, are a confirmation of IDA. Serum ferritin levels less than or equal to 100 ug/L indicate IDA 100% of the time. Additional diagnostic studies to confirm IDA include serum iron, total iron-binding capacity (TIBC), serum transferrin receptors, and mean corpuscular volume (MCV).

### Medical Management

Adjusting the diet to increase iron intake is the easiest and best way to prevent IDA, especially long term. Good dietary sources of iron include meat (especially red meat), dark green leafy vegetables (spinach, broccoli, peas), beets, dried beans, iron-fortified breakfast cereals and breads, and Cream of Wheat (Table 34.2). Ingesting citrus fruits such as oranges or grapefruits increases the vitamin C intake and may improve iron absorption.

If diet alone cannot restore iron levels, then iron supplementation is needed, and this can be done through iron preparations administered orally, intramuscularly, or intravenously. Oral supplementation is the first line of therapy. During iron therapy, patients must be monitored for nausea, abdominal discomfort, constipation, and/or diarrhea. Iron supplementation by parenteral means is indicated only in cases of severe gastrointestinal distress secondary to oral administration, malabsorption disorders, or in acute cases of IDA in which levels need to be increased more rapidly. Parenteral supplementation may be given by intramuscular (IM) or IV routes. In the past, iron dextran was the only IV supplement; however, because it often causes cardiotoxic side effects, and patients need to be closely monitored while infusing, newer formulations of IV iron supplements are now available. These newer solutions do not have major cardiac risks, and although they are much safer to administer to the patient, vital signs still need to be monitored while the iron preparation is being infused.

**Table 34.2** Food Sources of Iron, Vitamin B<sub>12</sub>, and Folic Acid

Foods	Iron	Vitamin B <sub>12</sub>	Folic Acid
Dark green vegetables	X		X
Beets	X		
Dried beans, legumes	X		X
Fortified grains (breads, cereal)	X		X
Meat	X	X	
Seafood		X	
Eggs		X	
Dairy products		X	
Nuts			X
Bran			X
Yeast			X

### Safety Alert

Because parenteral iron formulas stain the skin, the Z-track method is used when administering iron intramuscularly. The Z-track prevents leakage of irritating and discoloring medications, such as iron dextran.

### Complications

The longer that IDA persists, the greater the clinical manifestations worsen, and this significantly impacts the function and quality of life of the patient. This disorder can adversely affect chronic health conditions such as CHF or chronic renal failure, as well as impair thermoregulation and increase immune dysfunction.

Psychomotor abnormalities and cognitive impairment occur in children with IDA, impairing learning and the ability of the child to function adequately. Iron-deficiency anemia during pregnancy increases the risk for low birth weight, preterm labor, and perinatal and postpartum mortality of the infant and/or mother.

Excessive iron overload may occur in patients but typically is not a result of excessive oral supplement intake. Pica and multiple long-term blood transfusions are usually the causes of iron overload. Clinical manifestations include fatigue, heart palpitations, joint pain, nausea, vomiting, constipation and/or diarrhea, damage to the heart and arteries, and an increased risk of cancer. The health-care provider monitors the folate and TIBC levels when any supplementation is needed.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of IDA are related to the decreased oxygenation of body tissues. The severity of clinical manifestations is proportional to the severity of iron-store depletion. Clinical manifestations include:

- Decreased hematocrit and hemoglobin levels
- Decreased serum ferritin levels
- Tachypnea
- Shortness of breath
- Tachycardia
- Pallor
- Fatigue
- Blood loss
- Changes in level of consciousness
- Cognitive impairment
- Glossitis
- Physical abnormalities such as spoon-shaped fingernails

### Nursing Diagnoses

- **Inadequate tissue perfusion** related to decreased oxygen delivery as a result of decreased iron stores
- **Fatigue** related to inadequate oxygenation to body tissues
- **Activity intolerance** related to impaired oxygen-carrying capacity secondary to IDA

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Tachycardia and tachypnea are secondary to the heart and lungs compensating for decreased oxygenation of body tissues caused by decreased iron levels, which leads to decreased hemoglobin levels.*
- Serum hemoglobin and ferritin levels  
*With an iron deficiency, reflected by low ferritin levels, there is insufficient hemoglobin to deliver oxygen to the body tissues. Decreased hemoglobin and serum ferritin levels indicate IDA.*
- Fatigue, pallor, and shortness of breath  
*Fatigue, pallor, and shortness of breath worsen with increasingly decreased levels of iron, resulting in inadequate oxygen-carrying capacity.*
- Level of consciousness  
*Alterations in level of consciousness occur as a result of decreased iron levels that cause decreased oxygenation to the brain. If prolonged IDA is present in a child's developing brain, cognitive impairment could be permanent.*
- Blood loss, if present  
*The greater the blood loss, the worse the clinical manifestations are as a result of decreasing iron stores and decreased hemoglobin levels leading to inadequate tissue perfusion.*

#### ■ Actions

- Increase dietary iron.  
*Increasing iron intake through dietary sources increases the body's iron stores and results in increased hemoglobin levels, thus increasing tissue perfusion.*

- Increase intake of vitamin C.  
*Increasing vitamin C intake may increase iron absorption.*
- Administer iron-supplement therapy.  
*Iron-supplement therapy is necessary if iron stores need to be increased quickly or if malabsorption disorders are present, which interfere with the body's ability to incorporate iron from dietary sources.*
- Minimize blood loss.  
*Any obvious hemorrhaging needs to be controlled immediately to minimize blood loss. Excessive bleeding with menstruation may be controlled by various hormonal medications.*

#### ■ Teaching

- Dietary sources of iron  
*Good dietary sources include meat (especially red), dark green leafy vegetables (spinach, broccoli, peas), beets, dried beans, iron-fortified breakfast cereals and breads, and Cream of Wheat. Many Web sites are available for nutritional information (see Table 34.2).*
- Immediately report any signs of bleeding, increasing fatigue, or shortness of breath.  
*Most cases of IDA occur over a prolonged period of time. Therefore, clinical manifestations usually present when iron stores have already been significantly decreased.*
- Daily iron supplements must be taken as prescribed.  
*Iron supplements replace the body's iron stores and increase the production of hemoglobin molecules, leading to improved tissue perfusion. Oral supplements can cause constipation, diarrhea, nausea, or abdominal discomfort. Patients need to be instructed to report these side effects to the healthcare provider. If side effects are too severe, then supplementation via parenteral routes is available.*
- Dangers of lead exposure  
*In lower-socioeconomic environments, lead paint is still present in many buildings. Exposure to lead can lead to cognitive impairment and developmental abnormalities in children.*
- Prenatal teaching about iron intake  
*Inadequate iron intake by pregnant women has been linked to lower birth weight, preterm labor, and increased mortality of mother and child.*

#### Evaluating Care Outcomes

Iron-deficiency anemia is a reversible condition that can be managed by increasing dietary iron intake and/or through parenteral supplementation. Elevating iron levels allows the increased production of hemoglobin, which improves the oxygenation of body tissues. As tissue perfusion improves, so do clinical manifestations of fatigue, pallor, and shortness of breath. Heart rate and respiratory rate return to normal as the heart and lungs no longer need to compensate for inadequate tissue perfusion. Normal levels of hemoglobin and serum ferritin confirm the resolution of the anemia. However, children with prolonged IDA may continue to deal with cognitive impairment and developmental abnormalities caused by insufficient oxygenation to the developing brain. These children have special needs that will need to be addressed by other resources.

### Connection Check 34.1

Which patient is at greatest risk for developing IDA?

- A. A 6-year-old African American boy with no health problems
- B. A 15-year-old African American pregnant female
- C. A 52-year-old Mexican American female with hypertension
- D. A 72-year-old Caucasian male with cardiac disease

## Vitamin B<sub>12</sub> Anemia

### Epidemiology

Vitamin B<sub>12</sub>, also called **cobalamin**, deficiency occurs either when the body has inadequate sources of vitamin B<sub>12</sub> or because of malabsorption disorders that make dietary vitamin B<sub>12</sub> unavailable for body use. Unlike IDA, however, the body does not store vitamin B<sub>12</sub>, so daily intake is essential. It is estimated that 15% to 25% of older adults have a vitamin B<sub>12</sub> deficiency that is primarily due to the gradual gastric atrophy and decrease in gastric acid production associated with aging and not necessarily as a result of decreased intake. The slow progression of the anemia and nervous system degeneration in vitamin B<sub>12</sub> deficiency correlates with a delay in the presentation of clinical manifestations, which may take years to develop.

In addition to older adults, other groups at higher risk for developing a vitamin B<sub>12</sub> deficiency are individuals with a history of disorders that affect the absorption of vitamin B<sub>12</sub>. This includes patients with gastrointestinal resections; autoimmune disorders, including AIDS; chronic alcohol use; Crohn's disease; celiac disease; and long-term use of medications that decrease gastric acid secretions, such as proton-pump inhibitors or H<sub>2</sub> blockers. Because vitamin B<sub>12</sub> is found only in animal proteins, low socioeconomic status and long-term vegetarianism and veganism increase the risk of insufficient vitamin B<sub>12</sub> intake.

### Pathophysiology

Vitamin B<sub>12</sub> is a coenzyme required for normal function of the central nervous system, formation of red blood cells, and synthesis and regulation of DNA. Cellular metabolism is dependent on vitamin B<sub>12</sub> because it is essential to the synthesis of fatty acids and energy production. Vitamin B<sub>12</sub> (also known as *extrinsic factor*) is introduced to the body through dietary sources of animal proteins, including meat, seafood, eggs, and dairy products (see Table 34.2). The parietal cells of the stomach lining secrete a protein-binding substance known as *intrinsic factor* that binds with vitamin B<sub>12</sub>, leading to absorption in the ileum of the small intestine.

**Pernicious anemia** is caused by the lack of intrinsic factor. Although pernicious anemia is often erroneously used as a synonym for vitamin B<sub>12</sub>-deficiency anemia, in actuality, pernicious anemia is an autoimmune disease that leads to a vitamin B<sub>12</sub> deficiency because of the inability to absorb vitamin B<sub>12</sub> without intrinsic factor. Vitamin B<sub>12</sub> is also

required for the conversion of methylmalonyl coenzyme A, part of the Krebs cycle. It is necessary for the synthesis of certain neurotransmitters and phospholipids needed for normal nervous system function.

Vitamin B<sub>12</sub> and folate are cofactors essential in DNA synthesis and the methylation cycles of RBCs, part of cellular metabolism. This highly complex process includes converting a folate chain to homocysteine (an amino acid by-product) to methionine, an essential amino acid needed in the methylation cycle. A vitamin B<sub>12</sub> deficiency traps the folate in the methylation cycle (the methylfolate-trap hypothesis) and leads to increased homocysteine levels that are linked to impaired immune system function, certain cancers (breast, cervical, lung), and a high risk for cardiovascular events such as cerebrovascular accident (CVA) and myocardial infarction (MI). Because of the codependence of vitamin B<sub>12</sub> and folate on RBC production, it is necessary to determine the specific deficiency that causes the anemia. Supplementation of synthetic folic acid escapes this methylfolate trap, masking the vitamin B<sub>12</sub> deficiency, and therefore resolves the anemia but has no effect on the neurological symptoms produced by the deficit of vitamin B<sub>12</sub>. Nitrous oxide administered to a patient with a vitamin B<sub>12</sub> deficiency interferes with the methylation cycle by destroying methylcobalamin, the form of vitamin B<sub>12</sub> in human plasma. This leads to impaired RBC production, and a profound postoperative anemia results and can be fatal if the vitamin B<sub>12</sub> deficiency is not discovered.

### Clinical Manifestations

A deficiency of vitamin B<sub>12</sub> can cause neurological and psychiatric dysfunctions. Demyelination of nerves can lead to spinal cord degeneration, peripheral neuropathy, and altered mental status and is linked to depression. Visual disturbances may occur as a result of nerve atrophy in the eyes. Because of the changes in RBC production related to decreased vitamin B<sub>12</sub>, the patient may exhibit clinical manifestations observed in other types of anemia, including tachycardia, tachypnea, shortness of breath, dizziness, and fatigue.

With vitamin B<sub>12</sub> deficiency, the longer the body goes with inadequate levels of vitamin B<sub>12</sub>, the more severe the neurological deficits become, possibly becoming irreversible. Neurological clinical manifestations include the development of peripheral neuropathy that may progress to spinal cord degeneration. Paresthesias, numbness and tingling in the hands and feet, are usually the first neurological clinical manifestation to occur with vitamin B<sub>12</sub> deficiency. **Lhermitte's sign** is an electric-shock sensation produced by neck flexion and is rarely observed but may be seen in patients with vitamin B<sub>12</sub> deficiency. Central nervous system involvement may also lead to confusion, depression, mood swings, impaired taste and/or stinging sensation on the tongue, and impaired sense of balance, particularly in the dark. Dementia resembling Alzheimer's disease can occur in severe cases of vitamin B<sub>12</sub> deficiency. Visual disturbances may include the inability to distinguish the colors yellow and

blue or blindness. Clinical manifestations may also include alternating constipation and diarrhea, anorexia, menstrual irregularities, weight loss, glossitis, low-grade fever, and tinnitus (ringing in the ears). A comparison of clinical manifestations for all RBC disorders is presented in Table 34.3.

## Management

### Diagnosis

Because of the slow progression of a vitamin B<sub>12</sub> deficiency and delayed clinical manifestations, the results of a CBC may be the first indication that a problem exists, and further investigation is needed to determine the cause. The diagnosis of vitamin B<sub>12</sub> deficiency is made based on a history and physical examination and a vitamin B<sub>12</sub> serum assay blood test. Serum vitamin B<sub>12</sub> is not low in all individuals with a deficiency because there are inborn errors of vitamin B<sub>12</sub> metabolism that may cause serum levels to be normal, but low cellular levels may have already resulted in damage. Therefore, the vitamin B<sub>12</sub> serum assay test has its limitations and has a wide normal range (200 to 1,000 pg/mL). Patients with liver disease, lymphoma, and myeloproliferative disorders may have false-negative results. A more sensitive test for vitamin B<sub>12</sub> deficiency is to measure the level of methylmalonic acid (MMA), part of the methionine conversion, in the patient's urine or blood. An excess of MMA indicates a lack of vitamin B<sub>12</sub> in the tissues. Because patients with renal failure, dehydration, or hypovolemia can have falsely elevated serum MMA levels, a urinary MMA test is needed for accurate diagnosis in individuals with these disorders. Other relevant blood tests that may assist in determining vitamin B<sub>12</sub> deficiency include gastrin levels, intrinsic factor levels, and in rare instances, the **Schilling's test**, a radionuclide 24-hour urine test that indirectly measures intrinsic factor.

### Medical Management

Prevention of vitamin B<sub>12</sub> deficiency is important, and animal proteins provide the only source of vitamin B<sub>12</sub> in the world. Vitamin B<sub>12</sub> has not been discovered in any plants. Dietary sources of vitamin B<sub>12</sub> include meat, seafood, eggs, and dairy products. Long-term vegans/vegetarians or those of low socioeconomic status are at increased risk of deficiency and may need to take a daily supplement of vitamin B<sub>12</sub>. Oral supplementation of vitamin B<sub>12</sub> may not be sufficient once the deficiency is profound and the patient has developed clinical manifestations such as fatigue, weakness, and paresthesias. Once severe deficiency is determined, weekly vitamin B<sub>12</sub> injections are required.

### Complications

Vitamin B<sub>12</sub> deficiency impairs DNA synthesis and the body's ability to produce RBCs. As with any anemic condition, the longer the deficiency lasts, the more pronounced are the clinical manifestations of fatigue, pallor, dizziness, shortness of breath, and impacts on the functional ability of the individual and quality of life. Orthostatic hypotension, especially on standing, may be present.

**Table 34.3 Clinical Manifestations of Red Blood Cell Disorders**

Red Blood Cell Disorder	Identifying Clinical Manifestations

**Table 34.3 Clinical Manifestations of Red Blood Cell Disorders—cont'd**

Red Blood Cell Disorder	Identifying Clinical Manifestations
<b>Aplastic anemia</b>	Delayed wound healing
	Hand-foot syndrome
	Jaundice
	Fatigue
	Pallor
	Tachycardia
	Tachypnea
	Shortness of breath
	Dizziness
	Headache
Frequent infections	
Bruising	
Nosebleeds	
Gum bleeding	
<b>G6PD Deficiency</b>	Fatigue
	Pallor
	Tachycardia
	Tachypnea
	Shortness of breath
	Jaundice
	Dark urine
Splenomegaly	
<b>Polycythemia</b>	Fatigue
	Shortness of breath
	Dizziness
	Headache
	Pruritis
	Facial flushing
	Splenomegaly
	Pruritis
	Vision problems
	Weight loss
	Nosebleeds
	Bleeding gums
	Hypertension
	Thromboembolism

Pregnancy, hyperthyroidism, advanced stages of cancer, and intestinal tapeworms may increase vitamin B<sub>12</sub> needs despite a normally adequate intake of vitamin B<sub>12</sub> because of the increased demands of the body as cellular metabolism increases. Supplementation is usually helpful in these cases. Radiation for certain cancers may cause inflammation of the intestines that interferes with vitamin B<sub>12</sub> absorption.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of vitamin B<sub>12</sub> anemia are related to decreased production of RBCs due to impairment of DNA synthesis that leads to overall decreased hemoglobin and hematocrit levels. Patients are assessed for the following clinical presentation:

- Shortness of breath
- Tachypnea
- Tachycardia
- Pallor
- Fatigue
- Dizziness

Neurological clinical manifestations of vitamin B<sub>12</sub> deficiency are related to the impairment of DNA synthesis necessary for the formation and maintenance of myelin, neurotransmitters, and phospholipids (the principal component of the cell membrane).

- Numbness, tingling, or burning in hands or feet
- Altered mental status (confusion, dementia)
- Depression
- Mood swings
- Coordination and balance
- Impaired taste, stinging sensation on the tongue (can cause glossitis)
- Visual disturbances

#### Nursing Diagnoses

- **Inadequate tissue perfusion** related to decreased oxygenation as a result of decreased hemoglobin and hematocrit
- **Activity intolerance** related to impaired oxygen-carrying capacity secondary to vitamin B<sub>12</sub> deficiency
- **Chronic pain** related to inadequate vitamin B<sub>12</sub> levels as evidenced by peripheral neuropathy

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Vitamin B<sub>12</sub> deficiency impairs RBC production, with a resulting decrease in tissue perfusion. Tachycardia and tachypnea occur as the heart attempts to compensate for the decrease in tissue perfusion.*
- Fatigue, pallor, and shortness of breath  
*Fatigue, pallor, and shortness of breath worsen with increasingly decreased levels of RBCs, causing inadequate tissue perfusion.*

- Numbness, tingling, or burning of the hands or feet; confusion; mood swings  
*Neurological clinical manifestations occur because of the impairment of DNA synthesis of myelin sheath and neurotransmitters.*
- Decreased hemoglobin/hematocrit levels, decreased vitamin B<sub>12</sub> levels, elevated serum and urine MMA levels  
*A CBC shows decreased hemoglobin and hematocrit levels. The serum vitamin B<sub>12</sub> assay is decreased due to the lack of vitamin B<sub>12</sub> needed for synthesis.*
- Fall risk (safety)  
*Confusion, dementia, coordination and balance impairment, and visual disturbances make these patients at risk for falls. Paresthesia and tingling (peripheral neuropathy) can affect ambulation, gait, and stability. Severe neuropathy may take time to recover.*
- Intake and output  
*Constipation, diarrhea, and/or anorexia affect the absorption of vitamin B<sub>12</sub> and may worsen the problem.*

### Actions

- Ensure adequate vitamin B<sub>12</sub> intake.  
*Ensuring that the patient has an adequate intake of vitamin B<sub>12</sub> prevents clinical manifestations of anemia and degenerative neurological changes (see Table 34.3).*
- Administer vitamin B<sub>12</sub> therapy.  
*Oral supplementation in mild cases of vitamin B<sub>12</sub> deficiency may be helpful. In more severe cases, supplementation with parenteral therapy is required. Parenteral supplementation may be necessary for patients who lack intrinsic factor and cannot absorb oral supplementation. Vegetarians can prevent or treat this deficiency with oral supplements, vitamins, or fortified soy milk. When the deficiency is due to pernicious anemia or the absence of intrinsic factor, the replacement of vitamin B<sub>12</sub> involves 1-mg IM injections of cyanocobalamin vitamin B<sub>12</sub>.*
- Monitor use of folic acid.  
*Before starting a patient on folic acid, confirm that the patient does not have a vitamin B<sub>12</sub> deficiency. Folic acid resolves the anemia by escaping the methylfolate trap, but neurological degeneration due to vitamin B<sub>12</sub> deficiency continues.*
- Monitor use of nitrous oxide.  
*Nitrous oxide inactivates vitamin B<sub>12</sub> in the body. Prior to using for anesthesia, confirm that the patient is not vitamin B<sub>12</sub> deficient.*
- Assess pain and activity levels due to peripheral neuropathy.  
*Peripheral neuropathy may develop because of vitamin B<sub>12</sub> deficiency. Increasing pain may interfere with functional abilities. Because position sense, coordination, and balance are affected, physical therapy and occupational therapy should be considered along with the use of assistive devices.*

### Teaching

- Dietary sources of vitamin B<sub>12</sub>  
*Dietary sources of vitamin B<sub>12</sub> include meat, seafood, eggs, and dairy products.*

- Need for vitamin B<sub>12</sub> supplementation  
*Because of the lack of vitamin B<sub>12</sub> in plants, vegans/vegetarians may need daily oral supplementation. Patients may have a sore tongue and need bland, soft food frequently, along with mouth care.*
- Immediately report any clinical manifestations of fatigue, shortness of breath, paresthesias, and confusion.  
*Clinical manifestations usually present after prolonged vitamin B<sub>12</sub> deficiency. Resolution of the anemia does not stop neurological degeneration unless the deficiency is resolved.*
- Prenatal teaching  
*Pregnancy may increase the demand for vitamin B<sub>12</sub>. Prophylactic oral supplementation is recommended.*
- Radiation for advanced cancers  
*Radiation therapy may increase the need for vitamin B<sub>12</sub> supplementation. Patients with anemia do not respond as well to radiotherapy because of impairment of oxygen transport to cancer cells.*
- Actions of acid-reducing medications  
*Patients using these medications may develop vitamin B<sub>12</sub> deficiency because of a decrease in the function of the parietal cells of the stomach, which produce intrinsic factor.*

### Evaluating Care Outcomes

Vitamin B<sub>12</sub>-deficiency anemia is reversible. Increasing vitamin B<sub>12</sub> intake through diet and/or parenteral supplementation resolves the deficit and allows the increased production of RBCs and improves oxygenation of the body's tissues. As tissue perfusion improves, clinical manifestations of fatigue, pallor, and shortness of breath decrease. Heart rate and respiratory rate return to normal because the heart and lungs no longer need to compensate for inadequate tissue perfusion. Normal levels of hemoglobin, hematocrit, and serum vitamin B<sub>12</sub>, as well as decreased MMA levels, confirm the resolution of the anemia. However, if the vitamin B<sub>12</sub> deficiency becomes severe and is not treated promptly, degenerative neurological changes may be permanent.

### Connection Check 34.2

When a patient with vitamin B<sub>12</sub> deficiency is counseled about diet, what statement by the patient indicates an understanding of the cause of the anemia?

- “I know I need to eat more fruits and vegetables.”
- “I have cut out all fried foods in my diet.”
- “I have been eating more organic foods.”
- “I have been having beef or fish at least once a day.”

### Folic Acid Deficiency

#### Epidemiology

Folic acid is a water-soluble vitamin (B<sub>9</sub>). Folate is the form that is naturally found in foods, whereas folic acid is the synthetic supplementation form, and they are frequently used interchangeably. Folic acid, along with vitamin B<sub>12</sub>, is

necessary for a complex pathway that aids in DNA synthesis and the formation of heme, the iron-containing portion of the hemoglobin molecule. Folic acid deficiency is usually a result of inadequate dietary intake and frequently affects older adults, those with chronic illness, individuals who abuse alcohol, and individuals who go on extreme diets lacking folate. Deficits in folic acid also develop secondary to malnutrition, specific malignancies, Crohn's disease, celiac disease, and malabsorption due to gastrointestinal surgeries or medications. Patients with rheumatoid arthritis who are treated with methotrexate may develop folic acid deficiency secondary to the antagonistic effects of this medication on folic acid; this complication may be managed with folic acid supplementation. Dietary sources of folate include green leafy vegetables, bran, yeast, legumes, and nuts (see Table 34.2). Patients on hemodialysis are at higher risk for developing a folic acid deficiency because it increases folate excretion.

Folic acid deficiency during pregnancy is also linked to fetal neural tube defects and some congenital orofacial abnormalities. The precise mechanism is not completely understood; however, current evidence suggests that folic acid supplementation in pregnancy prevents these defects. It is hypothesized that folate deficiency impairs DNA synthesis during the crucial phase of neurological development of closure of neural tubes. It is recommended that pregnant women take folic acid supplementation of at least 400 mcg daily because this has led to decreased incidence and severity of spina bifida, cleft palate and lip, and other neural tube defects.

In the United States, fortification of cereals and certain grains, such as wheat flour, with folic acid has decreased the incidence of true folic acid deficiency (see Table 34.2). Except in circumstances where there are increased body requirements, such as during pregnancy, in childhood, and in individuals with excessive alcohol use, additional supplementation other than dietary sources is usually not required.

### Pathophysiology

Folate, along with vitamin B<sub>12</sub>, forms a complex pathway that is involved in DNA synthesis and is essential for cell maturation and replication. This is especially important in embryonic neural tube development, in the formation of heme for RBC maturation, and in the synthesis of certain neurotransmitters for brain development and maintenance. Decreases in folate levels delay erythrocyte maturation, thus lowering hemoglobin levels and causing anemia. Folate deficiency is thought to inhibit DNA synthesis to such an extent that during neural tube development, incomplete closure occurs in utero, with resulting congenital anomalies such as spina bifida, anencephaly, and cleft palate and lip. Incomplete synthesis of certain neurotransmitters, particularly in the first few months of life, may cause developmental delays in head growth, spasticity, and speech difficulties and lead to epilepsy. These disorders are a result of decreased transport of folate across the blood-brain barrier.

Folate enters the body through dietary sources or as folic acid supplementation and is absorbed in the jejunum portion of the small intestine. It is not unusual for deficits to occur in the presence of any problem affecting the jejunum, such as in gastric bypass surgery or the Whipple procedure (pancreatic duodenectomy), which is a surgical procedure for specific gastrointestinal cancers. The Whipple procedure involves the removal of the distal segment of the stomach, portions of the duodenum, the head of the pancreas, and the gallbladder and resects the remaining portions, allowing gastric and pancreatic enzymes, as well as bile, to flow into the jejunum for digestion. Specific medications such as oral contraceptives, metformin for type 2 diabetes mellitus, and chemotherapeutic agents (fluorouracil) may interfere with folic acid absorption. Folic acid supplementation may increase the hepatic metabolism of the anticonvulsant phenytoin (Dilantin), which may increase the incidence of seizure activity. It is advisable to correct the folic acid deficiency before initiating the medication because adding the supplement after the patient is on phenytoin may increase the likelihood of seizures.

Chronic alcohol use contributes to folic acid deficiency secondary to malnutrition that is frequently present in these patients. Alcohol also interferes with the absorption of folate. The RBCs in a patient with a history of alcohol abuse demonstrate an abnormal morphology and half the normal life span of 120 days. Alcohol can also damage or kill bone marrow and progenitor (stem) cells, which may lead to **pancytopenia**, an overall decreased proliferation of RBCs, WBCs, and platelets.

### Clinical Manifestations

Because of the effects on RBC development, patients with folic acid deficiency present with clinical manifestations consistent with other types of anemia, including pallor, tachycardia, tachypnea, dizziness, and fatigue. Additionally, because of the pancytopenia associated with folic acid deficiency, there are decreased numbers of platelets, increasing the risk of bleeding. It is essential to differentiate between a folate deficiency and a vitamin B<sub>12</sub> deficiency. The clinical manifestations of folic acid and vitamin B<sub>12</sub> deficiency are similar because they often coexist. The neurological manifestations of vitamin B<sub>12</sub> deficiency do not occur with folic acid deficiency but will persist if vitamin B<sub>12</sub> is not replaced. The neurological symptoms in severe vitamin B<sub>12</sub> deficiency involving pernicious anemia include psychiatric symptoms and peripheral neuropathy. If sensation is altered, it can affect gait and stability. Patients should avoid excessive heat or cold. Patients with vitamin B<sub>12</sub> and/or folic acid deficiencies may have fatigue, mood changes, memory difficulties, and weakness. Vitiligo, premature graying of the hair, and glossitis are often seen in patients who have pernicious anemia. Because the folate/vitamin B<sub>12</sub> codependency affects RBC maturation, folic acid replacement may reverse the anemia, but the neurological degeneration that occurs in vitamin B<sub>12</sub> deficiencies continues and may become irreversible.

## Management

### Diagnosis

A CBC confirms the diagnosis of anemia with decreased hemoglobin levels; however, the specific etiology of the anemia must be identified. Serum folate levels may or may not be decreased. Because folate is absorbed in the proximal segment of the small intestine and is quickly available for cell metabolism, serum folate levels should be a fasting blood test; otherwise, the level may be falsely elevated. A more reliable indicator is the RBC folate level. Folate that enters the RBC remains there for the life span of that cell. Thus, an RBC folate level reflects the serum folate level over the past 3 months. However, because 50% of patients with a vitamin B<sub>12</sub> deficiency also have low RBC folate levels, this is not a definitive test.

Serum MMA and homocysteine levels are the best laboratory tests used to differentiate between anemia caused by a folic acid deficiency and those secondary to a vitamin B<sub>12</sub> deficiency. Vitamin B<sub>12</sub> and folate are cofactors in the methylation cycle converting methylmalonyl coenzyme A to homocysteine to methionine as part of the Krebs cycle. In a vitamin B<sub>12</sub> deficiency, the serum MMA level is more sensitive and is elevated, whereas the homocysteine level remains normal. A folic acid deficiency causes the reverse: The homocysteine level is elevated, whereas serum MMA levels remain normal. Some conditions, such as renal insufficiency, may affect these results, so it is always important to consider the complete clinical presentation and not rely on one test to make a differential diagnosis.

### Medical Management

Fortification of cereals and grains with folic acid helps to reduce the incidence of this specific deficiency. In certain patient populations, however, oral supplementation is recommended. Folic acid supplementation is recommended in pregnant women, children in the first year of life, patients with a history of gastrointestinal resections, and individuals with a history of chronic alcohol use. It is recommended that pregnant women consume at least 400 mcg (normal recommendation for adult women) of folic acid daily in order to reduce the occurrence and severity of neural tube defects and some orofacial abnormalities in infants. For patients on certain medications that can interfere with folate absorption, such as oral contraceptives, metformin, and certain chemotherapeutic agents, oral or parental supplementation may be recommended. Short- or long-term supplementation depends on the length of treatment with the medication.

### Complications

Folic acid deficiencies interfere with the formation of heme, the oxygen-carrying portion of the hemoglobin molecule. Anemia left unresolved ultimately affects individual function. Folic acid deficiency may also cause neurological clinical manifestations such as confusion or disorientation. However, unlike a vitamin B<sub>12</sub> deficiency, these clinical manifestations are reversible and resolve with the resolution of the deficiency.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of anemia are related to incomplete DNA synthesis that affects the formation of heme and the maturation of the RBC, which causes a decreased hemoglobin level.

- Shortness of breath
- Tachypnea
- Tachycardia
- Fatigue
- Pallor
- Dizziness
- Confusion, disorientation
- Decreased hemoglobin
- Elevated homocysteine level with normal serum MMA levels

### Nursing Diagnoses

- **Inadequate tissue perfusion** related to decreased oxygenation as a result of decreased hemoglobin and hematocrit
- **Activity intolerance** related to impaired oxygen-carrying capacity secondary to folate deficiency
- **Risk for delayed development** related to incomplete neural tube closure secondary to folate deficiency

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Tachycardia and tachypnea are secondary to the heart and lungs compensating for decreased oxygenation of body tissues caused by the reduced production of heme and RBC maturation demonstrated by decreased hemoglobin levels.*
- Fatigue, pallor, and shortness of breath  
*Fatigue, pallor, and shortness of breath worsen with increasingly decreased levels of hemoglobin causing inadequate tissue perfusion.*
- Confusion, disorientation  
*Neurological clinical manifestations are caused by decreased oxygenation to the central nervous system.*
- Hemoglobin levels, serum folate levels, RBC folate levels, and increased serum homocysteine levels  
*Folic acid deficiency causes incomplete DNA synthesis that is necessary for the formation of heme, RBC maturation, and folate levels in the serum and RBCs and influences the metabolic pathway, which results in increased homocysteine levels.*

#### ■ Actions

- Ensure adequate folate/folic acid intake.  
*Ensuring adequate intake of dietary sources of folate and folic acid through food fortification prevents anemia and neural tube defects (see Table 34.2).*
- Administer folic acid supplements.  
*Folic acid is the synthetic form for supplementation. Supplementation is needed when the body has increased folate demands, such as in pregnancy, early childhood, or alcoholism.*

It is also needed when malabsorption of folate occurs because of disorders such as Crohn's disease, gastrointestinal resections, and the use of medications that interfere with folate absorption.

- Differentiate anemia caused by folic acid deficiency versus vitamin B<sub>12</sub> deficiency.

Supplementation of folic acid may reverse the anemia caused by vitamin B<sub>12</sub> but will not stop the neurological degenerations that occur with vitamin B<sub>12</sub> deficits. These neurological changes may become irreversible if misdiagnosed.

### Teaching

- Dietary sources of folate/folic acid

Good sources include fortified cereals and grains, legumes, green leafy vegetables, bran, yeast extracts, and nuts (see Table 34.2).

- Immediately report any clinical manifestations of fatigue, shortness of breath, dizziness, and confusion. Resolution of the anemia through supplementation or blood transfusions is needed to increase tissue perfusion.

- Prenatal teaching

Because of the strong link between folic acid deficiency and the occurrence of neural tube defects and orofacial abnormalities during embryonic development, it is essential to teach all women of childbearing years the importance of obtaining at least 400 mcg of folic acid daily during the preconception stage and during pregnancy.

- Need for supplementation

Individuals who have had gastrointestinal resections, such as gastric bypass surgery or a Whipple procedure, need education regarding folic acid supplementation. Individuals on certain anticonvulsants (e.g., phenytoin), oral contraceptives, metformin, and chemotherapeutic agents (fluorouracil, methotrexate) need to be educated about the importance of folic acid supplementation because ordered medications may interfere with the absorption of folate.

### Evaluating Care Outcomes

Resolution of the anemia is the most obvious clinical manifestation that the folic acid deficiency has resolved because the DNA synthesis pathway now has sufficient folate to complete the process. The hemoglobin level and serum folate level increase, and clinical manifestations such as fatigue or shortness of breath resolve. If neurological clinical manifestations continue after the hemoglobin returns to normal, assessment for possible vitamin B<sub>12</sub> deficiency is indicated. Folic acid supplementation during pregnancy usually results in an infant born without neural tube defects or orofacial abnormalities.

### Connection Check 34.3

The nurse understands that it is essential for the patient to have which blood test before initiating folic acid supplementation?

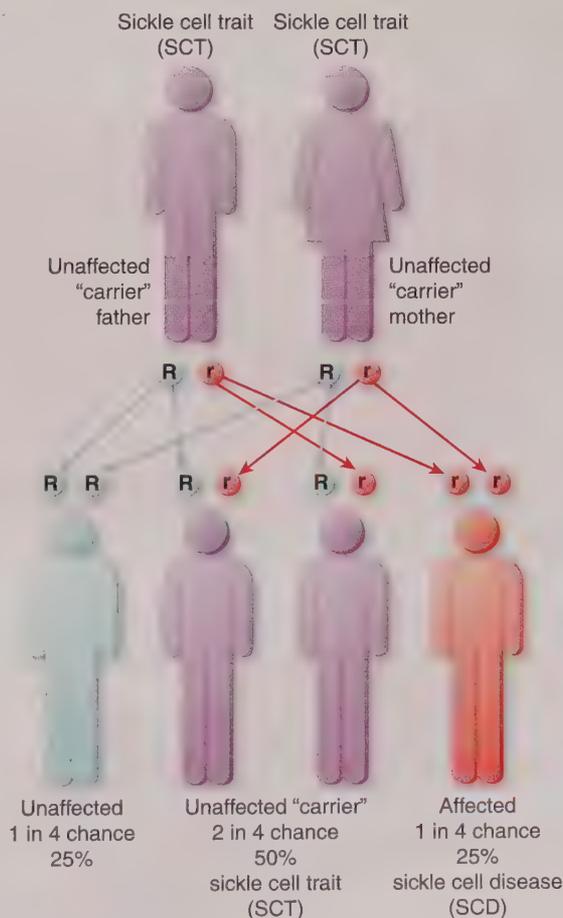

- Vitamin B<sub>12</sub> level
- Pregnancy test
- CBC
- Liver enzymes

## Sickle Cell Anemia

### Epidemiology

Sickle cell anemia is the most severe form of the inherited blood disorder sickle cell disease (SCD). The sickle cell trait (SCT) is a genetic mutation that must be present in both parents in order for this form of the disease to manifest in offspring. Parents who carry this gene have a one in four chance of producing a child with sickle cell anemia. Individuals who inherit the SCT from one parent and a normal copy of the gene from the other parent are sickle cell carriers and are said to have only SCT (Fig. 34.3).

Sickle cell disease affects millions of people throughout the world, predominantly descendants from tropical Africa. The rate of inheriting this genetic disorder may be as low as 20% in this population and as high as 40% in some areas. To a lesser extent, this disease affects many descendants of the Middle East and Mediterranean areas (Saudi Arabia, Turkey, Greece, and Italy), certain tribes of India, and Spanish-speaking regions of the Western Hemisphere (South and Central America, Cuba). Caucasians occasionally

**FIGURE 34.3** Diagram of how sickle cell disease is passed from parent to child.

R, dominant gene; r, recessive gene.

Blue, not a carrier; purple, carrier, but unaffected; red, affected.

Note that there is a 25% chance that one of their children will have sickle cell disease.

develop SCD when ancestry may have African descendants. It is estimated that as many as 2 million people in the United States are carriers of the SCT, whereas approximately 72,000 actually have SCD. Statistics show that 50% of children with SCD live to adulthood. Death prior to the age of 20 is usually the result of a sudden, severe crisis rather than the long-term deterioration caused by multiple episodes of thrombosis and infarction causing organ damage. In regions of the world where malaria is endemic, individuals with SCD seem to have some innate protection against this disease. When diagnosed in people with SCD, malaria appears to have a shorter course and be less intense than in those without SCD.

### Pathophysiology

Sickle cell disease is a genetic disorder of hemoglobin. A normal RBC is extremely malleable in order to be able to squeeze through minute capillaries to deliver oxygen. In SCD, the RBC goes through a morphological change when it is exposed to decreased oxygen tension. These RBCs become elongated and stiff and lose flexibility. On microscopic examination, these cells are sickle-shaped, thus the name of the disease (Fig. 34.4). Sickle-shaped RBCs carry less oxygen and are fragile. Because of the decreased flexibility and fragility, RBCs break apart (hemolysis) as they

pass through the capillary beds. The result is congestion and clumping in the capillary beds and the formation of thrombi (Fig. 34.5). Although the normal life span of an RBC is 120 days, in an individual with SCD, the normal life span is 15 to 20 days.

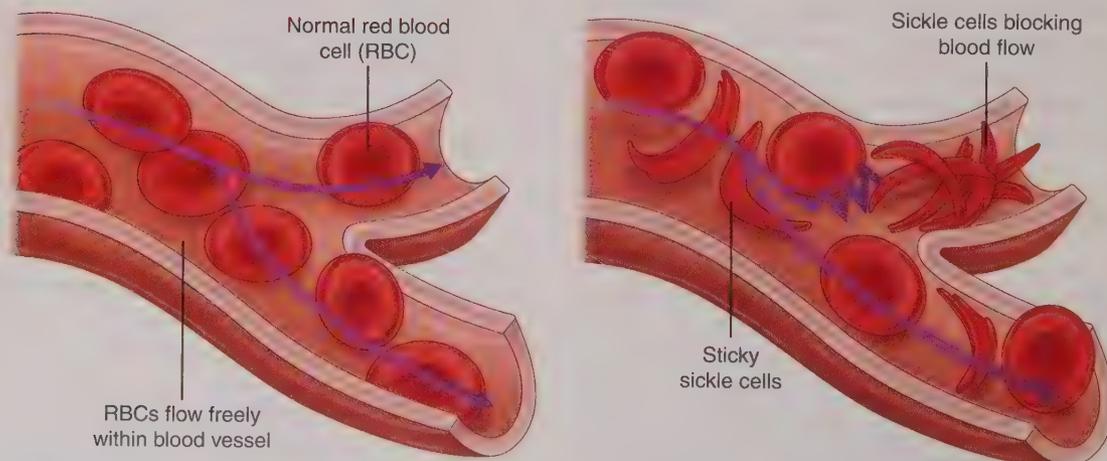

The hemolysis of the RBCs causes a decrease in the hemoglobin level and thus anemia. Destruction of RBCs also releases bilirubin, causing a rise in the serum bilirubin level. Additionally, possible congestion in the spleen due to the increased RBC fragments that must be phagocytized leads to an enlarged spleen and possible pain.

When the sickling process is rapid and severe, the patient has a sickle cell crisis. There are four types of crises: (1) vaso-occlusive, or painful, crisis (most common type) caused by the obstruction of vessels by hemolyzed cells, leading to tissue hypoxia and pain; (2) aplastic crisis in which the bone marrow ceases to produce RBCs, with a subsequent decrease in the blood reticulocyte count; (3) sequestration crisis caused by a sudden, massive pooling of RBCs in the spleen, with resulting hypovolemic shock and cardiovascular failure; and (4) hemolytic crisis, which results from an increased rate of RBC hemolysis with resultant decreased hemoglobin levels and increased jaundice.

Sickle cell crises are most often precipitated by anything that causes hypoxemia, increasing vasoconstriction and

**FIGURE 34.4** Peripheral blood smear showing sickled red blood cells. Note the difference between the sickled cells and the normal red blood cells.

**FIGURE 34.5** Sickled cells moving through a capillary and forming a thrombus.

sickling of the RBCs. Precipitating factors include dehydration, cold temperatures, infection, and environments with low oxygen tension, such as depressurized airplane cabins and high mountains. Crises may appear without any apparent reason and usually last several days to a week. They may occur frequently for a period of time and then be dormant.

### Clinical Manifestations

The presentation of sickle cell crises is most frequently associated with clinical manifestations related to the anemia, such as fatigue, pallor, and shortness of breath, and the vaso-occlusion of blood vessels resulting in pain and swelling. Any tissue may experience vaso-occlusion and tissue ischemia; however, pain usually occurs in the joints, bones, chest, and abdomen. Ischemic organ damage secondary to the vaso-occlusion causes cerebrovascular, pulmonary, and splenic infarctions; priapism in males (prolonged, painful erection); and kidney and liver damage. Fever may be present even in the absence of infection. Wound healing, especially in the extremities, is often delayed because of impaired circulation and venous stasis. Patients with SCD have an increased risk of developing infections, particularly respiratory infections caused by pneumococcus, pertussis, and *Haemophilus influenzae*.

Clinical manifestations usually do not present until after 6 months of age because the infant is protected by an increased level of fetal hemoglobin in the first few months of life. Long-term organ ischemia can lead to growth and developmental delays. The child with SCD may be smaller than peers. Puberty, with its secondary sexual characteristics, may be delayed, including late menstruation in females. Repeated episodes of crises and infarctions of the bones can lead to uneven development of the fingers and toes, known as hand-foot syndrome, which is characterized as swelling of the dorsal surfaces of the hands and feet, causing pain. Pregnancy, with its increased demand on the body, can be a cause for the exacerbation of SCD. Death is usually the result of CVA, infection, or long-term organ system damage.

### Management

#### Medical Management

There is no cure for SCD, and treatment is aimed at the prevention of crises and symptom management when crises occur. Long-term management is aimed at minimizing complications and organ dysfunction. Providing education to the patient and family is imperative, as is the need for an effective family support system.

During a crisis, oxygen therapy is implemented to reverse the hypoxia caused by decreased hemoglobin and vaso-occlusion of vessels. Aggressive hydration with oral and parenteral fluids increases blood volume and reduces renal vaso-occlusion caused by increased hemolysis of RBCs. Analgesia, usually from opiates, is administered for severe pain (see Evidence-Based Practice). Alternative and complementary treatments for pain management can also be taught and employed by the patient to minimize the use of strong analgesics. Antibiotics for infection are also initiated.

Several promising new treatments for SCD include the use of hydroxyurea, complete blood transfusions, and peripheral stem cell transplantation. Hydroxyurea, a chemotherapeutic agent, increases fetal hemoglobin production and is being used selectively. Hydroxyurea results in fewer episodes of crises and a reduction in acute chest syndrome in patients with frequent and severe sickle cell crises; however, it causes **myelosuppression** (the decreased ability of the bone marrow to produce any type of blood cell) and severe toxic effects. It is also potentially teratogenic (altering fetal development), so patients on hydroxyurea need extensive contraceptive counseling.

### Evidence-Based Practice

#### Acute Pain Management in Adults With Sickle Cell Disease

Sickle cell crises involve vaso-occlusive episodes (VOEs) that cause acute pain in patients with this disorder. Because pain management is such a priority in this situation, this quality improvement study was designed to try to determine why these patients often did not receive rapid pain management. Using a prospective pre-/post-evaluation design, patients 18 years old or older who presented with VOEs in an urgent care center after implementation of an evidence-based standard of care (EBPSC) were involved in this study. The results demonstrated a decrease in the mean time for administration of the first pain medication, as well as significantly increased satisfaction. The findings of this study demonstrate the importance of using an evidence-based approach to creating a positive patient experience.

Kim, S., Brathwaite, R. & Ook, K. (2017). Evidence-based practice standard care for acute pain management in adults with sickle cell disease in an urgent care center. *Quality Management in Health Care*, 26(2), 108-115.

An exchange blood transfusion, in which the entire blood volume is exchanged, is also a treatment performed on many patients with SCD. The goal of this treatment is maintaining the sickled hemoglobin to no more than 50% of the total hemoglobin in order to prevent or delay thrombotic episodes, including CVA. Although replacing sickled, diseased cells with healthy ones can prevent clinical manifestations for a short period of time, the patient's bone marrow will continue to produce RBCs that sickle when deoxygenated. Therefore, exchange blood transfusions are not a singular treatment. Patients receiving repeated exchange transfusions have an increased risk of blood transfusion reactions and iron overload. Iron is stored in the liver, and the majority of iron received from a blood transfusion goes into storage. High levels of iron in the liver

result in fibrosis and cirrhosis, leading to hepatomegaly and, ultimately, liver failure. Iron-chelating agents such as desferrioxamine may need to be simultaneously administered parenterally with transfusions to bind to the iron and decrease the morbidity of iron overload.

Peripheral stem cell transplantation is being attempted with a human leukocyte antigen (HLA)-matched sibling (one without the sickle cell trait) as the preferred donor, otherwise the best-matched donor available. Transplantation, which at this time provides the only chance of a cure, continues to have a high mortality rate, and the incidence of graft-versus-host disease (GVHD) increases morbidity. **Graft-versus-host disease** occurs when donor bone marrow or stem cells attack the recipient's tissues and occurs if the T cells in the graft (e.g., bone marrow or blood) are mature and can destroy the tissues in the graft recipient. If the recipient's immune system is normal, the grafted T cells are controlled, and no tissue destruction occurs. However, if the immune system is deficient, the grafted T cells remain unchecked and can attack the recipient's tissues, leading to death in some cases. Complications vary in severity but may be severe enough to eventually cause multisystem organ dysfunction and death. Although these treatments have been beneficial in many instances, long-term data are not available on efficacy. Currently, preventive measures such as prophylactic use of penicillin to prevent pneumococcal infection, vaccinations, and maintaining adequate hydration are first-line measures to decrease the incidence of crises.

Emotional support for the patient and his or her family is essential in order for the patient to be able to cope with SCD. Education for the entire family is needed, and genetic testing and counseling may be necessary. Healthcare personnel must be able to recognize if the patient, parents, and/or any other family members need any therapeutic counseling. Patients and family members need to be completely aware of the risk factors that may lead to a sickle cell crisis so that they can try to minimize these risks as much as possible. During a crisis, the patient needs support to decrease the anxiety brought on by the pain and shortness of breath. Patients with sickle cell disease are living longer today, and those who do usually have the strongest support systems.

### Complications

Complications of SCD are related to the intermittent episodes of hypoxemia, thrombus formation, and tissue hypoxia resulting in infarction and necrosis. These include acute chest syndrome, CVAs, infection, developmental delays and disabilities, and complications in pregnancy.

Pulmonary infarctions, or acute chest syndrome, are experienced by patients with SCD, and multiple episodes are common because of the recurrent nature of thrombosis and infarction experienced. Clinical manifestations include fever, chest pain, tachycardia, tachypnea, hypoxia, sputum production, increased WBCs, and a pulmonary infiltrate on x-ray that indicates an atypical pneumonia. These infection-related clinical manifestations make acute chest syndrome

different from patients who experience pulmonary infarction due to coronary artery disease. In adults, chest pain may be from infection, pulmonary infarction, or pulmonary fat embolism and has a higher mortality rate. Early diagnosis, rapid assessment, and intervention are related to improved morbidity and mortality.

Cerebrovascular accidents are one of the most serious complications of SCD and historically were thought to be secondary to the vaso-occlusion of small cerebral vessels with resulting tissue ischemia and necrosis. More recent studies indicate that CVAs may also be due to lesions on major blood vessels, particularly the internal carotids and anterior and middle cerebral arteries. Cerebrovascular infarctions are more common in children and older adults, whereas hemorrhagic CVAs occur more frequently in adults in their 20s. The reason for this difference in the type of CVA is still unknown, and patients who have had one CVA are at a higher risk for having subsequent CVAs. Neurological complications, such as cranial nerve palsies, seizures, and extremity paresthesias, may be observed in patients after a CVA.

Infection is the leading cause of hospitalization in patients with SCD; they are prone to infections because of the impaired function of the spleen and phagocytic action. Because pneumonia is common, often caused by the pneumococcus bacterium and *H. influenzae*, annual pneumococcal and flu vaccines are recommended for individuals with SCD. All recommended vaccinations against measles, mumps, and pertussis should be current as well as immunization against hepatitis B. Tuberculin skin testing should be performed every 2 to 3 years but annually in regions where the tuberculosis rate is higher. Osteomyelitis caused by *Salmonella* or *Staphylococcus* is not uncommon. Cuts, sores, and insect bites should be observed carefully because they are potential sources of infection.

Pregnancy can exacerbate SCD because the oxygenation demands of the body are increased. Anemia may also worsen, with subsequently more frequent sickling and crises. Infections, particularly pulmonary, are more common. Obstetrical complications include gestational hypertension, preterm labor, and smaller birth weights. Spontaneous abortions and stillbirths are common. Maternal and neonatal mortality are higher than in the general population. Pregnancy causes a greater need for iron and folic acid, and supplementation is particularly important so that multiple causes of anemia do not occur.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of sickle cell anemia are related to the sickling RBC leading to decreased oxygen-carrying capacity of hemoglobin, as well as complications of vaso-occlusion. Patients typically present with many of the following clinical manifestations:

- Tachypnea
- Shortness of breath

- Tachycardia
- Fatigue
- Pallor
- Jaundice

The complaint of pain during a crisis is the result of vaso-occlusion of blood vessels and the resulting tissue ischemia and hypoxia. It can also be caused by the clumping of cellular debris from the hemolysis of RBCs, particularly in joints, bones, the chest, and the abdomen. Chest pain, however, can also be caused by pulmonary infiltrates (pneumonia) or pulmonary infarction (emboli in the lung) causing tissue ischemia and also preventing adequate oxygen exchange.

Multiple episodes of crises and infarctions over a period of several years can result in the developmental problems seen in individuals with SCD:

- Hand-foot syndrome
- Delayed puberty with developmental delay of secondary sexual characteristics
- Cognitive impairment, ranging from learning disabilities to mental retardation
- Psychosocial issues

### Nursing Diagnoses

- **Impaired tissue perfusion** related to sickling of RBCs with resulting decreased oxygen-carrying capacity and tissue hypoxia
- **Activity intolerance** related to hypoxemia resulting from the sickling RBCs
- **Acute pain** related to clumping of sickled RBCs in the capillary beds, resulting in tissue ischemia
- **Risk for powerlessness** related to frequent sickle cell crises, often for no apparent reason

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Tachycardia and tachypnea are a result of the sickling of RBCs that causes a decreased oxygen-carrying capacity of the hemoglobin molecules. It is also a result of the decreased life span and increased destruction of RBCs.*
- Fatigue, pallor, and shortness of breath  
*Fatigue, pallor, and shortness of breath worsen with increasingly decreased levels of hemoglobin and RBCs causing inadequate tissue perfusion and hypoxia.*
- Pain, swelling in joints and extremities  
*Pain is caused by tissue hypoxia and clumping of cellular debris, particularly in the joints, bones, chest, and abdomen, leading to vaso-occlusion.*
- Jaundice  
*The decreased life span of RBCs in people with SCD and the increased destruction of those RBCs may cause an increase in serum bilirubin, leading to jaundice.*
- Hand-foot syndrome  
*Multiple episodes of crises and bone infarctions may lead to uneven growth of the fingers and toes.*

- Clinical manifestations of infection  
*Fever may be present without infection. However, infection must be ruled out. X-rays to eliminate pneumonia or osteomyelitis may be necessary. Any skin lesions must be assessed for infection. Dental hygiene should not be overlooked as a source of infection.*
- Hemoglobin and serum bilirubin levels  
*The sickled RBCs have decreased hemoglobin levels, and increased hemolysis of RBCs elevates serum bilirubin.*
- Serum iron, vitamin B<sub>12</sub>, and folate levels  
*Because of the lower-socioeconomic status of a large percentage of African descendants globally, malnutrition is a concern. Frequently, patients with SCD also have decreased levels of iron, vitamin B<sub>12</sub>, and folic acid. These deficiencies complicate the anemia and need to be corrected.*
- Psychosocial issues  
*Patients with SCD may have anger and/or depression in response to chronic disease. Frequent absences from work may interfere with employment, leading to feelings of guilt or anger.*

#### ■ Actions

- Administer oxygen.  
*Oxygen assists in decreasing hypoxia and minimizing the severity of the crisis.*
  - Provide aggressive hydration.  
*Aggressive hydration increases blood volume (easing clumping of debris in capillaries) and flushes the kidneys, minimizing the risk for renal failure.*
  - Administer pain medication.  
*Administering analgesia, usually opiates, helps manage the pain caused by vaso-occlusion.*
  - Administer blood transfusions.  
*Blood transfusions may be needed in cases where the anemia is profound to improve oxygen delivery to the tissues.*
  - Administer antipyretics.  
*Antipyretics help reduce fever if present and decrease the fluid loss associated with temperature elevation and increased metabolic rate.*
  - Provide supportive measures.  
*A sickle cell crisis can be frightening to all involved, the individual with SCD as well as the family. The nurse needs to provide emotional support and be cognizant of the possible need for counseling. Contact additional resources if needed.*
- #### ■ Teaching
- Pathophysiology of disease  
*Parents need to understand the disease and its unpredictable course. The need for medical intervention early in a crisis can make the difference between a crisis lasting several hours or several days. Timely medical intervention can also minimize potential complications.*
  - Infection prevention measures  
*Because patients with SCD are prone to infection as a result of impaired function of the spleen, the need for updated immunizations and annual flu and pneumococcal vaccines is essential. Good dental hygiene and frequent dental check-ups*

and careful monitoring of any cuts, sores, and insect bites are also key to minimizing infections.

- Avoid cold temperatures and wearing tight, restrictive clothing.  
*Taking measures that may prevent vasoconstriction may help prevent sickle cell crises.*
- Avoid high altitudes and depressurized airplanes.  
*Avoiding environments with low oxygen tension may minimize sickling of RBCs and prevent a sickle cell crisis.*
- Avoid dehydration.  
*Being adequately hydrated helps blood move freely through capillary beds.*
- Avoid overexertion.  
*It is important for the patient with SCD to take rest periods to avoid undue stress on the cardiovascular system.*
- Maintain activities of daily life within prescribed limitations.  
*Although care and special considerations need to be taken into consideration, it is still important for the person living with SCD to live as normal a life as possible. Therapy and counseling should be recommended if the patient needs assistance in coping with this chronic disease.*
- Risk of more frequent sickle cell crises during pregnancy  
*Because of the body's increased demands during pregnancy, exacerbation of the SCD may occur. Pregnant individuals with SCD need to be monitored closely because they have a higher risk of maternal and infant mortality.*
- Fetal complications  
*Low birth weight, gestational hypertension, preterm labor, spontaneous abortions, and stillbirths are also higher in this population because of increased oxygen demands during pregnancy.*
- Genetic counseling  
*Because SCD is an inherited disease, genetic counseling is recommended for all individuals with SCD or the SCT.*

### Evaluating Care Outcomes

Sickle cell disease, a heredity disorder, has no cure. The goals are minimizing episodes of sickle cell crisis, symptom management during times of crisis, and minimization of complications. Providing prompt and appropriate care during a crisis, patient and family education regarding the disease and the importance of prophylactic care, and psychological and genetic counseling when necessary helps the individual with SCD improve quality of life as much as possible. Successful outcomes for a patient with SCD include the ability to live a relatively normal life and minimize sickle cell crises.

### Connection Check 34.4

Which activity should be avoided in a patient with sickle cell anemia?

- A. Driving to the beach 3 hours away
- B. Going to a concert
- C. Running in a 5-k race
- D. Carpentry work

## Aplastic Anemia

### Epidemiology

Aplastic anemia, also called hypoplastic anemia, is a rare disease process that develops due to bone marrow depression or damage and is often acquired secondary to infections, including hepatitis and human immunodeficiency virus. It is also associated with treatments using high-dose radiation or chemotherapy for cancer, exposure to toxic chemicals administration of specific medications (chloramphenicol and gold compounds), and autoimmune disorders. The incidence of aplastic anemia in the United States is estimated to be approximately two to four cases per million people. Although this disease occurs in all age groups, there is a small peak in childhood, usually secondary to inherited marrow dysfunction; a second peak in people between the ages of 20 and 25; and an increased incidence in people older than 60 years of age. The male-to-female ratio is 1:1 in the United States. Although there is an increased incidence in males in Asia, there is no corresponding increased incidence of Asian Americans, suggesting that environmental factors in Asia, rather than heredity or gender, have a role in this increase.

### Pathophysiology

The damage to the bone marrow, whether secondary to chemicals or medications or an autoimmune response, results in decreased production of red blood cells, white blood cells, and platelets. In cases where bone marrow damage leads to decreased erythrocytes, granulocytes, and platelets, the condition is known as pancytopenia. Although the exact mechanisms leading to aplastic anemia are not clearly understood, the exposure to infectious agents, chemicals, and other insults to bone marrow leads to a cellular immune response. The result of this response is the production of cytokines that suppress both stem cell growth and development.

### Clinical Manifestations

The clinical presentation of aplastic anemia may be insidious or chronic. However, in cases secondary to some type of myelotoxin (poison that directly damages bone marrow), the presentation may be sudden and severe. Similar to other anemias, clinical manifestations of aplastic anemia are typically associated with decreased RBCs and include fatigue, shortness of breath, tachycardia, pallor, dizziness, and headache. Clinical manifestations related to decreased WBCs include increased susceptibility to infections, as well as frequent and prolonged infections. Because aplastic anemia may also lead to thrombocytopenia, the patient may also present with unexplained and increased incidence of bruising, nosebleeds, gum bleeding, and prolonged bleeding from cuts and other injuries.

### Management

#### Medical Management

#### Diagnosis

Diagnostic testing for aplastic anemia includes a CBC, coagulation tests, iron levels, hemoglobin electrophoresis, and a bone marrow biopsy. The CBC results reveal pancytopenia, including decreased reticulocyte, WBC, and platelet counts.

Due to the potential for thrombocytopenia, coagulation testing is important to evaluate the risk for bleeding. Patients with aplastic anemia are typically treated with blood transfusions, and repeated transfusions may lead to increased iron levels. Hemoglobin electrophoresis is often used in the evaluation of anemias because it is used to identify different forms of hemoglobin (Hgb). In aplastic anemia, there may be an increase in Hgb F, which is normally found in small amounts in adults. Bone marrow results typically demonstrate a lack of hematopoietic cells with a predominance of fat cells.

### Treatment

During the diagnostic evaluation phase of aplastic anemia, blood transfusions are a primary treatment. However, the goal of treatment is to minimize transfusions to decrease the sensitization that ultimately increases the risk for bone marrow transplantation rejection. The preferred treatment for aplastic anemia is bone marrow transplantation from an HLA-matched sibling donor. Other treatments focus on stimulating bone marrow with medications such as filgrastim (Neupogen®) and epoetin-alfa (Epogen®), which stimulate the bone marrow production of cells and relieve symptoms. In patients over the age of 60, immunosuppressive therapy is preferred. This therapy is also used in patients with no HLA-matched sibling donor. In patients who develop aplastic anemia secondary to chemotherapy or radiation treatments, Epogen or Neupogen may be used to stimulate bone marrow activity; however, the bone marrow usually recovers once these treatments are completed.

### Complications

Aplastic anemia has a high mortality rate of greater than 70%, and these patients are at increased risk of complications associated with pancytopenia. Low RBCs decrease the oxygen-carrying capacity and may result in decreased cellular and tissue perfusion. The patient is at increased risk of hemorrhage and severe infection secondary to decreased platelets and WBCs, respectively. In patients who undergo bone marrow transplantation, there is an increased risk of GVHD.

### Nursing Management

#### Assessment and Analysis

Because aplastic anemia potentially decreases RBCs, WBCs, and platelets, patients are at risk for decreased oxygen-carrying capacity, infection, and bleeding, respectively, the nurse needs to monitor for the following clinical manifestations:

- Shortness of breath
- Tachycardia
- Elevated temperature
- Bruising
- Bleeding gums
- Nosebleeds
- Fatigue
- Pallor
- Dizziness
- Headache

### Nursing Diagnoses

- **Activity intolerance** related to decreased oxygen carrying capacity secondary to decreased RBCs
- **Risk for injury** related to decreased platelets secondary to bone marrow suppression
- **Risk for infection** related to decreased WBCs secondary to bone marrow suppression

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Tachycardia and tachypnea are secondary to heart and lung compensation for the decreased oxygen-carrying capacity of RBCs. Temperature may be elevated due to inflammatory or infectious processes.*
- CBC results  
*Bone marrow suppression caused by aplastic anemia results in pancytopenia, leading to decreased RBCs, WBCs, and platelets*
- Bone marrow results  
*Aplastic anemia leads to a lack of hematopoietic cells, with a predominance of fat cells.*
- Oxygen saturation  
*Severe anemia leads to insufficient hemoglobin to carry oxygen; oxygen saturation levels may decrease.*
- Signs of bleeding  
*Due to decreased platelets, the patient is susceptible to bleeding gums, nosebleeds, and increased time to stop bleeding from trauma, venipuncture, injections, and other causes.*
- Fatigue and pallor  
*Decreased oxygen to tissues secondary to decreased RBCs leads to fatigue, particularly on exertion, and pallor due to decreased perfusion.*
- Dizziness and headache  
*Decreased oxygen may lead to dizziness and headache.*

#### ■ Actions

- Provide supplemental oxygen.  
*Supplemental oxygen is needed to treat decreased oxygenation and perfusion secondary to decreased Hgb.*
- Administer blood products.  
*Blood components, including packed red blood cells and platelets, may be required for the treatment of symptomatic pancytopenia.*
- Implement bleeding precautions.  
*Decreased platelets increase the risk of bleeding, and bleeding precautions include the use of soft toothbrushes and direct pressure to venipuncture and injection sites until bleeding stops, among others.*
- Protect from injury.  
*Due to pancytopenia, the patient is at risk for decreased tissue perfusion that can result in dizziness and falls. The patient is also at risk for bleeding and infections.*

#### ■ Teaching

- Avoid exposure to potential infection (individuals with acute infection, crowded places, etc.).  
*Due to decreased WBCs, the patient is at increased risk of infection, and crowded places may increase the chances of exposure to people with infectious diseases.*

- Report all temperature elevations.  
*Patients with aplastic anemia may present with a low-grade temperature with an infection due to bone marrow depression that impacts WBC production and maturation.*
- Avoid activities with the potential for trauma or injury.  
*Potential trauma and injury increase the risk of bleeding due to thrombocytopenia.*
- Clinical manifestations of anemia  
*Because aplastic anemia is a medical emergency, the patient and family need to be instructed to contact the healthcare provider at the first signs of anemia, infection, and bleeding.*
- Nutritional intake  
*Adequate nutritional intake enhances immune function and resistance to infection.*

### Evaluating Care Outcomes

Patients living with aplastic anemia must be constantly vigilant for potential exacerbations. In chronic cases, positive outcomes include stable CBC and platelet counts, with the absence of infection and bleeding. As tissue perfusion is improved, clinical manifestations of tachycardia, shortness of breath, fatigue, and pallor resolve. Healthcare providers managing patients with this disorder need to be attentive to potential complications associated with the administration of specific medications.

## Glucose-6-Phosphate Dehydrogenase Deficiency

### Epidemiology

Glucose-6-phosphate dehydrogenase (G6PD) is a metabolic enzyme that is important to RBC metabolism because it protects the RBCs from oxidative stresses that can lead to cellular destruction. It is a hereditary disorder that leads to hemolysis when the patient is exposed to specific foods (e.g., fava beans), medications (antimalarial medicines, high doses of aspirin, NSAIDs, and sulfa medications), infection, or stress. In the United States, the incidence of G6PD deficiency is greater in blacks and men. It is estimated that 10% to 14% of African American males in the United States have the gene for this disorder. Similar to patients diagnosed with sickle cell anemia, patients with G6PD have protection against malaria.

## Genetic Connections

### G6PD Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, the most common enzyme disorder in humans, is an inherited recessive X-linked disorder. The mutation is found on the gene locus Xq28, a genetic marker located on the X chromosome.

### Pathophysiology

Due to the lack of G6PD, RBCs break down prematurely, resulting in hemolysis. During an acute episode of hemolysis in patients with this disorder, the body continues to produce new RBCs. This deficiency is often the cause of mild to severe jaundice in newborns.

### Clinical Manifestations

Patients diagnosed with G6PD deficiency may present with pallor, jaundice, dark urine, fatigue, shortness of breath, tachycardia, and an enlarged spleen. The pallor results secondary to decreased RBCs, and the jaundice and dark urine develop secondary to bilirubin buildup from the hemolysis. The fatigue, shortness of breath, and tachycardia result from the decreased oxygen-carrying capacity of the damaged RBCs. Splenomegaly develops secondary to the elevated numbers of lysed RBCs circulating through the spleen.

### Management

#### Medical Management

##### Diagnosis

Diagnostic testing for G6PD deficiency includes CBC, reticulocyte count, and blood smear analysis for Heinz bodies (accumulation of degraded Hgb in RBCs). The CBC in patients with this disorder reveals a mild to severe anemia. In patients with G6PD deficiency, the increased reticulocyte count reflects the production of new red blood cells secondary to hemolysis. The blood smear analysis may reveal RBC abnormalities, including the presence of Heinz bodies. Liver enzymes may be elevated in G6PD deficiency due to RBC destruction. Direct DNA testing and sequencing of the G6PD gene are also important to the diagnosis of this disorder.

##### Treatment

Once definitively diagnosed, prevention is the key to the management and treatment of G6PD deficiency. Avoiding foods and medications that cause hemolysis is indicated. In the case of severe hemolysis, blood transfusions may be necessary because these transfused RBCs are not G6PD deficient and have a normal life span. Folic acid may also be prescribed to support RBC synthesis. Splenectomy may be indicated in patients with an enlarged spleen due to frequent episodes of hemolysis.

##### Complications

Although rare, adult patients with G6PD deficiency are at risk for severe anemia. There is also a risk of kidney damage secondary to increased circulating lysed RBCs through the renal tubules. In newborns, this deficiency is implicated in prolonged neonatal jaundice and kernicterus, a bilirubin-induced brain disorder.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of G6PD deficiency are directly related to the RBC lysis that results secondary to the lack

of this important enzyme. The nurse monitors for the following in these patients:

- Shortness of breath
- Tachycardia
- Pallor
- Decreased RBCs and Hgb
- Elevated reticulocyte count
- Heinz bodies on the blood smear
- Elevated liver enzymes
- Jaundice
- Dark urine
- Enlarged spleen

With severe anemia, the patient needs to be monitored for cardiovascular deterioration, including a decreased level of consciousness and hypotension.

### Nursing Diagnoses

- **Inadequate tissue perfusion** related to decreased circulating RBCs secondary to hemolysis
- **Activity intolerance** related to decreased oxygen-carrying capacity of lysed RBCs

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*The G6PD enzyme is required for RBC development, and in its absence, anemia may develop. With the decreased oxygen-carrying capacity of the Hgb, tachycardia and tachypnea may develop as a compensatory mechanism.*
- Shortness of breath, pallor, and fatigue  
*These clinical manifestations are exacerbated by the decreased oxygen-carrying capacity of the lysed RBCs.*
- CBC and reticulocyte count  
*Decreased RBCs, hematocrit, and hemoglobin result due to hemolysis. The reticulocyte count may be increased in an attempt to replace the lysed cells.*
- Oxygenation saturation  
*With severe anemia leading to insufficient hemoglobin to carry oxygen, oxygen saturation levels may decrease.*
- Blood smear analysis  
*The G6PD deficiency results in RBC abnormalities and the accumulation of degraded Hgb (Heinz bodies). When a Heinz body is identified by macrophages in the spleen, the macrophage engulfs the Heinz body and a small piece of the RBC membrane, resulting in misshapen RBCs, called bite cells, in the RBC analysis.*
- Liver enzymes and bilirubin levels  
*The excessive amounts of heme released from RBC destruction are catabolized to bilirubin concentrations that exceed the liver's ability to conjugate. This also results in the accumulation of indirect bilirubin.*
- Skin color and urine color  
*The bilirubin accumulation in the circulation leads to jaundice and dark urine color.*

#### ■ Actions

- Provide supplemental oxygen.  
*Supplemental oxygen is needed to treat decreased oxygenation and perfusion secondary to decreased Hgb.*
- Implement bleeding precautions.  
*Decreased platelets increase the risk of bleeding, and bleeding precautions include the use of soft toothbrushes and direct pressure to venipuncture and injection sites until bleeding stops, among others.*
- Administer folic acid.  
*Folic acid facilitates RBC production; G6PD places the patient in a state of high RBC synthesis.*

#### ■ Teaching

- Avoid fava beans.  
*Because the lack of G6PD leads to hemolysis in response to the ingestion of fava beans, the patient and family need to understand the importance of avoiding this food.*
- Avoid medications that increase the risk of crises (aspirin, NSAIDs, etc.).  
*Because these medications increase the risk of bleeding, the patient and family are taught to avoid these medications.*
- Clinical manifestations of anemia  
*Because prevention is so critical to G6PD deficiency management, the patient and family need to understand the importance of immediately reporting signs of anemia.*

### Evaluating Care Outcomes

In adults with diagnosed G6PD deficiency, preventive measures and knowledge of the disease process are key to the management of this disorder. Avoiding foods and medications that exacerbate this disorder and recognizing the relationship between stress and G6PD deficiency will result in decreased episodes. In stable patients, clinical manifestations of decreased tissue perfusion (tachycardia, shortness of breath, fatigue, and pallor) decrease. Healthcare providers managing patients with this disorder need to be attentive to the potential complications associated with the administration of specific medications.

## Polycythemia Vera

### Epidemiology

**Polycythemia**, or **erythrocytosis**, is an increase in the production of RBCs and can be a primary or secondary disorder. Primary polycythemia, or **polycythemia vera** (PV), is a disorder of the bone marrow in which there is an increased production of RBCs that may be accompanied by an increased production of WBCs and platelets. Polycythemia vera has been found to be caused by a mutation in a gene known as the Janus kinase 2, or **JAK2**, gene in 90% of cases. The **JAK2** gene is associated with signal transduction to hematopoietic cells. The reason for this genetic mutation is unknown, and it occurs after birth. According to the National Heart, Lung, and Blood Institute, PV is extremely rare, and only 5 out of 1 million people are diagnosed with this disorder annually. The disorder is found

in men more often than women, and most adults are older than 60 years of age at the time of diagnosis. It is exceedingly rare in those younger than 20. Although PV is not hereditary, in some cases there is a familial tendency, indicating that other genetic factors may also be involved. Exposure to radiation has also been associated with an increased incidence of this disorder. In PV, most patients not only exhibit an increase in RBC counts but also an increase in the number of WBCs and platelets.

Secondary polycythemia occurs in response to the body's hypoxic state and may be considered appropriate or inappropriate. Appropriate secondary polycythemia occurs in situations caused by exposure to environments that have low oxygen tension, such as occurs with high altitudes and heavy smoke. The body compensates by producing more RBCs, thus increasing the oxygen-carrying capacity of the blood. This is a temporary response until the body becomes more acclimated to that environment. Inappropriate secondary polycythemia occurs when the body responds to a stimulus in an inappropriate way by secreting additional erythropoietin, which results in increased RBC production. This inappropriate erythrocytosis may occur in kidney disease and certain tumors. In secondary polycythemia, the WBC and platelet counts remain normal in the presence of the increased RBC production compared with PV, in which the number of all blood cells is elevated.

## Genetic Connections

### Polycythemia

Although most cases of polycythemia are acquired during a person's life, some cases appear to be inherited. Mutations in the *JAK2* and *TET2* genes appear to have a role in the development of this order.

### Pathophysiology

In normal hematopoiesis (formation of blood cells), the body's response to a state of hypoxia is to increase RBC production, known as erythrocytosis or polycythemia. This erythrocytosis increases the oxygen-carrying capacity of the blood, and increased production of RBCs thickens the blood, making it more viscous. This **hyperviscosity**, or thickened blood, slows down the circulation of the blood. In a state of polycythemia, the hematocrit is greater than 48% in women and greater than 52% in men. Hemoglobin levels are greater than 16.5 g/dL and 18.5 g/dL in women and men, respectively, and the total RBC count is greater than 6 million/mm<sup>3</sup>. Resolution of the hypoxia reverses this process, and normal levels are once again achieved.

In PV, a gene mutation, the *JAK2* gene, stimulates the overproduction of not only RBCs but also WBCs and platelets. Because RBCs have a much larger mass than WBCs or platelets, the increase in RBCs makes the blood

more viscous. As the hyperviscosity increases, circulation slows as the heart labors to pump the thickened blood. Even though there is an increase in the volume of RBCs, the body becomes hypoxic as the hyperviscosity slows oxygen exchange to the tissues.

The erythrocytosis that occurs in appropriate secondary polycythemia is in response to a hypoxic state caused by a low-oxygen-tension environment. **Erythropoietin** is released from the kidneys, which stimulates RBC production in order to resolve the body's perceived oxygen deprivation. At higher altitudes or in mountainous regions, atmospheric pressure is lower than that at sea level. This lower pressure decreases the rate of oxygen exchange because of the difference between atmospheric and alveolar pressures. People exposed to higher altitudes develop appropriate secondary polycythemia to compensate for the lower pressure. This natural erythrocytosis is why many athletes train at higher altitudes—the body's elevated RBC count may give the athlete an “edge” over competitors when competing at lower altitudes due to increased oxygen-carrying capacity. Appropriate secondary polycythemia can also be seen in patients with chronic obstructive pulmonary disease (COPD), patients with heart failure, and patients with a history of heavy cigarette smoking because the body attempts to compensate for the impaired tissue perfusion caused by decreased alveolar function. Certain tumors, such as pheochromocytomas (hypersecreting tumors of the adrenal medulla) and cerebellar hemangiomas, may excrete an erythropoietin-stimulating substance that causes an inappropriate secondary polycythemia.

### Clinical Manifestations

Polycythemia vera is a slowly progressive disease and may take years to produce clinical manifestations, which are related to the blood's hyperviscosity, the hypoxic state, and the congestion of organs by the blood cells. The clinical presentation includes shortness of breath, difficulty breathing when lying flat, headache, dizziness, weakness, splenomegaly, and blurred vision. Pruritus (itchiness), especially after a warm bath, and flushing of the face most likely occur as a result of vascular dilation and engorgement of the capillaries from the increased RBCs. The hyperviscosity of the blood and the slowing of blood flow also increase the risk for clot formation. Patients with PV may present with nosebleeds and bleeding gums because the hyperviscosity leads to thrombosis, and fewer circulating platelets are present to form clots in response to injury. Without treatment, patients with PV are at increased risk of death secondary to CVAs, MI, pulmonary embolus, or hemorrhage.

### Management

#### Diagnosis

Because the onset of PV is insidious, the disorder is often discovered during routine blood tests. Complete blood count results include an increased RBC count of greater than 6 million/mm<sup>3</sup>, and the hematocrit can exceed 60%. Because splenomegaly is often seen in about 75% of patients,

the bone marrow becomes fibrotic and is unable to produce sufficient cells. To make the diagnosis, the World Health Organization (WHO) recommends hemoglobin levels of greater than 16.5g/dL in men and greater than 16.0g/dL in women. In PV, elevated WBC and platelet counts may also be present as a result of the gene mutation's effect on the bone marrow production of blood cells. In secondary polycythemia, the WBCs and platelets remain in the normal range. Other laboratory tests that may aid in diagnosis are an erythropoietin level, blood smear, bone marrow biopsy, and genetic testing. A complete history and physical examination are often keys to diagnosing the cause of the polycythemia.

### Medical Management

Treatment of PV is aimed at reducing the hyperviscosity and preventing hemorrhage. Therapeutic phlebotomy involves removing blood to decrease blood volume and viscosity. A unit of blood (350 to 500 mL) is removed weekly until the hematocrit is less than 45%, then only as needed. The patient usually feels more comfortable immediately because this reduces congestion of organs such as the spleen and liver. Repeated phlebotomies may cause iron-deficiency anemia, so serum ferritin levels are monitored as well as CBCs. Phlebotomy, however, does not decrease WBC or platelet levels if elevated in PV, and chemotherapeutic agents such as hydroxyurea or interferon may be given to suppress bone marrow production. Radiation may also be employed to suppress the bone marrow. These treatments may have the undesirable side effect of causing leukemia. Antiplatelet medications, such as anagrelide or low-dose aspirin, may be prescribed to reduce the risk of thrombosis.

When secondary polycythemia is appropriate, treatment of the underlying condition usually resolves the polycythemia. Prevention of secondary polycythemia includes the cessation of activities such as smoking or mountain climbing, which deprive the body of oxygen. Maintaining a healthy lifestyle contributes to preventing conditions that cause polycythemia.

Symptom management in patients with PV is important to maintain quality of life. Regular moderate exercise to improve circulation and decrease thrombosis is emphasized. Medications to minimize itching may be prescribed, as well as interventions focused on avoiding extreme temperatures, taking extra care of the hands and feet, guarding against injury, drinking at least 3 L of fluid daily, avoiding tight clothing, elevating the feet while at rest, and reporting any chest pain or dyspnea.

### Complications

The main complications of PV are thrombosis and hemorrhage. As the blood becomes hyperviscous, there is a slowing of blood flow and increased risk of thrombosis. As multiple thromboses occur, injury may result in hemorrhage as the number of circulating platelets available to respond to the injury is decreased. Most deaths in patients with PV are secondary to MI or cerebrovascular attack, followed by other

thromboembolic events such as pulmonary infarction. Gastrointestinal hemorrhage occurs because of abnormally formed platelets and a decrease in circulating platelets. Reductions in blood viscosity and volume help to prevent these complications. Abnormal bone marrow scarring may occur from the overproduction of cells, leading to myelofibrosis, which ultimately results in lower-than-normal blood counts of all cells. If the bone marrow begins to grow uncontrollably, acute myelogenous leukemia (AML) occurs. Heart failure is a result of the constant strain on the heart of pumping the hyperviscous blood.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of polycythemia are related to hyperviscosity, hypervolemia, and engorgement of the capillaries. It is important that the nurse observe for the following in patients with this disorder:

- Shortness of breath, especially when supine
- Fatigue
- Dizziness
- Headache
- Generalized pruritus, especially after a warm bath
- Flushing of the face
- Feeling of fullness in the left upper abdomen (engorged spleen and/or liver)
- Vision problems
- Weight loss

Sudden chest pain, headache, or shortness of breath may be the result of a thromboembolic event, and immediate medical attention is needed.

#### Nursing Diagnoses

- **Ineffective tissue perfusion** related to hyperviscosity and poor oxygen exchange
- **Activity intolerance** related to impaired tissue perfusion secondary to hyperviscosity and poor oxygen exchange
- **Risk for ineffective coping** related to clinical manifestations of shortness of breath, fatigue, itching, and anorexia

#### Nursing Interventions

##### ■ Assessments

- Shortness of breath/dyspnea, especially when supine  
*Because of decreased oxygen delivery to the tissues, respiratory effort increases in an attempt to improve oxygen delivery.*
- Headache  
*Headache is a result of the increased blood volume and hyperviscosity in PV. A sudden, severe headache may be a clinical manifestation of a CVA as the result of clot formation.*
- Dizziness  
*Dizziness in PV occurs because of impaired tissue perfusion as the blood flow slows secondary to blood hyperviscosity.*
- Generalized pruritus, especially after a warm bath  
*The itchiness in PV is most likely due to the vascular dilation and capillary engorgement as a result of the increased blood*

cell production with resulting increased blood volume. This can be painful due to swelling from the histamine release and increased number of basophils and may be triggered by the exposure to water (aquagenic pruritus).

- Flushing of the face  
*Flushing in PV occurs secondary to capillary engorgement caused by the increased blood volume. This plethora causes a ruddy complexion.*
- Feeling of fullness in the left upper abdomen  
*The abdominal fullness (which may become painful) is due to the organ congestion secondary to the hyperviscosity and increased blood volume.*
- Fatigue  
*Fatigue occurs because of the increased workload of the heart and poor tissue perfusion secondary to the hyperviscosity. Angina and intermittent claudication can occur.*
- Vision problems  
*Blurred vision or blind spots occur from poor tissue perfusion or vascular damage to small vessels in the eye secondary to hyperviscosity.*
- Weight loss  
*The feeling of fullness in the abdomen in the left upper quadrant is caused by organ congestion that leads to abdominal pain, early satiety, and/or anorexia. Patients with elevated hemoglobin and hematocrit should be checked for an enlarged spleen on physical exam by the healthcare provider.*
- RBCs, hemoglobin, and hematocrit  
*Overproduction of RBCs is a result of stimulation of the bone marrow secondary to either a gene mutation or the body's hypoxic state. This may lead to angina, hypertension, and thrombophlebitis, especially if the patient has cardiac disease.*
- Bone marrow biopsy results  
*Examination of the bone marrow shows the **panmyelosis** (overproduction of RBCs, WBCs, and platelets) in PV.*
- Erythropoietin level  
*In secondary polycythemia, the hypoxic state stimulates the release of erythropoietin by the kidneys.*
- Vital signs during therapeutic phlebotomy  
*If blood loss is not too fast, the patient may develop signs of hypovolemia, including hypotension and tachycardia.*
- Uric acid level  
*The rapid turnover of red blood cells associated with PV may result in an elevated uric acid level. This increase in uric acid can cause gout and kidney stone formation.*

### ■ Actions

- Obtain routine CBCs.  
*If the patient is undergoing therapeutic phlebotomy, blood count checks are done to maintain a hematocrit below 45% in men and below 42% in women. If the patient is on chemotherapeutic agents, CBCs are indicated to monitor the degree of myelosuppression.*
- Increase fluid intake.  
*Increased fluid intake may reduce the hyperviscosity of the blood.*

- Ensure adequate rest.  
*Frequent rest periods may be needed to help the patient deal with the increased workload on the heart due to the hyperviscosity and the patient's subsequent shortness of breath.*
- Elevate lower extremities when sitting.  
*Elevation of the lower extremities aids the circulation in returning to the heart and minimizes the risk of thrombus formation secondary to venous stasis.*
- Modify cardiovascular risk factors.  
*Obesity, hypertension, diabetes, and smoking can increase the risk of thrombosis, CVA, MI, or deep vein thrombosis (DVT). Avoid restrictive clothing and crossing legs. Encourage smoking cessation. Implement DVT prophylaxis.*

### ■ Teaching

- Clinical manifestations of severe thromboembolic events  
*Patients need to understand the clinical manifestations of MI, CVA, and pulmonary infarction in order to seek immediate medical attention.*
- Rationale for aggressive hydration  
*Aggressive hydration daily is necessary to minimize hyperviscosity.*
- Eat small, frequent meals.  
*Small, frequent meals are usually better tolerated because of the abdominal fullness caused by the hyperviscosity and resulting organ congestion.*
- Avoid tight, restrictive clothing.  
*Tight clothing impairs circulation.*
- Avoidance of extreme temperatures of heat and cold  
*Itching is worsened by warm baths as a result of capillary engorgement. Cold temperatures cause vasoconstriction. Limit bathing to 30 minutes, and baths should use tepid water. Hot water can also exacerbate symptoms. Avoid vigorous drying off. Use mild soap and apply lotion after bathing. Colloidal oatmeal treatment may be added to bath water to decrease itching.*
- Observe bleeding precautions.  
*Patients need to observe bleeding precautions because of the risk of hemorrhage from impaired platelet function.*
- Routine moderate exercise  
*Regular exercise improves circulation and decreases the risk of thrombosis formation.*
- Regular laboratory tests  
*The CBC must be monitored for sudden changes, which may indicate a status change in the disorder of PV.*
- Genetic testing  
*Genetic testing may show abnormalities, such as mutations in the JAK2-STAT pathway, that stimulate abnormal cell growth. A positive JAK2 genetic mutation can result in increased cellular bone marrow and a low serum erythropoietin level, which may be hereditary in PV.*

### Evaluating Care Outcomes

Polycythemia vera is a slowly progressive disorder characterized by elevated RBCs. With proper treatment, complications may be prevented or delayed. Patients need lifelong

healthcare attention and need to understand how to deal with the clinical manifestations associated with this disorder. Being able to improve quality of life and prevent major thromboembolic events and hemorrhage is the goal. Resolution of the hypoxic state is the goal in secondary polycythemia.

### Connection Check 34.5

Which factor places the patient at a higher risk for developing secondary polycythemia?

- A. Type 2 diabetes mellitus
- B. History of alcohol abuse
- C. Smoking
- D. Hypertension

### CASE STUDY: EPISODE 2

A physical examination of Mr. Owens shows a well-developed male. His vital signs are as follows: temperature (T) 98.6°F (37.0°C), pulse (P) 102 bpm, respirations (R) 18, blood pressure (BP) 150/92 mm Hg, O<sub>2</sub> saturation 93% on room air. Lungs are clear bilaterally. Heart rate is regular. Bowel sounds are present. The provider orders a chest x-ray, CBC, comprehensive chemistry panel, serum ferritin level, vitamin B<sub>12</sub> assay, serum folate level, and urinary MMA. The chest x-ray shows some signs of COPD but no infiltrates. The CBC results are as follows: RBC 3.2 million cells/mm<sup>3</sup>, Hgb 9.4 g/dL, Hct 28.1%, WBC 6.2 × 10<sup>3</sup>/mm<sup>3</sup>, platelets 97,000/mm<sup>3</sup>. Chemistry panel results are within normal range, as are the different serum levels and urinary MMA. The provider subsequently refers Mr. Owens to an oncologist, who orders a bone marrow biopsy, positron emission tomography (PET) scan, and genetic testing...

## BLEEDING DISORDERS

### Thrombocytopenia

Thrombocytopenia is defined as a reduced number of platelets below the average range of 150,000 to 450,000/mm<sup>3</sup>. It is not a disease but rather a complication of other disorders or a syndrome as a result of other events occurring in the body. Thrombocytopenia occurs as a result of a decreased production of platelets by the bone marrow or increased platelet destruction. Antibodies that increase platelet destruction may be genetic, acquired, or medication induced. Antiplatelet antibodies bind to the plasma membrane of platelets, causing platelet sequestration and destruction by the mononuclear phagocytes in the spleen and other lymph tissue at a rate that exceeds the abilities of the bone marrow

to produce platelets. In approximately 70% of the cases of idiopathic thrombocytopenic purpura (ITP), there is an antecedent viral disease that precedes the eruption of petechiae or purpura by 1 to 3 weeks. High levels of IgG are found bound to platelets and may represent immune complexes on the platelet surface. Hemorrhagic conditions such as ITP, hemophilia, and disseminated intravascular coagulation (DIC) present with thrombocytopenia and heparin-induced thrombocytopenia (HIT). With all of these disorders, the main complication is the risk for hemorrhage. These hemorrhagic conditions are discussed in this section because of the relationship to platelets and the bleeding potential represented. The risk of developing thrombocytopenia varies throughout the life span of the individual.

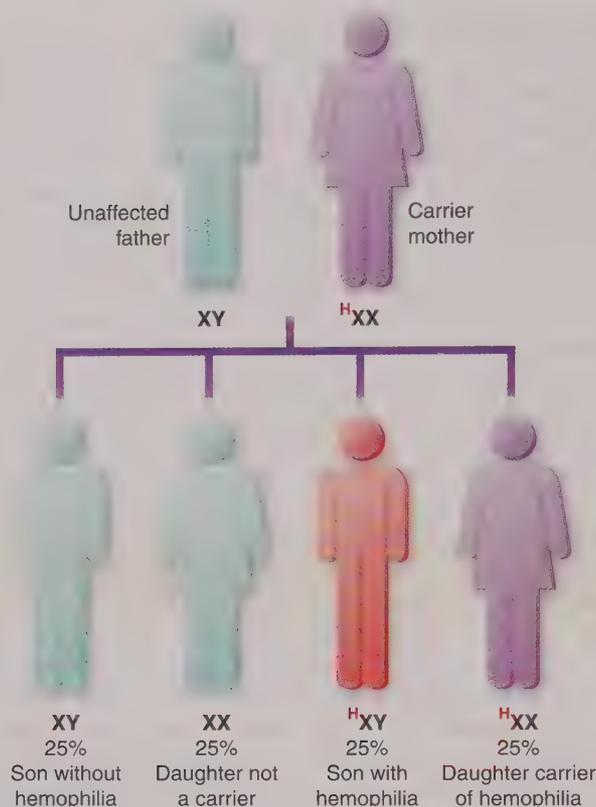

### Epidemiology

There are numerous causes for thrombocytopenia, including malignancy, infection, certain medications (e.g., sulfa medications), autoimmune conditions (e.g., lupus), and DIC. It is now called immune thrombocytopenia purpura and is the most common autoimmune platelet consumption disorder, and it can be acute or chronic. It may follow a viral infection in children, and pregnancy can induce thrombocytopenia. Approximately 6% to 15% of pregnant women may develop a low platelet count in the final trimester of pregnancy, referred to as gestational thrombocytopenia, that is usually mild and resolves spontaneously during the postpartum phase. Because a low platelet count during pregnancy may be indicative of other diseases, such as ITP, if the patient had thrombocytopenia prior to pregnancy, develops it during the first or second trimester, or presents with a platelet count of less than 75,000 in the third trimester, further evaluation is indicated to rule out ITP.

Acute ITP may occur between the ages of 2 and 6, whereas chronic ITP occurs most often in women between the ages of 15 and 40. Childhood ITP usually presents rapidly and resolves spontaneously within a few weeks to 6 months, whereas chronic adult ITP usually has a more insidious onset and rarely results in remission. The incidence of ITP is estimated at 3.8 million patients in the United States. Risk factors include being of African descent and obese. The female-to-male ratio is approximately 2:1, with the incidence peaking between the ages of 20 to 30 years; however, this ratio becomes about equal after the age of 60 years.

**Hemophilia** is a group of bleeding disorders in which, although thrombocytopenia may be present, clotting factors VIII (hemophilia A) and IX (hemophilia B or Christmas disease) are inadequate. Hemophilia is a hereditary disorder carried by females on the X chromosome. The manifestation of hemophilia only presents clinically in males, approximately 1 in 5,000 to 7,000. Hemophilia occurs in all ethnic groups. A female carrier of the hemophilia gene has a 50% chance of passing this disorder to any male offspring (Fig. 34.6).

Disseminated intravascular coagulation occurs secondary to severe trauma to the body. Because DIC is not a disease but a result of trauma or severe tissue injury, incidence rates

**FIGURE 34.6** Hemophilia inheritance pattern. This disorder is inherited from the female but present in the male.

are not measured. Severe trauma may include crush injuries, burns, sepsis, and shock. Obstetrical complications such as abruptio placentae or retained products of conception (placenta or fetal tissue) also cause DIC. Tissue necrosis following extensive abdominal surgery with leakage of intestinal contents may also lead to DIC. Rarely, snakebite, heatstroke, or fat embolism from long-bone fractures lead to DIC. Certain cancers such as leukemia or widespread metastasis may also result in DIC, and there is a high mortality rate with DIC because of multisystem organ dysfunction and hemorrhage.

Heparin-induced thrombocytopenia (HIT) may occur in patients receiving heparin for an existing thrombus or clot. While thrombocytopenia occurs, patients typically do not have bleeding episodes, and additional thrombi occur or the existing thrombus enlarges. There are concerns that the use of heparin to maintain the patency of central lines predisposes patients to the development of HIT.

### Pathophysiology

Idiopathic thrombocytopenia purpura usually follows a viral infection or immunization in children. In adults, ITP may be medication induced or secondary to an autoimmune disorder. In all cases, it appears to be an immune system dysfunction in which antiplatelet antibodies are formed, which increases platelet destruction. Rather than the 7- to 10-day life span, the platelets may be destroyed in a matter of hours.

The clotting factors that are lacking in hemophilia interfere with the normal clotting mechanism of the body. The two most common forms are hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency). Minor injuries can result in significant blood loss, and in cases of severe hemophilia, spontaneous bleeding may occur. **Hemarthrosis**, bleeding in the muscles and joints, can be common and eventually disabling as joint deformities occur from repeated bleeding episodes. Severe trauma in a patient may result in the development of DIC. In a complex sequence initiated by the injury, all platelets and clotting factors form multiple thrombi throughout the body secondary to alteration of the body's normal anticoagulant mechanisms. When all the body stores of platelets and clotting factors are exhausted, spontaneous bleeding occurs from nearly every orifice because there are insufficient circulating platelets and clotting factors to stop the bleeding. The multiple emboli cause tissue necrosis, leading to multisystem organ dysfunction.

Heparin-induced thrombocytopenia appears to be the result of an immune response by the body. Although heparin is a natural substance in the body, the administration of exogenous heparin in some patients leads to the body producing antibodies against the "foreign" heparin. It typically occurs 5 to 14 days after the first administration of heparin. In a complex sequela, these antibodies initiate a response that culminates in the formation of new blood clots and a resulting fall in the platelet count as they are consumed (used) to form these thrombi.

### Clinical Manifestations

With a reduced number of platelets, easy bruising and petechiae are usually the first clinical manifestations with all forms of thrombocytopenia. Bleeding may occur from the nose, around the gums, or from the gastrointestinal tract. In severe cases, bleeding in vital organs such as the brain may prove fatal.

### Management

#### Diagnosis

The treatment of ITP depends on the level of thrombocytopenia present. If platelet counts remain above  $100,000/\text{mm}^3$ , an observational strategy is usually employed through routine CBC analyses. A CBC with a manual differential can confirm the diagnosis of thrombocytopenia, which is defined as platelets less than  $150,000/\text{mm}^3$ . In addition to the CBC, a bone marrow biopsy confirms the diagnosis of ITP. Prolonged prothrombin time, partial prothrombin time, and thrombin time are helpful in diagnosing DIC, as well as a reduced fibrinogen level, elevated fibrin split products, and elevated dimers (cross-linked fibrin fragments). Clotting factors (e.g., factors VIII, IX) may aid in the diagnosis of both hemophilia and DIC. A blood smear is helpful in determining the morphology of the platelets. An additional test, in addition to a CBC to diagnose HIT, is the enzyme-linked immunosorbent assay (ELISA), which is an immunoassay test to determine the presence of the antibodies.

## Medical Management

If the thrombocytopenia becomes more profound, treatment with glucocorticoids has proven to be beneficial. Glucocorticoids increase platelet counts by decreasing the antiplatelet antibody production, improving production of platelets by the bone marrow, and decreasing the phagocytosis that is consuming the platelets. In extreme cases, performing a splenectomy has improved platelet counts because the spleen is the primary site of platelet destruction.

In hemophilia cases, depending on the type of hemophilia, replacement of the missing clotting factors is indicated. Replacement of factor VIII resolves bleeding in hemophilia A, whereas factor IX is used in hemophilia B. These clotting factors are delivered intravenously from recombinant DNA products, which do not contain human blood components. For minor injuries, treatment should be obtained as soon as possible with as many as three treatments (one treatment daily). Major traumas need replacement of clotting factors for 7 to 10 days or until healing is assured. Prophylactic treatment with clotting factors may be indicated for some surgeries with factor replacement for up to 7 to 10 days postoperatively. Prompt treatment with clotting factors minimizes complications caused by bleeding, such as joint deformities, which were prevalent prior to factor replacement.

Resolution of the underlying condition that initiates the clotting cascade is imperative in treating DIC, for example, immediate antibiotic therapy to treat the sepsis. Providing supportive care in the form of administering blood, platelets, fresh frozen plasma, and **cryoprecipitate** (plasma product rich in factor VIII) may be employed to maintain hemostasis. These patients are managed in an intensive care setting where they can be closely observed with hemodynamic monitoring equipment. Mortality rates are high in patients who develop DIC, although exact numbers are not known because the cause of death is usually attributed to the underlying disorder.

Stopping the heparin administration is the first step in treating HIT. However, because the formation of additional thrombi occurs frequently in these patients, an anticoagulant is required to prevent further thrombus formation and the production of the antibodies, allowing the platelet count to recover. Warfarin should not be used because it can cause skin gangrene in this population. Three anticoagulants have been approved for use in patients diagnosed with HIT: danaparoid (not available in the United States), lepirudin, and argatroban. Platelet transfusions are discouraged because they may increase thrombus formation.

## Complications

Risk of hemorrhage is the major complication of any condition that results in thrombocytopenia, and the severity of the thrombocytopenia determines whether there is a risk of spontaneous bleeding. Although the initial clinical manifestations of thrombocytopenia are ecchymosis and petechiae, as the platelet count decreases, normal activities such as tooth brushing or sneezing may produce spontaneous bleeding. Patients are instructed about bleeding precautions (Box 34.1) when the

## Box 34.1 Bleeding Precautions for the Patient With Thrombocytopenia/Bleeding Disorders

1. Use a soft-bristle toothbrush or gauze to clean the teeth. No flossing.
2. Use an electric razor for shaving.
3. Encourage the use of shoes or slippers when out of bed.
4. Maintain a clutter-free environment to minimize bruising.
5. Use a stool softener daily to decrease constipation and straining during bowel movements.
6. Avoid rectal thermometers, suppositories, enemas, and vaginal douches.
7. Avoid sexual intercourse when the platelet count is extremely low.
8. Do not blow nose.
9. When using a knife is necessary, make sure the blade is sharp. More force is required for dull knives.
10. If a laceration occurs, apply direct pressure and/or ice for no less than 5 minutes until bleeding stops.
11. Procedures such as intramuscular injections, arterial sticks, and peripheral blood draws should be kept to a minimum.

platelet count drops below  $100,000/\text{mm}^3$  and especially when it is below  $50,000/\text{mm}^3$ . Spontaneous bleeding becomes a real concern when the platelets are less than  $20,000/\text{mm}^3$ . Transfusions of platelets are usually not given until the platelets are less than  $20,000/\text{mm}^3$  because of the risks involved with blood product transfusions; however, if an invasive procedure is being considered, transfusions may be given prophylactically to minimize the risk of bleeding. Close monitoring is indicated in patients with any type of severe trauma in order to detect early manifestations of DIC because early recognition of thrombocytopenia may be key in determining a patient's prognosis.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of thrombocytopenia are a result of the decreased number of platelets, and the nurse correlates the following findings to this disorder:

- Ecchymosis
- Petechiae
- Nosebleeds
- Bleeding gums
- Black, tarry stools
- Hematuria

### Nursing Diagnoses

- **Risk of injury: bleeding** related to decreased number of platelets
- **Risk for effective therapeutic regimen management** related to possible frequent administration of platelets and/or clotting factors
- **Fear** related to hemorrhaging from low platelet count

## Nursing Interventions

### Assessments

#### Platelet count

A decreased platelet count is seen on the CBC. Further testing indicates whether it is due to increased platelet destruction or decreased platelet production. In pregnant patients, monitor liver function tests and platelet count during the pregnancy. Monitor for easy bruising, and report any clinical manifestations of bleeding to the healthcare provider. Watch for excessive postpartum hemorrhage or clots. Place patient on bleeding precautions if the platelet count is below normal, hematocrit is low, or liver function tests are elevated.

#### Ecchymosis

Ease of bruising increases as the number of platelets decreases and tissue injury increases with contact.

#### Petechiae/purpura

Intradermal bleeding occurs as a result of platelet reduction.

#### Frank bleeding (nosebleeds; bleeding gums; black, tarry stools; or hematuria)

Parts of the body where mucous membranes are thin or cells rapidly divide are more prone to bleeding when platelet counts are decreased.

### Actions

#### Implement bleeding precautions (see Box 34.1).

Due to decreased platelet count, the patient is at increased risk of bleeding from minor injuries, venipuncture, and so forth.

#### Minimize blood loss from lacerations or venipuncture. If bleeding occurs, apply direct pressure and/or application of ice to cause vasoconstriction to stop bleeding. This includes direct pressure on sites after blood draws and venipuncture.

#### Avoid intramuscular injections.

Intramuscular injections can cause bleeding into the muscle, and the bleeding can be difficult to manage.

#### Avoid rectal temperatures, enemas, suppositories, and douches.

These procedures can tear the thin mucosa of the rectum, anus, and vagina, leading to bleeding.

#### Provide a safe environment.

Keep the patient's room clutter-free to minimize patient injury that leads to bruising.

#### Use minimal inflation when assessing blood pressure.

Overinflation of the blood pressure cuff can cause bruising. Inflate the cuff only until the pulse is obliterated. Avoid automatic blood pressure cuffs.

#### Minimize blood draws.

Blood draws should be kept to a minimum. The use of venous access devices should be considered if frequent blood draws are necessary to prevent the need for multiple venipuncture. Report low platelet counts to the healthcare provider.

### Teaching

#### Instruct patient/family on bleeding precautions (see Box 34.1).

Teaching patients how to minimize bleeding helps them function with thrombocytopenia or bleeding disorders and to minimize the risk of hemorrhage.

- Instruct the patient to avoid sexual intercourse when the platelet count is less than 50,000/mm<sup>3</sup>.  
*Sexual intercourse during periods of extreme thrombocytopenia can tear the mucous membranes of the vagina or rectum, causing hemorrhage.*
- Necessity of frequent CBCs, laboratory tests  
*Patients need to understand the importance of frequent CBCs to monitor the thrombocytopenia.*

### Evaluating Care Outcomes

The goal of patient care is to prevent hemorrhage. The key to managing the thrombocytopenia in ITP, hemophilia, DIC, and HIT is to provide supportive care and treat the underlying condition. Close surveillance is required, along with administration of specific medications or blood products to minimize the risk of bleeding. Patients must demonstrate an understanding of the nature of the condition and the importance of performing interventions to minimize bleeding episodes.

### Connection Check 34.6

Which nursing action is indicated for the patient with thrombocytopenia?

- Avoid intramuscular injections.
- Encourage the patient to drink plenty of fluids.
- Place the patient on isolation precautions.
- Encourage frequent rest periods.

## WHITE BLOOD CELL DISORDERS

### Leukemia

#### Epidemiology

Leukemia, a malignant disease or “blood cancer,” is a disorder of the bone marrow in which WBCs begin multiplying uncontrollably. There are several types of leukemia, each named for the type of progenitor, or stem, cell from which it evolves. Leukemia is classified as acute or chronic, originating from a lymphoid stem cell (lymphocytes) or myeloid stem cell (granulocytes or neutrophils, erythrocytes, monocytes, and platelets). The four major leukemias are acute myelogenous leukemia (AML), chronic myelogenous leukemia (CML), acute lymphoblastic leukemia (ALL), and chronic lymphocytic leukemia (CLL). Acute myelogenous leukemia and ALL have acute, sudden onsets. Although CML and CLL may be present for years, they eventually degenerate into an acute phase and progress to death if untreated.

Genetic anomalies may be present in some cases, such as CML, also known as chronic myeloid leukemia, in which the presence of the Philadelphia chromosome (abnormal chromosome 22) has been confirmed in more than 90% of patients. Patients with Down's syndrome have also been shown to be at higher risk for developing leukemia because of the association between Down's syndrome and the

Philadelphia chromosome. Down's syndrome is associated with ALL. The Philadelphia chromosome, which is a balanced mutation of chromosome 9 and 22 resulting in the production of bcr/abl kinase proteins, is responsible for the aberrant cell growth seen in CML. However, the Philadelphia chromosome is rarely positive in children with Down's syndrome. Exposure to radiation or benzene has been linked to the development of AML or ALL; there was a high incidence of these acute leukemias following the Hiroshima and Nagasaki bombings in World War II. Patients who have been treated with chemotherapeutic agents and/or radiation therapy are at risk for developing leukemia several years after treatment as a result of possible alterations in bone marrow function. Smoking is also linked to leukemia. In general, leukemia is more prevalent in white males over the age of 60, but its incidence is not limited to age, sex, or race. Acute lymphoblastic leukemia is the most prevalent form of leukemia to occur in childhood.

### Pathophysiology

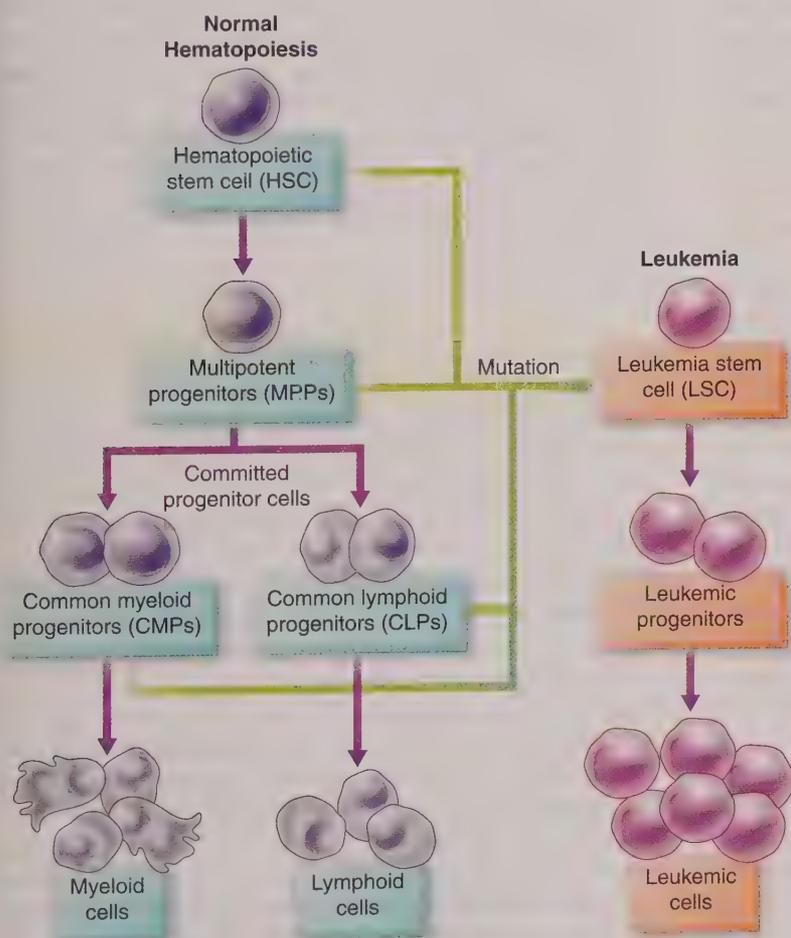

In leukemia, an unknown stimulus mutates either a myeloid or lymphoid stem cell. This single cell clones itself, producing an immature WBC known as a leukemic cell, or blast, which never matures as a result of the mutation. This cloning process becomes uncontrollable, filling the bone marrow with these leukemic cells, which subsequently get pushed

into the circulation. This uncontrollable production of WBCs is called **leukocytosis** (Fig. 34.7). Because of the mutation, these WBCs never mature and do not respond to the normal signal that leads to programmed cell death, or **apoptosis**. The bone marrow, spleen, and lymph tissue become congested with the blasts, leading to lymphadenopathies, splenomegaly, and infiltration of the body's mucous membranes and lungs.

### Clinical Manifestations

Secondary to the blast congestion, lymph glands in the neck, axillae, or groin and the left upper abdominal quadrant may become swollen and painful. The risk of infection is increased because these leukemic WBCs do not mature; therefore, the number of mature infection-fighting cells, or neutrophils, decreases. This is a condition known as **neutropenia**. Low-grade fevers are commonly observed upon diagnosis in response to minor infections. Major infections such as pneumonia usually do not occur until after chemotherapy initiation, which can cause profound neutropenia where the absolute neutrophil count (ANC) is less than  $1,000 \text{ mm}^3$ .

As leukemia progresses, the bone marrow, which is congested with leukemic cells, is not able to adequately produce RBCs and platelets. Patients often present with clinical manifestations of anemia, including fatigue, pallor, weakness, and shortness of breath, as well as bruising, petechiae,

**FIGURE 34.7** Normal hematopoiesis compared with the development of leukemic cells.

nosebleeds, and bleeding gums from the decreased number of platelets. Patients often present with low-grade fever in response to exposure to organisms that the immune system can usually handle. Leukemia left untreated is fatal, with infection being the primary cause of death.

## Management

### Diagnosis

Often a patient presents to the healthcare provider with complaints of flu-like symptoms such as fatigue, low-grade fever, and pallor, although many times a patient is asymptomatic, and a routine CBC reveals the leukemia. A CBC not only reveals the leukocytosis, or increased WBC count, but also demonstrates anemia and thrombocytopenia that occurs as a result of the congested bone marrow. A history and physical examination are performed. Confirmation of the diagnosis of leukemia usually follows a bone marrow biopsy that shows the type of leukemia and extent of the malignancy. Genetic testing can be performed on these cells to determine any chromosomal abnormalities.

### Medical Management

Systemic chemotherapy is initiated to destroy the leukemic cells and induce a remission that indicates that the bone marrow is free of leukemic cells and is able to produce healthy blood cells. Remission does not indicate a cure. Radiation therapy is sometimes used as part of this treatment. There are many different chemotherapeutic agents employed today in the treatment of leukemia, and they may be administered solely or in combination regimens. Numerous clinical trials are ongoing, all with the goal of inducing remission.

Treatment strategies consist of two main phases: remission induction and post-remission maintenance. Remission induction includes the initial administration of chemotherapeutic agents. High doses of chemotherapy are given and may be accompanied by radiation therapy. This usually causes the patient to become acutely ill. This is very difficult on the patient, especially if asymptomatic at the time of diagnosis, because the patient may feel the treatment is worse than the disease. Education regarding the progression of the disease and the need for chemotherapy, as well as helping the patient to establish a good support system, is crucial in the early stages of treatment. Routine CBCs to monitor the progression of myelosuppression caused by chemotherapy is indicated to prevent complications. Transfusions of RBCs and/or platelets are usually an aspect of the supportive care for these patients.

In the past, chemotherapy almost always led to infection as a result of the neutropenic state that these medications produce. The advent of granulocyte colony-stimulating factors (GCSFs) has changed this because they are frequently given post-chemotherapy to stimulate the bone marrow to produce neutrophils. Filgrastim (short-acting) and pegfilgrastim (long-acting) are given as subcutaneous injections. In many cases, these medications prevent some patients from developing post-chemotherapeutic infections.

After the induction phase, which may lead to a state of remission or partial remission, the patient usually enters a post-remission maintenance phase of care. Chemotherapy may continue at lower doses and/or less frequently in order to suppress the formation of leukemic cells. This may continue for months or years.

Transplantation is currently the only possibility for a cure from leukemia. Previously, bone marrow transplantation (BMT) was the only type of transplantation, but peripheral stem cell transplantation (PSCT) or hematopoietic stem cell transplantation (HSCT) are now more often used. With both procedures, donor cells are needed to transplant into the bloodstream of the patient, either the patient's own (**autologous**) or from a donor (**allogeneic**). The advantage of PSCT over BMT is primarily one of comfort for the donor. In a BMT, bone marrow is harvested via a large needle inserted into the iliac bone. (The bone marrow biopsy procedure is described in Chapter 33). The stem cells in a PSCT are gathered in a manner similar to donating blood from a peripheral vein. The stem cells are then separated in an apheresis machine (a machine that separates the stem cells from the rest of the blood components), and the blood is returned to the donor minus the stem cells. The success rate of transplantation is approximately the same for both procedures.

A transplantation is not without its potential complications in the form of graft-versus-host disease (GVHD) when donor bone marrow or stem cells attack the recipient. Managing GVHD is complicated and requires maintaining a balance between allowing the body some degree of immune response and suppressing this response to the extent that it can be fatal if the body's immune system successfully destroys the new stem cells. Despite enduring a transplantation, there is also the possibility that the leukemia can return, causing a relapse.

### Complications

Complications of leukemia are usually a result of the treatment for the disorder and the myelosuppression that occurs after chemotherapy or radiation. Although the disease itself may eventually be fatal as a result of infection or hemorrhage, the best chances of remission and prolonging life are specific treatments. The myelosuppression, a result of chemotherapy or radiation, can be profound. The resulting neutropenia places the patient at high risk of developing an infection, possibly life threatening. A fever is called a neutropenic fever when a patient's ANC is less than 1,000. Patients are instructed to institute neutropenic precautions (Box 34.2) because this is a dangerous situation for the patient, and immediate administration of IV antibiotics is indicated for patient survival. The post-treatment myelosuppression also leads to anemia. Thrombocytopenia is another complication and, just as with the RBCs and WBCs, may be suppressed by chemotherapy or radiation. Patients need continual education about bleeding precautions (see Box 34.1). Excessive bruising, petechiae, nosebleeds, conjunctival hemorrhaging, bleeding gums, hemoptysis, hematuria, or any gastrointestinal

## Box 34.2 Neutropenic Precautions

1. Frequent hand washing or the use of alcohol-based hand sanitizer by the patient and others coming into contact with the patient.
2. Avoid crowds. If the neutropenic patient must go out, a mask is indicated.
3. Avoid obviously sick people, small children, and pets while the neutrophil count is low.
4. Wash all raw fruits and vegetables well before eating. It is best to avoid fruits such as raspberries and blackberries that have little bumps and ridges and cannot be washed well.
5. Monitor temperature daily, and contact the healthcare provider if the temperature is greater than 100.4°F (38°C).
6. For fevers, rigors (shaking chills), and obvious clinical manifestations of illness, seek immediate medical attention. Rapid treatment with IV antibiotics is crucial to prevent sepsis and death.
7. There should not be any live plants or cut flowers in the home environment because they breed bacteria and mold. This also includes while the patient is in the hospital.
8. Avoid standing water in appliances such as humidifiers because this also breeds mold and bacteria.
9. If patients are started on prophylactic antibiotic, antiviral, and antifungal therapies, stress the importance of taking prescribed medications daily and completing the entire course of antibiotics.
10. A patient with neutropenia requires a private room if hospitalized.
11. Avoid rectal temperatures, suppositories, and enemas because of the normal bacteria in the rectum that could enter the bloodstream if there is rectal trauma associated with these interventions.

bleeding needs to be immediately reported to healthcare personnel.

### Nursing Management

#### Assessment and Analysis

Leukemia is usually discovered in a routine CBC because the patient is often asymptomatic. Clinical manifestations that may cause a patient to seek medical attention are a result of the anemia and thrombocytopenia that occur as a result of the bone marrow being clogged with WBCs.

- Leukocytosis
- Neutropenia
- Anemia
- Thrombocytopenia
- Shortness of breath, especially on exertion or lying flat
- Excessive bruising
- Petechiae
- Fatigue
- Pallor
- Dizziness
- Fatigue
- Low-grade fevers in response to minor infections

#### Nursing Diagnoses

- **Risk for infection** related to immature leukemic cells' inability to fight infection or neutropenia
- **Risk for impaired tissue perfusion** related to the bone marrow's decreased ability to produce adequate RBCs because of the congestion caused by the increased number of leukemic WBCs
- **Risk for bleeding** related to the bone marrow's decreased ability to produce adequate platelets because of the congestion caused by the increased number of leukemic WBCs
- **Risk for compromised family coping** related to the diagnosis of leukemia and lifestyle changes to accommodate treatment

#### Nursing Interventions

##### Assessments

- Vital signs  
*Low-grade fevers in response to minor infections by cuts, abrasions, sores, and so forth occur because of the decrease in mature neutrophils needed to produce a more pronounced temperature elevation.*
- Fatigue, pallor, dizziness, shortness of breath  
*These clinical manifestations of anemia occur as a result of decreased erythrocytosis because the bone marrow is congested with WBCs.*
- Excessive bruising, petechiae (different from a rash—when you push, petechiae do not blanch)  
*These clinical manifestations of thrombocytopenia occur as a result of decreased production of platelets because the bone marrow is congested with WBCs, and there may be spontaneous bleeding into the subcutaneous tissues.*
- CBC values  
*Leukocytosis of leukemic WBCs occurs from a single mutation. The excessive WBCs clog the bone marrow, resulting in decreased production of RBCs and platelets.*

##### Actions

- Administer chemotherapy as prescribed.  
*The patient is started on chemotherapy to destroy the leukemic cells.*
- Institute neutropenic precautions.  
*The patient needs to take extra precautions to prevent infection due to low neutrophil counts.*
- Prophylactic use of antibiotics, antivirals, and antifungals as ordered  
*A prophylactic regimen of antibiotics, antivirals, and antifungals is often initiated to provide added protection against infection when the neutrophil count is low.*
- Administer IV antibiotics.  
*When the ANC is less than 1,000, it is imperative to start IV antibiotics immediately in order to prevent sepsis and possible death.*
- Symptom management (nausea/vomiting/diarrhea, ulcerations of the mouth)  
*Post-chemotherapy/post-radiation symptom management is continuously assessed to maintain the patient's quality of life.*

*Antiemetics or antidiarrheal medication are indicated to minimize discomfort as well as to decrease fluid loss.*

- Administer ordered blood products.

*The patient may require blood products as cell counts (RBCs and platelets) drop because of the myelosuppression caused by chemotherapy.*

### ■ Teaching

- Neutropenic precautions (see Box 34.2)

*It is essential that the patient/family is instructed in order to prevent a major infection or to initiate treatment immediately upon exhibiting the clinical manifestations of an infection.*

- Clinical manifestations of anemia

*In order to minimize the anemia and its complications, education is essential for prompt administration of growth factor or transfusions.*

- Manifestations of thrombocytopenia

*It is essential that the patient/family seek medical attention if the patient has any early signs of bleeding.*

- Bleeding precautions (see Box 34.1)

*The patient needs to have practical knowledge about how to prevent bleeding when the platelet count is low.*

- Diagnosis of leukemia

*The patient/family needs to understand the course that the leukemia takes and why it is important to follow treatment plans as recommended.*

- Adverse reactions of chemotherapy or radiation

*The patient/family needs to know what side effects may occur as a result of the treatment regimen in order to notify healthcare personnel of any problems that need to be addressed.*

- Possibility of sterility

*Chemotherapy or radiation can render the patient sterile. The patient needs to be educated on alternative methods of family planning, including sperm or egg donation.*

### Evaluating Care Outcomes

Untreated leukemia is a fatal disorder. The goals of treatment are to induce a remission for the patient and to minimize or prevent complications. Treatments are considered effective when the patient has decreased clinical manifestations of anemia, infection, and bleeding. Prolonging life and improving the quality of life are important considerations in treating patients with leukemia. Symptom management of the chemotherapy and radiation therapy aids in improving the quality of life. At present, a BMT or PSCT is the only chance of achieving a cure for leukemia.

### Connection Check 34.7

The nurse correlates which diagnostic result as increasing the risk for infection in the patient with leukemia?

- WBC  $11^3/\text{mm}^3$
- ANC  $500 \text{ mm}^3$
- Hgb  $8.6 \text{ g/dL}$
- Platelets  $112,000 \text{ mm}^3$

## LYMPH DISORDERS

### Malignant Lymphomas

Malignant lymphomas are divided into two main classifications: Hodgkin's lymphoma, or Hodgkin's disease, and non-Hodgkin's lymphoma (NHL). Hodgkin's lymphoma is characterized by the presence of Reed–Sternberg (RS-H) cells, which are specific giant lymphocytes associated with this disorder. The category of NHL includes all other types of lymphoma, most of which evolve from B- and T-lymphocyte cells. Natural killer cells infrequently develop into lymphomas. The causes of all lymphomas are unknown.

### Epidemiology

Hodgkin's lymphoma accounts for approximately 14% of all lymphomas and has a higher survival rate than non-Hodgkin's lymphoma. The incidence of all lymphomas occurs more in men than in women. There is an increased risk in childhood through early adulthood; then the incidence declines until after the age of 55, when it again increases. In the United States, Hodgkin's lymphoma occurs more in those of Caucasian descent, followed by those of African and then Asian descent. There is a higher incidence of Hodgkin's lymphoma in those of higher socioeconomic status, but the reason is unknown. Other risk factors for Hodgkin's lymphoma include infection with the Epstein–Barr virus and being a first-degree relative (parent or sibling) of someone with Hodgkin's disease, both of which suggest possible infectious or familial causes of Hodgkin's disease.

Non-Hodgkin's lymphomas (NHLs) represent approximately 4% of total cancer incidence and account for 4% of cancer-related deaths. An individual has approximately a 1 in 50 chance of developing NHL. The incidence in men is greater than in women, and in the United States, it occurs more in those of Caucasian as compared with African descent. The documented incidence of NHL is higher in industrialized countries than in developing countries. Variations of NHL have different incidences in various geographical areas, and the incidence peaks in preadolescence, then generally occurs again in late adulthood. Causes of NHL are linked to exposure to certain pesticides; therefore, there are higher rates of lymphomas in individuals associated with farming and gardening. Individuals with autoimmune disorders and a history of organ transplantation also have higher rates of NHL. Being infected with HIV/AIDS, the Epstein–Barr virus, human herpesvirus 8, and *Chlamydia* and *Helicobacter pylori* bacteria also increases the risk of developing NHL. Additionally, prior treatment for Hodgkin's lymphoma or with radiation increases the risk of NHL.

### Pathophysiology

Malignant lymphomas evolve from a single progenitor, or stem, cell in a lymph node that develops into a solid tumor or mass. As the cancer cells multiply and divide, they spread from the involved lymph node through the lymph system and can eventually affect other lymphoid tissue, including the spleen. When the cancer is left untreated, the involvement

of major organs can occur as a result of metastasis or pressure from the mass. The differentiating characteristic of Hodgkin's disease and NHL is the presence or absence of the RS-H cell, a multi-nucleoli cell. The RS-H cell is present in Hodgkin's disease and absent in NHL. The presence of metastasis beyond the lymph node is termed *extranodal lymphoma* and helps determine the treatment and prognosis.

### Clinical Manifestations

The clinical manifestations of Hodgkin's disease (HD) and NHL are similar, and patients usually do not seek medical attention until the disease has progressed to the point where systemic involvement has occurred. Clinical manifestations include painless swelling of the lymph nodes in the neck, underarm, and groin; low-grade fevers for no apparent reason; drenching night sweats; unexplained weight loss of more than 10% in less than 6 months; and fatigue. These are known as the "B symptoms" because of the systemic action of the B lymphocytes. Generalized pruritus, or itching, with pronounced excoriation from scratching is present in a large percentage of patients presenting with HD, although the origin is unknown. Another unique feature of HD, which has no known etiology, is alcohol-induced pain at the site of the involved lymph node after a few sips of any alcoholic beverage.

Staging of lymphomas is generally characterized by the classification system established by the World Health Organization (Table 34.4). Staging also is further differentiated between "E" for extranodal and "S" for the involvement of the spleen. Depending on the type of lymphoma, these tumors are usually also classified as indolent (slowly progressive), aggressive, or highly aggressive.

The involvement of major organ groups may also cause further clinical manifestations that cause individuals to seek medical attention. Clinical manifestations of shortness of breath and a feeling of fullness may occur as the enlarging lymph nodes spread to the spleen or liver or compress the vena cava or spine.

### Management

#### Diagnosis

A detailed history and physical examination are the first steps to diagnosing a malignant lymphoma, usually followed

by radiological testing that may include a routine chest x-ray, computed tomography (CT) scan, positron emission tomography (PET) scan, or magnetic resonance imaging (MRI). A lymph node biopsy usually provides a definitive diagnosis. Examination of the tissue and determining the presence of the RS-H cells determine whether the patient has HD or NHL. A CBC may show evidence of bone marrow involvement with possible anemia and abnormal WBC count. If bone marrow involvement is suspected, a bone marrow biopsy may be indicated. A lumbar puncture is performed if central nervous system involvement is suspected.

#### Medical Management

Treatment of malignant lymphomas usually involves the use of chemotherapeutic agents and/or radiation therapy to destroy the tumor cells. Surgical intervention to remove the tumor may also be indicated. If the individual has been diagnosed with an indolent NHL, a wait-and-see approach may be used initially because of the slow growth of the tumor. Stem cell transplantation may be indicated in some patients, but this depends on the type and stage of the disease. The rationale for transplantation is to destroy the mutant lymphoid stem cells with chemotherapy/radiation and then replace them with healthy donor cells. The success of stem cell transplantation in the lymphoma population varies and may depend on the aggressiveness of the underlying disease.

#### Surgical Management

If a splenectomy is required to treat lymphomas, respiratory problems may occur because of the spleen's proximity to the diaphragm and the need for a high abdominal incision. Pneumonia and atelectasis are possible complications due to postoperative pain and the patient's reluctance to cough and deep breathe. Development of pancreatitis may occur because the tail of the pancreas is near the spleen and may be damaged during surgery. Because of the spleen's role in the immune system, infection is a serious postoperative complication. Overwhelming post-splenectomy infection is a serious complication that has a high mortality rate because sepsis can quickly occur and is usually a result of streptococci, *Neisseria* spp., or influenza. Patients should maintain lifetime vaccinations against these organisms if a splenectomy is performed.

#### Complications

As the cancer progresses, complications involving major organs and structures can occur, including superior vena cava (SVC) syndrome, spinal cord compression, hypercalcemia, **myelodysplasia** (abnormal blood cell production), severe hepatic or renal dysfunction, hyperviscosity of blood, or venous thrombotic events. Superior vena cava syndrome, spinal cord compression, and hypercalcemia are considered oncological emergencies, and individuals who develop these conditions need immediate medical attention. A splenectomy may be necessary in some patients because of splenic involvement, either as the primary site (tumor in the spleen) or from metastasis of the cancer.

**Table 34.4 World Health Organization Staging of Lymphoma**

Stage	Description
Stage I	Cancer is limited to a single node.
Stage II	Cancer is found in two or more lymph nodes on the same side of the diaphragm.
Stage III	Cancer is found in lymph groups on both sides of the diaphragm.
Stage IV	Cancer is found in one or more organs in addition to lymph nodes.

In SVC syndrome, the enlarging lymph node compresses the flexible superior vena cava. Edema of the face and one or both arms, shortness of breath, chest pain, or dysphagia develops because there is engorgement in the upper torso and impaired venous return. Compression of the inferior vena cava may occur, but the clinical manifestation of fullness in the abdomen is not as dramatic or life threatening. Thrombosis may occur as venous flow is impeded by the expanding lymph node, slowing blood flow and increasing stasis.

Compression of the spinal cord may result in neurological deficits and paralysis because the expanding tumor may apply pressure on the spinal cord or nerve roots. Neurological deficits and paralysis depend on the location of the spinal cord or nerve root compression. In many cases, immediate radiation or chemotherapy is initiated to reduce the tumor, which decreases the pressure on the spinal cord.

Hypercalcemia is a result of metastasis to the bones that causes bone breakdown (resorption by osteoclasts), and calcium is released into the bloodstream. Hypercalcemia occurs as the serum calcium level exceeds 11 mg/dL, and clinical manifestations range from dehydration and polyuria to decreased neuromuscular activity, confusion, stupor, heart block, and death.

As the bone marrow becomes involved, myelodysplasia (impaired production of RBCs, WBCs, and platelets) occurs. The patient may exhibit clinical manifestations of anemia. White blood cells may be abnormally high or low. In either case, the number of neutrophils is low, and the patient is at risk for infection. Inadequate platelet production places the patient at risk for bleeding. Hyperviscosity can occur as a result of the myelodysplasia or impaired hepatic or renal function and places the patient at a higher risk of developing thrombotic events.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of malignant lymphomas are a result of the enlarging lymph node(s) and systemic involvement of the B lymphocytes. The nurse monitors for the following clinical manifestations in patients with lymphomas:

- Painless swelling of the cervical, axillary, and inguinal nodes
- Low-grade fevers of unknown origin
- Drenching night sweats
- Unexplained weight loss of greater than 10% in less than 6 months
- Fatigue
- Anemia
- Neutropenia
- Thrombocytopenia

The cause of the generalized pruritus and the alcohol-induced pain in HL is still unexplained.

### Nursing Diagnoses

- **Risk for infection** related to bone marrow involvement and adverse effects of treatment

- **Activity intolerance** related to anemia caused by bone marrow involvement
- **Risk for ineffective coping** related to the diagnosis and lifestyle changes to accommodate treatment

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Low-grade fever, drenching night sweats, weight loss, and fatigue are a result of B-cell involvement, which causes systemic clinical manifestations.*
- Pain, breathing pattern, face/neck  
*Shortness of breath, chest pain, dysphagia, and edema of the face and/or arms may indicate SVC syndrome with resulting venous congestion.*
- Neurological status  
*The expanding lymphoma may cause spinal cord or nerve root compression.*
- Cervical, axillary, and inguinal lymph nodes  
*Enlarged lymph nodes are a result of the expanded lymphoma, and the swelling may be painless.*
- Skin  
*Generalized pruritus/itching can increase the risk of bleeding.*
- CBC results  
*A CBC may show bone marrow involvement with impaired blood cell production, resulting in decreased RBCs, WBCs, and platelets.*
- Lower extremities  
*Pain or swelling may occur secondary to thrombus formation if lymphoma compresses veins, slowing blood flow and increasing venous stasis.*
- Serum calcium levels  
*If metastasis of the lymphoma involves the bones, the resulting bone breakdown releases calcium, causing hypercalcemia.*
- Activity tolerance  
*Fatigue may develop as a result of the anemia caused by myelosuppression.*

#### ■ Actions

- Administer blood products as ordered.  
*Transfusions may be required as blood counts drop because of the myelosuppression that occurs as a result of the treatment regimens.*
- Administer chemotherapeutic agents.  
*Patients will be started on chemotherapy as a primary treatment of lymphoma.*
- Administer IV fluids as prescribed.  
*Increased insensitve fluid loss may develop secondary to fevers and drenching sweats. Additionally, in patients with hypercalcemia secondary to bone breakdown, increased fluids decrease the calcium concentration in the kidneys and decrease the risk of calcium-containing renal calculi.*
- Symptom management  
*Symptom management of the disorder itself, as well as symptoms that may occur as a result of the chemotherapy and radiation, is the focus of nursing care. Easing the discomfort*

of itching and the drenching night sweats is important to the comfort of the patient with Hodgkin's disease, as is managing any clinical manifestations of therapy such as nausea and vomiting.

- Obtain routine CBCs.

*Myelosuppression may be a result of chemotherapy or radiation therapy. Hemoglobin and WBC counts need to be monitored closely, as does the platelet count.*

- Provide emotional support.

*Emotional support is essential to patients with a cancer diagnosis. Helping them to deal with fears of death and dying and referring them to needed resources are essential to helping them manage the course of the disease.*

### ■ Teaching

- Disease process

*Knowledge of the disease and its course and treatment helps patients better manage the condition and may improve compliance with ordered interventions.*

- Risk of infection

*Patients and family need to understand the importance of good hand hygiene to minimize infection and require instruction to stay away from crowds and obviously sick people when neutrophil counts are low.*

- Maintaining treatment schedules

*Chemotherapy and radiation therapy schedules are determined from the results of clinical trials to provide the best chance of remission and/or cure. Patients need to understand the importance of keeping scheduled treatment appointments.*

- Encourage frequent rest periods.

*Fatigue may be a result of the anemia caused by bone marrow involvement and/or compounded by the myelosuppression as a result of treatment.*

- Dietary intake

*Instruction may be necessary for maintaining adequate nutrition.*

- Clinical manifestations of potential complications

*Patients need to understand the importance of seeking immediate medical attention for clinical manifestations, such as shortness of breath, edema of the face and/or arms, chest pain, fevers when neutropenic, or any neurological deficits, that may indicate complications.*

- Possibility of sterility

*Chemotherapy or radiation therapy may cause sterility. Those in childbearing years need to be educated about alternative ways of conceiving, including sperm and egg banking.*

### Evaluating Care Outcomes

Improving the quality of life of patients with malignant lymphomas is the goal of nursing care. Medical and nursing interventions are based on providing patient comfort from the clinical manifestations as well as managing the adverse reactions caused by treating the lymphoma with chemotherapy, radiation, and/or PSCT. The effectiveness of treatments is correlated with normal blood cell counts,

sufficient energy to participate in normal activities of daily living, no bleeding, and the absence of infections. Patients and families require education about the various options for managing these clinical manifestations as well as the possible complications of both the disorders and the treatments. When untreated, malignant lymphomas are fatal.

### Connection Check 34.8

A patient with lymphoma is beginning the induction chemotherapy regimen. Which information is most essential for the nurse to include in the treatment plan?

- Advance directives
- Bleeding precautions
- Importance of frequent rest periods
- Neutropenic precautions

### Multiple Myeloma

Multiple **myeloma** is a hematologic malignancy involving cells of the immune system that produce antibodies. It is thought that this cancer is caused by an overgrowth of a single clone of stimulated immunoglobulin secreting “B” lymphocytes or plasma cells. The excess antibodies produced by these malignant plasma cells accumulate as extra immunoglobulin or gamma globulin; therefore, multiple myeloma is often referred to as a monoclonal gammopathy.

### Epidemiology

Multiple myeloma, an incurable B-cell malignancy, is responsible for approximately 13% of all hematologic cancers, and the incidence is about 5 to 7 cases per 100,000 per year. According to the American Cancer Society, this plasma cell malignancy occurs twice as often in African Americans than Caucasian Americans. Men have a slightly higher risk of developing this type of cancer than women. The average age for developing multiple myeloma is 62 years old, and the risk of developing this type of cancer goes up as people age. Less than 1% of the cases of multiple myeloma are diagnosed in individuals who are younger than 35 years old. In 2018, the American Cancer Society estimated that about 16,400 men and 14,370 women were diagnosed that year. The lifetime risk for an individual living in the United States is about 0.8%. The reported risk factors for developing multiple myeloma include exposure to herbicides, insecticides, petroleum, heavy metals, plastics, and radiation. Individuals with other plasma cell diseases, such as monoclonal gammopathy of undetermined significance (MGUS) or solitary plasmacytoma, are at higher risk of developing multiple myeloma later in life. The survival for this type of malignancy ranges from 1 year to 10 years, with a mean survival of 3 years. The 5-year survival rate, according to the American Cancer Society, is 46.6%.

## Pathophysiology

Multiple myeloma arises from an asymptomatic premalignant proliferation of monoclonal plasma cells. The malignant cells of multiple myeloma, plasma cells and plasmacytoid lymphocytes, are the most mature cells of the B lymphocytes. B-cell maturation is associated with a programmed rearrangement of DNA sequences in the process of encoding the structure of mature immunoglobulins. In this disease, there is an overproduction of monoclonal immunoglobulin G (IgG) and immunoglobulin A (IgA) as well as the light chains that are found in the serum or urine using electrophoresis. Interleukin 6 (IL-6), tumor necrosis factor, and interleukin 1b are currently being studied to determine if these cytokines play a role in the growth of myeloma cells and the pathogenesis of multiple myeloma. This neoplastic proliferation of plasma cells involves more than 10% of the bone marrow, and these bone lesions are caused by an imbalance in the function of osteoblast and osteoclasts.

## Genetic Connections

### Multiple Myeloma

Genomic instability with translocations of the immunoglobulin heavy-chain locus chromosome 14q32 accounts for 50% of the cases. Secondary late-onset translocations and gene mutations are implicated in disease progression. Genetic abnormalities alter the expression of the adhesion molecules on the myeloma cells, resulting in the “up-regulation” of cell-cycle regulatory proteins and anti-apoptotic proteins. Researchers are now examining the microenvironment of tumor cells to determine whether or not they play a role in the development of myelomas. The prognosis for these patients depends on the tumor burden and the proliferation rate of the malignant cells.

## Clinical Manifestations

The patient with multiple myeloma often presents to the healthcare provider with a history of fatigue, weakness, bone pain, recurrent infections, weight loss, and paresthesia. Bone pain, particularly back pain, is a common presenting complaint and is secondary to lytic destruction. The weakness, pallor, and fatigue are related to the anemia associated with this disease process. This malignancy is characterized by six cardinal features: lytic bone disease, the presence of a monoclonal antibody protein referred to as the “M” protein, anemia, renal insufficiency, hypercalcemia, and an infectious diathesis or tendency/predisposition to infection.

## Management

### Diagnosis

The differential diagnosis of multiple myeloma is made when there is a monoclonal plasma cell count greater than or equal to 10%, presence of serum or urine monoclonal proteins, and myeloma-related organ dysfunction. The CRAB criterion is useful when formulating a diagnosis of multiple myeloma and includes *hyperCalcemia* (serum calcium greater than 11.5 mg/dL), *Renal insufficiency* (serum creatinine greater than 2 mg/dL), *Anemia* (hemoglobin less than 10 g/dL or greater than 2 g/dL below the lower limit of normal range), and *Bone disease* (lytic lesions, severe osteopenia, or pathological fractures).

Diagnostic studies include a CBC; electrolytes, including serum calcium; uric acid and creatinine levels; serum and urine protein electrophoresis with immunofixation (detection and typing of monoclonal antibodies or immunoglobulins in serum or urine); quantification of serum and urine monoclonal proteins; and measurement of free light chains. C-reactive protein and beta-2 microglobulin (expression of tumor burden) are also assessed. There is a positive presence of Bence Jones protein due to the excretion of light chains of immunoglobulins in the urine. The excess of light chains is directly toxic to renal structures and is an important aspect of the complications found in multiple myeloma. The diagnostic evaluation may also include bone marrow aspiration, skeletal survey, and bone-density measurements. An MRI may be performed to rule out spinal cord compression if the patient complains of back pain. Multiple myeloma is also suspected if there is a high ratio of total protein to albumin or if the patient presents with spinal cord compression.

### Medical Management

First-line therapy includes the use of bisphosphonates, radiation therapy, DVT prophylaxis, dexamethasone, autologous stem cell transplantation, and high-dose chemotherapy (thalidomide, lenalidomide, bortezomib). Thalidomide and lenalidomide were originally used for the treatment of pregnancy-associated morning sickness but were withdrawn from the market due to teratogenicity (damage to the unborn fetus). However, both thalidomide and lenalidomide possess potent activity and are approved for the treatment of patients with newly diagnosed multiple myeloma or heavily pretreated relapsed or refractory multiple myeloma.

### Complications

As the disease progresses, complications develop secondary to the underlying pathophysiology as well as to some of the treatment approaches, such as side effects of chemotherapy. Hematologic complications include anemia, bone marrow failure, and bleeding disorders. There is also increased susceptibility to infections, and bone complications include pathologic fractures, spinal cord compression, and hypercalcemia secondary to bone breakdown. Neurological

complications may develop, such as spinal cord and nerve root compression and intracranial plasmacytomas (tumor consisting of abnormal plasma cells in the bony skeleton). Renal failure may develop secondary to renal stones and demineralization of bone or the toxic effects of Bence Jones protein on the renal epithelial cells.

## Nursing Management

### Assessment and Analysis

The clinical presentation of multiple myeloma is related to the multisystem effects of this disease process and often includes the following:

- Bone pain, particularly in the back
- Numbness and tingling associated with neuropathies
- Anemia (normocytic, normochromic)
- Weakness, pallor, and fatigue
- Increased susceptibility to infection
- Hypercalcemia
- Hypercalciuria
- Renal stones

### Nursing Diagnoses

- **Acute/chronic pain** related to decreased integrity/destruction of bone
- **Impaired physical mobility** related to pain and possible fracture
- **Risk for infection** related to chemotherapy-related immunosuppression and plasma cell malignancy
- **Risk for injury** related to pathological fractures/decreased integrity of bone
- **Impaired urinary output** related to renal damage
- Fear related to cancer diagnosis

### Nursing Interventions

#### Assessments

- Vital signs  
*Tachycardia and tachypnea are secondary to the heart and lungs compensating for decreased oxygenation of body tissues secondary to anemia. Elevated temperature may indicate an infectious process.*
- Fatigue, pallor, and shortness of breath  
*Fatigue, pallor, and shortness of breath worsen with increasingly decreased levels of hemoglobin causing inadequate tissue perfusion.*
- Pain  
*Pain, particularly back pain, develops secondary to bone destruction/breakdown.*
- Paresthesias  
*Nerve root compression may develop secondary to vertebral collapse secondary to bone breakdown.*
- Intake and output  
*Renal damage may occur secondary to myeloma cast neuropathy or calcium precipitation that results from the bone breakdown.*

- Serum and urine calcium  
*Bone breakdown may lead to hypercalcemia and hypercalciuria that can result in calcium precipitation in the kidney tubules.*
- Serum blood urea nitrogen (BUN) and creatinine  
*Damage to the distal and collecting tubules of the kidney may lead to renal insufficiency that elevates both serum and creatinine levels.*

#### Actions

- Administer chemotherapy.  
*Destroys the abnormal cells*
- Administer bisphosphonate therapy as ordered.  
*Bisphosphonate therapy reduces bone disease, fractures, and skeletal complications.*
- Administer pain medications as ordered.  
*Pain may develop related to bone destruction, nerve compression, or renal stones.*
- Encourage fluid intake as tolerated.  
*Increasing fluid intake can facilitate diluting the elevated serum and urine calcium levels.*
- Position patient to facilitate comfort.  
*Nerve root and spinal compression may be relieved by positioning that minimizes the compression.*
- Encourage ambulation as tolerated.  
*Ambulation supports bone activity (buildup) and minimizes the complications of immobility, such as DVT and muscle wasting.*

#### Teaching

- Immediately report any clinical manifestations of fatigue, shortness of breath, dizziness, or confusion.  
*Resolution of the anemia through supplementation or blood transfusions is needed to increase tissue perfusion.*
- Report any sudden onset of severe pain or new location, especially of back pain, which could indicate a pathological fracture.  
*Vertebral collapse or a pathological fracture may present with sudden, severe pain due to damage to nerves and surrounding tissues.*
- Report changes in sensation, increased numbness and tingling, or changes in motor function.  
*Nerve root compression or spinal cord compression, associated with damage to bone, presents with these clinical manifestations.*
- Instruct in the use of nonpharmacological pain management methods, such as music, relaxation, deep breathing, imagery, distraction, and progressive muscle relaxation.  
*These nonpharmacologic methods or complementary health approaches may support management, with or without concomitant pain medication administration.*

#### Evaluating Care Outcomes

Symptom management and preventing complications are priorities in evaluating care outcomes for patients with multiple myeloma. Pain that is controlled and the absence

of infection are the goals of treatment, as well as facilitating optimal renal function. Patients with multiple myeloma require consistent healthcare follow-up, as well as psychosocial support due to the lack of a cure for this disease. Patients must demonstrate an understanding of the nature of the condition and the importance of performing interventions to minimize complications.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Owens has a bone marrow biopsy, which confirms the diagnosis of acute myelogenous leukemia (AML). A repeated CBC with a differential shows Hgb 9.1 g/dL, Hct 27.9%, WBC  $9.8 \times 10^3/\text{mm}^3$ , and platelets  $72,000/\text{mm}^3$ , and the ANC is  $3.1/\text{mm}^3$ . Mr. Owens's oncologist recommends that he immediately start chemotherapy treatment with a regimen of daunorubicin and Ara-C. This regimen is repeated through several cycles, or courses, of chemotherapy. Two weeks after induction of chemotherapy, Mr. Owens's CBC results are Hgb 7.9 g/dL, Hct 23.8%, WBC  $5.5 \times 10^3/\text{mm}^3$ , ANC  $0.6/\text{mm}^3$ , and platelets  $19,000/\text{mm}^3$ . He is given transfusions of packed RBCs, platelets, and an injection of filgrastim (Neupogen), a granulocyte colony-stimulating factor (GCSF), and is started prophylactically on moxifloxacin, acyclovir, and Diflucan. Supportive care with transfusions and growth factors is repeated as indicated by routine CBCs. Six months after chemotherapy induction, Mr. Owens achieves a remission, confirmed by a bone marrow biopsy.

#### Case Study Questions

- When a history of Mr. Owens is completed, which factor does the nurse determine is the highest risk for leukemia?
  - Age
  - Gender
  - Worked in an oil refinery
  - Smoker
- Which CBC result correlates with a diagnosis of leukemia for Mr. Owens?
  - RBC 3.2 million cells/ $\text{mm}^3$
  - WBC  $6.2 \times 10^3/\text{mm}^3$
  - Hct 28.1%
  - Platelets  $97,000/\text{mm}^3$
- After Mr. Owens starts chemotherapy treatment, his laboratory results are Hgb 7.9 g/dL, Hct 23.8%, WBC  $5.5 \times 10^3/\text{mm}^3$ , ANC  $0.6/\text{mm}^3$ , and platelets  $19,000/\text{mm}^3$ . Which potential complication is the nurse's first priority?
  - Anemia
  - Leukocytosis
  - Thrombocytopenia
  - Infection

- Which statement by Mr. Owens informs the nurse that he needs more education about bleeding precautions regarding his thrombocytopenia?
  - "I need to buy an electric razor to use for shaving."
  - "I have an appointment with the dentist to get my teeth cleaned."
  - "I guess I have to stop walking around barefoot."
  - "My wife has been after me to clean up my clutter in the family room. I guess I better do that."
- Mr. Owens should notify medical personnel and/or go to the emergency department immediately if he experiences any of the following symptoms: (*Select all that apply.*)
  - T 102°F (38.9°C)
  - Chills
  - Nosebleed that lasts more than 10 minutes
  - Diarrhea, three episodes within a 24-hour period
  - Facial flushing

## CHAPTER SUMMARY

Nonmalignant hematological disorders include nonproliferative or decreased production of red blood cells (RBCs), increased destruction of RBCs, or severe blood loss. Anemia indicates hematological dysfunction that requires a determination of etiology and severity, and the cause of the anemia is important and can indicate the type of treatment that is indicated. Nutritional deficiencies leading to a decreased production or life span of the RBCs are evident in iron, vitamin B<sub>12</sub>, or folic acid deficiency. Destruction of RBCs can be caused by artificial heart valves or genetic mutations. A decreased life span and hemolysis of the RBCs occur in sickle cell disease. Sickle cell disease can result in vasoocclusive crises during hypoxic situations. Blood loss can result from trauma, injury, peptic ulcer disease, polyps, colon cancer, or genetic abnormalities such as hemophilia. Iron-deficiency anemias are often caused by inadequate dietary iron intake of meat, dark green leafy vegetables, dried beans, beets, and iron-fortified breads and cereals. Other causes include hemorrhage (including heavy menstrual bleeding), ulcerative gastrointestinal problems, poor iron absorption, and some gastrointestinal surgeries. Iron is essential to the formation of hemoglobin, and deficiency causes symptoms of anemia. Treatment includes an iron-rich diet or oral supplementation. In cases of poor absorption or gastrointestinal surgeries, supplementation can be delivered in an intramuscular (IM) or IV formulation.

Vitamin B<sub>12</sub> deficiency occurs because of inadequate dietary intake of meat, seafood, eggs, and dairy products or malabsorption disorders including gastrointestinal resections, autoimmune diseases, alcoholism, Crohn's disease, and long-term use of medications such as proton-pump

inhibitors or H<sub>2</sub> blockers. In addition to symptoms of anemia, unresolved vitamin B<sub>12</sub> deficiency leads to neurological clinical manifestations such as peripheral neuropathy, confusion, depression, impaired taste, impaired equilibrium, and visual disturbances. Treatment includes adequate dietary intake of vitamin B<sub>12</sub> or supplementation (oral or parenteral) in cases of malabsorption.

Folic acid is provided in the diet from fortified cereals and grains, legumes, green leafy vegetables, bran, yeast, and nuts. Clinical manifestations of folic acid deficiency include symptoms of anemia as well as neural tube and orofacial abnormalities in infants. Short- or long-term supplementation of folic acid depends on the causative factors.

Sickle cell disease is an inherited disorder passed down from parents who each carry the sickle cell gene. Individuals with sickle cell disease often present with sickle cell crises that are precipitated by anything that causes hypoxemia or increases vasoconstriction, leading to the sickling of the RBCs. Clinical manifestations of a sickle cell crisis include fatigue, pallor, and shortness of breath, as well as pain in the joints, bones, chest, and abdomen as the RBCs sickle, causing decreased oxygen-carrying capacity and increased hemolysis of RBCs. Treatment is aimed at the prevention of crises and symptom management, and long-term management is aimed at minimizing complications and organ dysfunction.

Aplastic anemia is a rare disease due to bone marrow suppression that results in pancytopenia. A medical emergency, the mortality rate is greater than 70%. Clinical manifestations develop secondary to decreased production of RBCs, including tachycardia, shortness of breath, fatigue, and pallor. The decreases in WBCs puts the patient at higher risk for infection, and the decreased platelets increase the patient's risk of bleeding. Diagnosed via complete blood count (CBC), reticulocyte count, hemoglobin electrophoresis, and bone marrow biopsy, management of this disease is aimed at replacing blood components, stimulating bone marrow function, and bone marrow transplantation (if there is an available HLA-matched sibling donor). Nursing management focuses on managing tissue perfusion, preventing infection, and monitoring the risk for bleeding.

A lack of glucose-6-phosphate dehydrogenase, a metabolic enzyme that protects RBCs from oxidative stresses that can lead to cellular destruction, results in G6PD deficiency. An inherited recessive X-linked disorder, the diagnosis is made through DNA testing, as well as evaluation of the CBC, reticulocyte count, and blood smear analysis. Clinical manifestations develop secondary to hemolysis that results from the G6PD deficiency and include shortness of breath, tachycardia, pallor, elevated liver enzymes, jaundice, and splenomegaly. Prevention is the key to the management of this disease and focuses on medications and the avoidance of certain foods (fava beans). Nursing management focuses on minimizing the complications associated with decreased tissue perfusion and maximizing oxygenation.

Polycythemia is an increase in the production of RBCs. Clinical manifestations include headache, dizziness, shortness

of breath, generalized pruritus, flushing of the face, fatigue, vision problems, and a feeling of fullness in the left upper abdomen. Treatment ranges from doing nothing, when the patient is at higher altitudes, to performing therapeutic phlebotomies to reduce blood volume in order to ease symptoms.

Thrombocytopenia is the decreased production of platelets resulting in clinical manifestations of excessive bruising, petechiae, epistaxis, bleeding gums, black and tarry stool, and/or hematuria. Treatment aims at preventing or minimizing blood loss from hemorrhage. Hemophilia is a hemorrhagic genetic disorder resulting from decreased clotting factors VIII or IX and may include thrombocytopenia. Treatment is aimed at replacement of the missing clotting factor in order to minimize blood loss. Disseminated intravascular coagulation occurs secondary to severe trauma and leads to abnormal thrombosis formation and breakdown, consuming clotting factors and placing the patient at risk of bleeding. Treatment is aimed at providing supportive care and resolution of the underlying condition. Heparin-induced thrombocytopenia (HIT) appears to be an immune response of the body to the administration of heparin occurring 5 to 14 days after introduction, causing the formation of multiple thrombi and spontaneous bleeding. Cessation of heparin administration is the initial step in correcting HIT.

Malignant hematological disorders include two types of white blood cell (WBC) malignancies: lymphoid and myeloid. This can be further divided into the two large groups of leukemia and lymphoma based on the clinical and pathologic presentation. Leukemia is a type of "blood cancer" resulting from an uncontrollable production of WBCs. This extreme leukocytosis results in extremely high WBC counts and decreased RBC and platelet counts due to the congested bone marrow. Clinical manifestations include signs of anemia (fatigue, pallor, shortness of breath, weakness), bruising, petechiae, nosebleeds, bleeding gums, and low-grade temperatures. Leukemia may be classified as acute or chronic, always becoming fatal if left untreated. Treatment includes symptom management and chemotherapy to attempt remission. Transplantation of peripheral blood stem cells or bone marrow is the only chance of a cure at this time.

Malignant lymphomas are a result of the proliferation of lymphocytes, which eventually spread from the originating lymph node to other areas of the lymph system, ultimately metastasizing to non-lymphoid tissue and resulting in death. Lymphomas are classified as either Hodgkin's lymphoma or non-Hodgkin's lymphoma. Clinical manifestations include painless swelling of cervical, axillary, or inguinal nodes; low-grade fever; night sweat; fatigue; unexplained weight loss; and generalized pruritus. Treatment focuses on symptom management and aims at remission induction through chemotherapy/radiation administration. Currently, peripheral blood stem cell or bone marrow transplantation provides the only chances for a cure.

Multiple myeloma is a cancer of the bone marrow in which abnormal plasma cells proliferate. Because plasma cells or mature B lymphocytes normally produce antibodies that are used to fight infection, these abnormal plasma cells reduce the ability of the body's immune system to work properly. When the malignant plasma cells expand, they crowd out the other normal cells usually produced in the bone marrow. This causes infiltrations, destruction of bone,

and can metastasize to other organs and lymph nodes. Treatment focuses on the use of chemotherapeutic agents, radiation, or stem cell transplantation to reduce tumor burden, modify bone-related pain, and prevent skeletal-related events such as pathological fractures and spinal cord compression. Renal function is monitored carefully to address fluid and electrolyte balance and prevent damage related to protein and toxins accumulated in the kidneys.

## Promoting Health in Patients With Neurological Disorders

### Chapter 35

## Assessment of Neurological Function

*Mallory Trosper*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the neurological system
2. Discussing the function of the neurological system
3. Describing the procedure for completing a history and physical assessment of neurological function
4. Correlating relevant diagnostic examinations to neurological function
5. Explaining nursing considerations for diagnostic studies relevant to neurological function
6. Discussing changes in neurological function associated with aging

#### CONCEPTS

- Assessment
- Cognition
- Medication
- Neurologic Regulation
- Safety
- Sensory Perception

#### ESSENTIAL TERMS

Adrenergic receptors  
Afferent neurons  
Alpha receptors  
Aqueduct of Sylvius  
Arachnoid membrane  
Autonomic nervous system (ANS)  
Axon  
Babinski sign  
Basal ganglia  
Beta receptors  
Blood-brain barrier (BBB)  
Brainstem  
Cell body  
Central nervous system (CNS)  
Cerebellum  
Cerebrospinal fluid (CSF)  
Cerebrum  
Cholinergic fibers  
Circle of Willis  
Corpus callosum  
Decussation  
Dendrites  
Dermatome  
Dura mater  
Efferent neurons  
Enteric system  
Falx cerebri  
Foramen magnum  
Frontal lobe  
Glasgow Coma Scale (GCS)  
Gray matter  
Hydrocephalus  
Hypothalamus  
Interneurons  
Limbic system  
Lower motor neurons  
Medulla oblongata  
Meninges  
Midbrain  
Mini-Mental Status Examination (MMSE)  
Muscarinic receptors  
Myelin sheath  
Neuroglial cells  
Neurons  
Neurotransmitters  
Nicotinic receptors  
Occipital lobe  
Parietal lobe  
Peripheral nervous system (PNS)  
Phrenic nerve  
Pia mater  
Pons  
Reticular formation  
Subarachnoid space  
Synaptic knob  
Temporal lobe  
Thalamus  
Upper motor neurons  
White matter

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Anthony Smith, a 57-year-old businessman, has been complaining of severe headaches for several weeks. He does not have a history of headaches in the past and is concerned. The headaches do not seem to be correlated with his eating or drinking habits or related to stress, as he has been on vacation for the past week and a half. He made an appointment with his health-care provider, who recommended he follow up with a neurologist. He has an appointment next week...

## INTRODUCTION

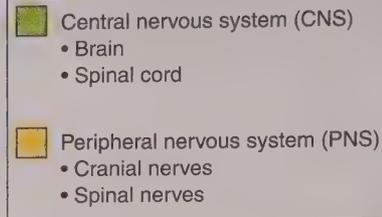

The nervous and endocrine systems of the body maintain homeostasis and coordination of the body's functions. The focus of this chapter is the neurological system and how it maintains homeostasis and coordination of neurological function. The endocrine system is discussed in Chapter 40. The neurological system works through electrical and chemical messages transmitted from sensory organs to the brain and spinal cord and reciprocating messages transmitted back to target organs and cells. It is divided into two parts (Fig. 35.1):

- The **central nervous system (CNS)**, which consists of the brain and spinal cord
- The **peripheral nervous system (PNS)**, which includes 12 pairs of cranial nerves that originate in the brain, 31 pairs of spinal nerves that originate in the spinal cord, and the **autonomic nervous system (ANS)**; (Fig. 35.2). The ANS is further divided into the sympathetic and parasympathetic systems. Another segment of the ANS, the **enteric system**, is the “nervous system” of the gastrointestinal (GI) tract. Sometimes referred to as the “second brain,” it has autonomous control of the process of digestion. The sympathetic and parasympathetic branches of the ANS are discussed in this chapter.

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

### Nerve Cell Types and Functions

The nervous system consists of two types of specialized cells, neurons and neuroglia. **Neurons** are impulse-conducting cells that facilitate communication within the nervous system. **Neuroglial cells** are specialized cells that support and protect the neurons.

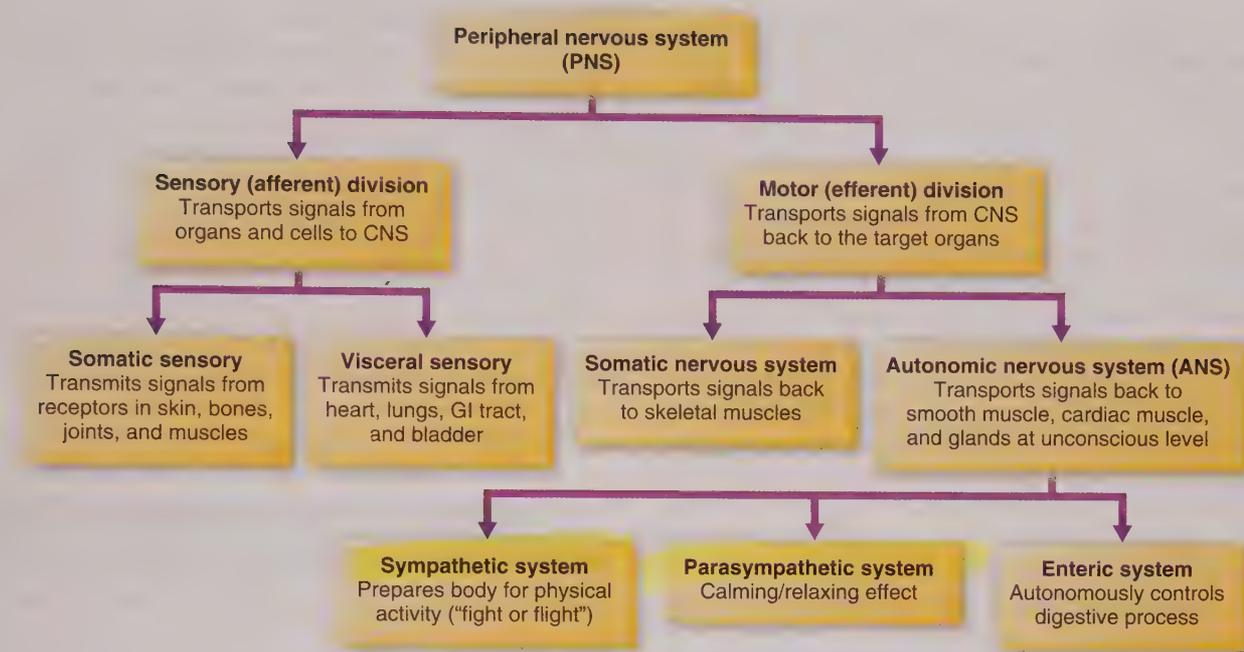

**FIGURE 35.1** The nervous system. The nervous system consists of the central nervous system (brain and spinal cord) and the peripheral nervous system (cranial nerves, spinal nerves, and autonomic nervous system).

### Neuroglial Cells

Neuroglial cells are up to 10 times more common than neurons. *Glial* (Greek origin) means “glue,” and these neuroglial cells hold the neurons together and provide support, nutrition, and protection. These cells have the ability to multiply, making them a common source for tumor growth in the brain and spinal cord. Neuroglial cells include:

- **Astrocytes**, meaning “stars,” provide structure and support. These cells attach to blood vessels, neurons, and the **pia mater**, the innermost layer of the **meninges**, which are the fibrous membrane layers that protect the brain and spinal cord. Astrocytes restrict substances from entering the neurons (the blood–brain barrier [BBB], discussed in detail later in the chapter). Astrocytes also assist in the conduction of impulses and are known to clear cellular debris.
- **Ependymal cells** line the ventricles of the brain and central canal of the spinal cord. They assist in the production of **cerebrospinal fluid (CSF)** and protect the brain from foreign materials that might enter through the bloodstream.

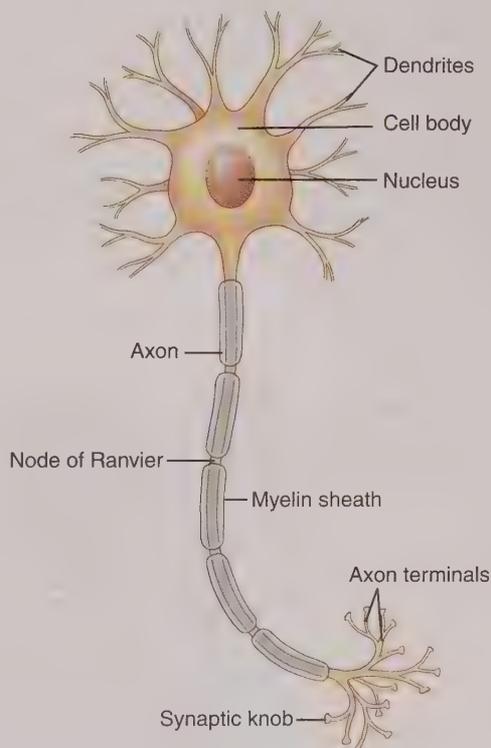

**FIGURE 35.2** Functional organization of the peripheral nervous system. The peripheral nervous system includes 12 pairs of cranial nerves that originate in the brain, 31 pairs of spinal nerves that originate in the spinal cord, and the autonomic nervous system that is divided into the sympathetic and parasympathetic systems. The enteric system is the nervous system of the gastrointestinal tract.

- *Microglial cells* are small cells that become phagocytic when they encounter inflammation or debris. They are a means of defense.
- *Oligodendrocytes* are small cells that form myelin sheaths. These sheaths cover the axons of the neurons in the CNS and aid in conduction of impulses.
- *Schwann cells* form myelin sheaths that cover axons in the PNS.

### Neurons

Neurons are the specialized communication cells of the brain and spinal cord. They receive stimuli and transmit or conduct information in response to the stimuli. There are three types of neurons: afferent (sensory), efferent (motor), and interneurons. The **afferent neurons** detect sensory stimuli from receptors, such as sensory nerve endings, and transmit them to the CNS. **Efferent neurons** transmit messages from the brain back to the muscles or glands that respond and are considered motor nerves. **Interneurons**, located entirely in the CNS, integrate incoming and outgoing messages, process and store information, and “make decisions” about the body’s response to the stimuli. They account for approximately 90% of the body’s neurons. Major components of neurons (Fig. 35.3) are:

- The cell body (soma)
- The dendrites
- The axons
- Myelin sheath
- Axon terminal
- Synaptic knob

**FIGURE 35.3** Structure of the neuron. The cell body is the control center of the neuron and includes a nucleus. Dendrites are short, treelike structures that receive stimuli and transmit them to the cell body. The axon is a process that extends away from the cell body, carrying impulses to another neuron, muscle cell, or organ cell. Axons branch out at the end and terminate at the axon terminal and the synaptic knob. The synaptic knob contains neurotransmitters that transmit impulses from one cell to another.

Similar to other cells, the **cell body** contains a nucleus, nucleolus, endoplasmic reticulum, Golgi apparatus, mitochondria, and other organelles. The cell body is the control center of the neuron. **Dendrites** are short, treelike structures that receive stimuli and transmit them to the cell body. The **axon** is a process that extends away from the cell body, carrying impulses to another neuron, muscle cell, or organ cell. Axons branch out at the end and terminate at the axon terminal and the synaptic knob. The **synaptic knob** contains **neurotransmitters**, chemical messengers that transmit impulses from one cell to another.

There are two types of tissues in the nervous system, gray matter and white matter. **Gray matter** contains the cell bodies, dendrites, and axon terminals of the neuron. Because the gray matter also contains the synapses, this is where cell-to-cell communication takes place. **White matter** contains the neuronal axons. The axons are covered with a **myelin sheath** that insulates the axon and speeds impulse transmission. This tissue is labeled white matter because of the color of the myelin. The myelin sheath is not continuous but is segmented in evenly spaced intervals, with the spaces between the segments called the *nodes of Ranvier*.

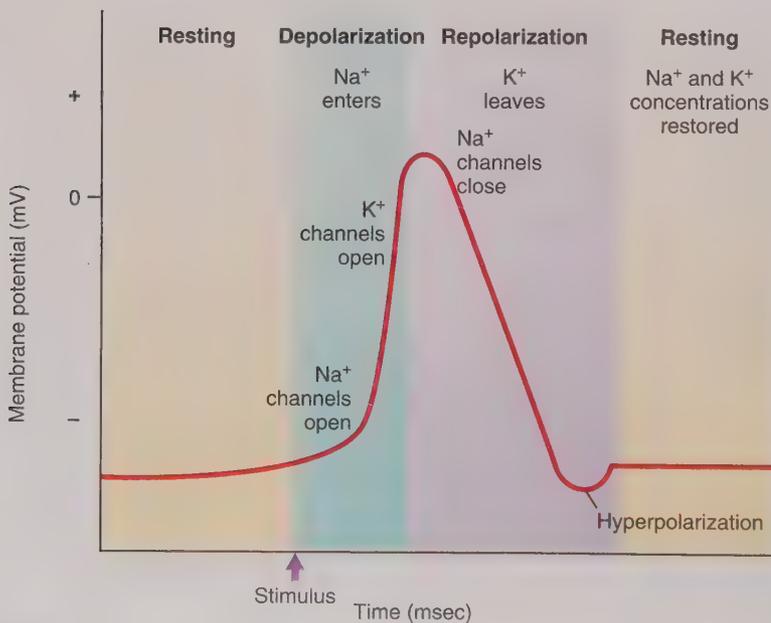

### Conduction of Nerve Impulses

The action potential of a nerve cell facilitates the transmission of information from a presynaptic neuron to a receptor, which occurs when the action of the sodium–potassium pump creates changes in the electrical balance between the outside and the inside of the cell (Fig. 35.4). Sodium primarily resides extracellularly; potassium is predominantly intracellular. At rest, the cell has a negative charge inside and a positive charge on the outside. When the cell receives a stimulus, sodium channels are opened. Potassium channels also open but much more slowly. The opening of the sodium channels allows positively charged sodium to enter

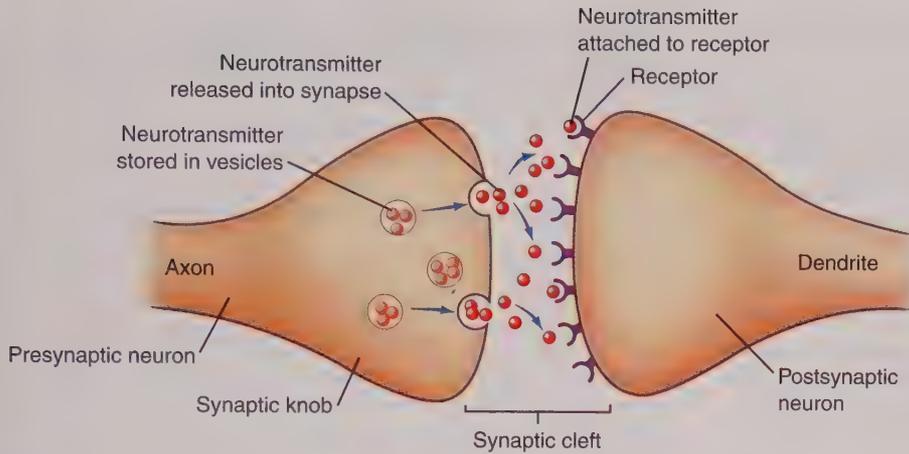

the cell, which makes the inside of the cell positive. This is the depolarization phase of the action potential. Repolarization occurs when sodium channels close and potassium channels open fully, allowing potassium to exit the cell. This repolarization results in a return to the negative charge inside the cell or a return to the resting cell membrane potential. The nerve cell actually becomes hyperpolarized, or more negative than the resting membrane potential, initially during repolarization. This hyperpolarization makes the cell refractory to another impulse. During hyperpolarization, the sodium–potassium pump gradually reestablishes the resting intracellular and extracellular sodium and potassium concentrations.

The synapse is the site where electrical impulses (information) travel from one neuron to another neuron, gland, or muscle. It consists of three components: the presynaptic neuron, synaptic cleft, and receptor site or postsynaptic neuron (Fig. 35.5). The presynaptic neuron houses the synaptic knob filled with membrane-bounded vesicles containing neurotransmitters. The neurotransmitters diffuse across the synaptic cleft to the receptor site of the receiving neuron, gland, or muscle. The release of neurotransmitters results in the transmission of the electrical impulse and allows cells to communicate with each other.

Neurotransmitters can be excitatory or inhibitory (Table 35.1). Excitatory neurotransmitters open sodium channels, causing depolarization in the postsynaptic membrane, initiating an action potential. Inhibitory neurotransmitters open chloride channels, allowing negatively charged chloride ions into the cell. This causes the postsynaptic membrane to become hyperpolarized, thus refractory to impulses and less excitable. Examples of excitatory neurotransmitters are acetylcholine and norepinephrine. Inhibitory neurotransmitters include gamma-aminobutyric acid (GABA) and dopamine.

**FIGURE 35.4** Action potential. The action potential of a nerve cell facilitates the transmission of information from a presynaptic neuron to a receptor through the action of the sodium–potassium pump. At rest, the cell has a negative charge inside and a positive charge on the outside. When the cell receives a stimulus, sodium channels are opened, allowing positively charged sodium to enter the cell, which makes the inside of the cell positive. This is the depolarization phase of the action potential. Repolarization occurs when sodium channels close and potassium channels open fully, allowing potassium to exit the cell. This repolarization results in a return to the negative charge inside the cell or a return to the resting cell membrane potential.

**FIGURE 35.5** Structure of a synapse. The synapse is the site where electrical impulses travel from one neuron to another neuron, gland, or muscle, and consists of three components: the presynaptic neuron, synaptic cleft, and receptor site or postsynaptic neuron. The neurotransmitters diffuse across the synaptic cleft to the receptor site of the receiving neuron, resulting in the transmission of the electrical impulse.

**Table 35.1** Chart of Neurotransmitters

Neurotransmitter	Class
Acetylcholine	Excitatory
Glutamate	Excitatory
Norepinephrine	Primarily excitatory
Serotonin	Inhibitory
Gamma-aminobutyric acid (GABA)	Inhibitory
Dopamine	Inhibitory

## The Central Nervous System

The CNS consists of the brain and spinal cord. The brain is enclosed and protected by the skull; the spinal cord is enclosed and protected by the vertebral column.

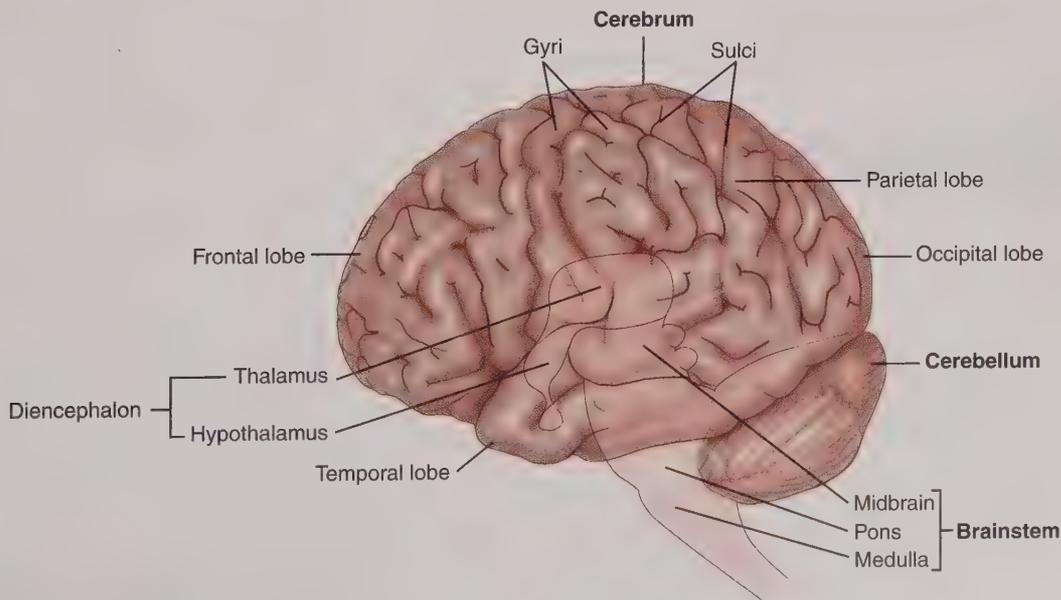

## Brain

The brain is divided into three parts (Fig. 35.6):

- The cerebrum
- The cerebellum
- The brainstem

## Cerebrum

The **cerebrum**, the largest portion of the brain, is covered by a thin layer of gray matter, the cerebral cortex. The majority of the cerebrum is white matter containing myelinated nerve fibers or tracks that carry information or impulses to other areas of the cerebrum and other areas of the brain or spinal column. The longitudinal fissure divides the cerebrum into the right and left hemispheres, which are connected by the **corpus callosum**, a band of thick fibers that facilitates communication between the hemispheres. The surface of the cerebrum has folds (**gyri**) separated by grooves (**sulci**). The deeper sulci are called **fissures**. The folds of the cerebrum create a greater surface area that

**FIGURE 35.6** Structures of the brain. The brain is divided into the cerebrum, the cerebellum, and the brainstem. The cerebrum includes the frontal, parietal, temporal, and occipital lobes. The brainstem includes the midbrain, pons, and medulla.

allows for more information-processing activity than a smooth surface.

The cerebrum is divided into four major lobes: frontal, parietal, temporal, and occipital. The **frontal lobes** are located in the front area of the brain and are largely responsible for motor movement and personality. Located behind the frontal lobes, the **parietal lobes** control sensation and perception. The **temporal lobes** are located on the sides of the brain, beneath the parietal lobes, and control sound recognition and language, and the **occipital lobe**, located at the back of the brain, is responsible for vision. See Table 35.2 for more details about the function of each lobe. The cerebrum also contains the thalamus, basal ganglia, hypothalamus, and limbic system.

### Thalamus

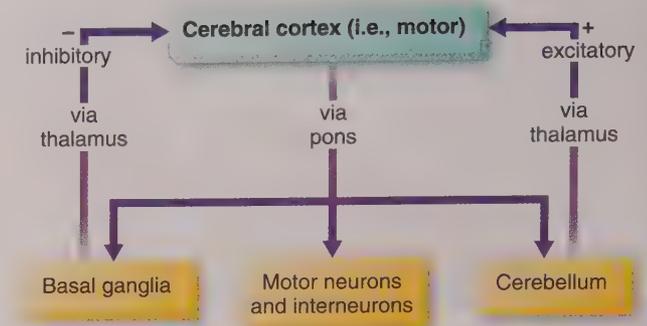

The **thalamus** is the relay center for sensory impulses to the cerebral cortex. All information traveling to the cerebral cortex is filtered through the thalamic nuclei. This includes information for pain, temperature, taste, smell, hearing, equilibrium, vision, and touch. The thalamus also relays information from the cerebellum and basal ganglia to the cerebral cortex, and in this way, it helps regulate motor control.

### Basal Ganglia

The **basal ganglia**, in coordination with the cerebellum, regulate movement by sending information back and forth through the thalamus to the cerebral cortex (Fig. 35.7). The signals from the basal ganglia are inhibitory, whereas the signals from the cerebellum are excitatory. Coordinated movement is achieved through the balance of both systems operating properly, whereas problems in the basal ganglia result in movement disorders (e.g., Parkinson's disease).

### Hypothalamus

The **hypothalamus** is the main regulator for the ANS and sends signals to the brainstem, regulating, among other things, the heart rate and blood pressure. The hypothalamus

**FIGURE 35.7** Control of coordinated movement. The basal ganglia, in coordination with the cerebellum, regulate movement by sending information back and forth through the thalamus to the cerebral cortex. The signals from the basal ganglia are inhibitory, and the signals from the cerebellum are excitatory.

regulates metabolism, reproduction, growth, and stress responses by secreting hormones that control the anterior pituitary gland (discussed in detail in Chapter 40). Additional functions are thermoregulation and the regulation of food and water intake, sleep, memory, and emotional behavior.

### Limbic System

The **limbic system** consists of the cingulate gyrus, the hippocampus, and the amygdala. It has a primary role in memory and emotions and also has a center for gratification and aversion. When stimulated, the gratification center produces sensations of pleasure or reward, whereas the stimulation of the aversion center produces objectionable feelings of grief or dread.

### Brainstem

The **brainstem** consists of three areas: the medulla, pons, and midbrain. The reticular formation or reticular activating system runs through all levels of the brainstem. All conduction of the motor and sensory tracts is relayed through the brainstem to the cerebellum and cerebrum. Ten of the 12 cranial nerves originate in the brainstem. Any injury or trauma to this area can be life threatening.

### Reticular Formation

The **reticular formation** consists of networks of neural cells and has the following functions:

- Motor control, coordination, maintaining balance and posture during movement
- Respiratory and cardiac control
- Pain modulation by providing a route of passage for pain signals from the periphery
- Alertness and sleep by controlling some of the sensory stimuli that reach the cerebral cortex

### Medulla Oblongata

The **medulla oblongata** is continuous with the spinal cord and is located at the level of and below the **foramen magnum**, the opening in the skull that allows the spinal cord to connect with the brainstem. All impulses from the brain to

**Table 35.2 Cerebral Lobes and Functions**

Lobe	Function
<b>Frontal</b>	Motor cortex, voluntary movement; Broca's expressive speech center—dominant hemisphere; personality; behaviors: social, sexual, judgment, and problem solving
<b>Parietal</b>	Sensation interpretation and perception; spatial relationships such as body position; integration of sensory input, especially visual input
<b>Temporal</b>	Auditory sensation and perception; long-term memory; Wernicke's receptive speech center
<b>Occipital</b>	Process visual information; perception of color and shapes

the spinal cord pass through the medulla oblongata. The reticular formation networks located in the medulla oblongata contain the respiratory and cardiac centers. Heart rate, blood pressure, and the regulation of the rhythm and depth of breathing are controlled here. Vomiting, coughing, sneezing, and swallowing are all controlled here as well. Four cranial nerves originate here: glossopharyngeal (IX), vagus (X), spinal accessory (XI), and hypoglossal (XII).

### Pons

The **pons** rests above the medulla oblongata below and anterior to the midbrain and relays all impulses between the brain and the spinal cord. Four cranial nerves originate in the pons: trigeminal (V), abducens (VI), facial (VII), and acoustic (VIII).

### Midbrain

The **midbrain** contains the nerve pathways between the cerebrum and the medulla oblongata. It also includes the **aqueduct of Sylvius** of the ventricular system, which connects the third and fourth ventricles (discussed in more detail in the following discussion). Cranial nerves III and IV, which control eye movement (oculomotor and trochlear, respectively), originate here.

### Cerebellum

The **cerebellum** is located in the base of the brain or posterior fossa, behind the medulla oblongata and pons. Attached to the brainstem by nerve fibers known as peduncles that carry signals to and from the cerebellum, the cerebellum is divided into left and right lobes that are connected by

a narrow structure called the *vermis*. The cerebellum is primarily responsible for coordination of muscle activities, fine motor movement, balance, and equilibrium. Patients with disturbances in the cerebellum usually present with gait and balance issues. The cerebellum also has a role in nonmotor functions such as speech, sensing, and emotion.

## Blood Flow in the Brain

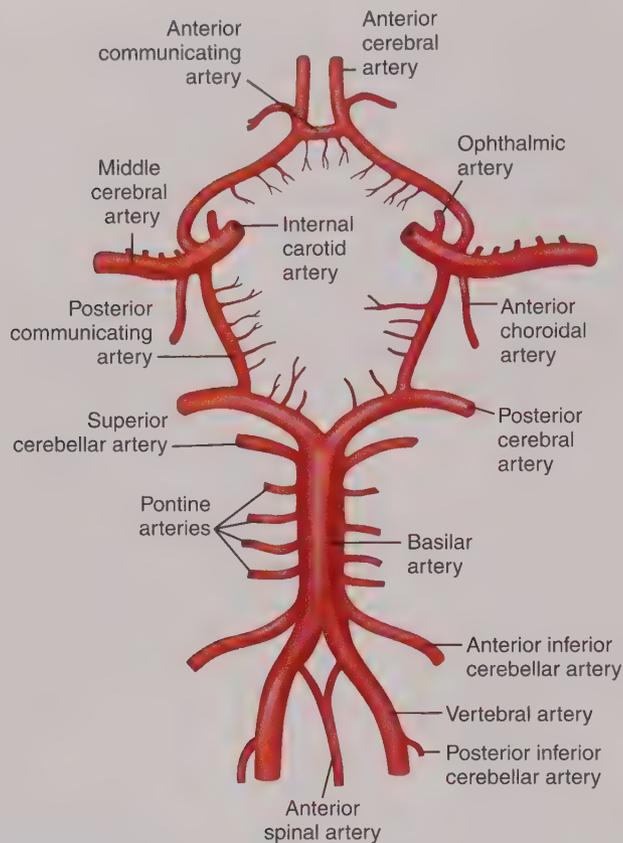

### Arterial Circulation of the Brain

The arterial circulation of the brain is supplied by the right and left internal carotid arteries and the right and left vertebral arteries. The internal carotid arteries (ICA) are the primary supply of blood to the cerebrum. They divide into the anterior cerebral artery (ACA) and middle cerebral artery (MCA) and are connected to each other by a small anterior communicating artery (ACOM). Ninety percent of all strokes involve the MCA of the brain. The vertebral arteries join to form the basilar artery, which then divides into the posterior cerebral arteries. These supply blood to the occipital lobe, the cerebellum, and the brainstem. Table 35.3 displays which arteries supply circulation to specific areas of the brain and the disorders that result from poor or blocked circulation.

**Circle of Willis.** The internal carotid arteries and the vertebrbasilar arteries join together via the posterior communicating artery at the base of the brain to form the **circle of Willis** (Fig. 35.8), which is a critical collection of vessels. The ACA, MCA, and posterior cerebral artery all arise from this circle, providing blood flow throughout the brain. If

**Table 35.3 Arterial Circulation of the Brain (Circle of Willis)**

Name of Artery	Blood Flow to:	Dysfunction With Poor Blood Supply
<b>Middle cerebral artery</b>	Provides blood flow to the lateral aspect of the frontal, temporal, and parietal lobes	Contralateral motor and sensory deficits, speech and language deficits (aphasia)
<b>Internal carotid arteries</b>	Provide blood flow to the anterior portion of the brain	Same as middle cerebral artery (MCA)
<b>Anterior cerebral artery</b>	Provides blood flow to the medial aspect of the frontal and parietal lobes	Contralateral motor and sensory dysfunction
<b>Vertebral artery</b>	Forms three branches: posterior spinal artery provides flow to posterior one-third of dorsolateral spinal cord; anterior spinal artery provides flow to two-thirds of anterior aspect of spinal cord; posterior inferior cerebellar artery (PICA) provides flow to posterior cerebellum	Dizziness, poor balance, ataxia, sensory, coordination deficits, and dysphagia
<b>Basilar artery</b>	Forms two branches: anterior inferior cerebellar artery (AICA) provides flow to the anterior cerebellum; superior cerebellar artery provides flow to superior surface of the cerebellum and portions of the midbrain and pons	Vertigo, diplopia, headache, impaired vision, coma
<b>Posterior cerebral artery</b>	Provides flow to the medial and inferior surfaces of the occipital and temporal lobes	Visual changes

**FIGURE 35.8** Cerebral blood supply and the circle of Willis. The anterior cerebral artery, middle cerebral artery, and posterior cerebral artery all arise from the circle of Willis to provide blood flow throughout the brain.

the arteries in the circle of Willis are blocked or ruptured, inhibiting or decreasing blood flow, arterial circulation throughout the brain may be impacted, leading to damage secondary to hypoperfusion and ischemia.

**Venous Blood Flow**

Venous blood flow or drainage occurs through the dural sinuses, which are venous channels found between the dura mater and the brain. Blood from the deep internal and external veins, as well as CSF from the subarachnoid space, empties into these channels to be transported back to the

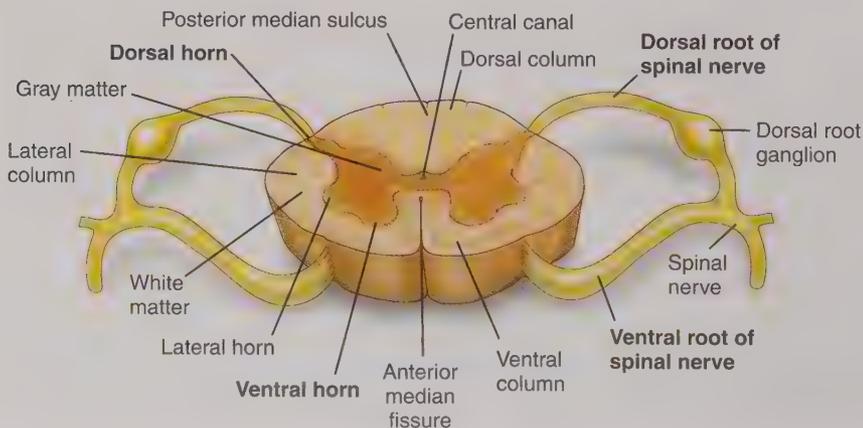

heart via the internal jugular vein. Unlike other veins in the body, these veins do not have valves.

**Safety Alert** The internal jugular vein travels through the neck. For patients with increased intracranial pressure (ICP) due to bleeding or edema, it is imperative to keep the head in proper alignment to allow venous flow or drainage of blood from the brain back to the heart. For sedated patients or those with a decreased level of consciousness (LOC), the nurse may need to provide support to the head to maintain proper alignment that facilitates venous outflow. Increased ICP is discussed in detail in Chapter 39.

**The Spinal Cord**

The spinal cord is the pathway that carries information to and from the brain and the rest of the body through the spinal nerves of the peripheral nervous system (PNS). Located within and protected by the vertebral column, a series of stacked bony structures, the spinal cord begins at the brainstem and extends to the level of lumbar vertebrae 1 and 2 in adults. It is made up of both gray matter and white matter. The gray matter of the cord containing non-myelinated tissue is responsible for the synaptic transmission of information from cell to cell. In cross section, the gray matter appears as an H within the white matter (Fig. 35.9). The H-shaped area is divided into the posterior, or dorsal, horn and the ventral, or anterior, horn. Nerve fibers that carry impulses into the spinal cord are contained within the dorsal nerve root that enters the cord through the dorsal horn. Nerve fibers that carry impulses out of the spinal cord are contained in the ventral nerve root and exit the cord through the ventral horn. A spinal nerve is a combination of fibers from both the dorsal and ventral nerve roots. Spinal nerves are discussed in detail later in the chapter.

The white matter (myelinated tissue) contains the ascending and descending tracts, which transmit information to and from the brain and target organs or cells. Ascending

**FIGURE 35.9** Structure of the spinal cord. The H-shaped area is divided into the dorsal (posterior) horn and the ventral (anterior) horn. Nerve fibers that carry impulses into the spinal cord are contained within the dorsal nerve root that enters the cord through the dorsal horn. Nerve fibers that carry impulses out of the spinal cord are contained in the ventral nerve root and exit the cord through the ventral horn.

pathways contain sensory neurons and carry impulses up the spinal column to the brain. Descending pathways contain motor neurons and carry impulses down the spinal column to target muscles. Some pathways, during ascent or descent, undergo **decussation** or “crossover” in the spinal column, which results in the right side of the brain controlling the left side of the body, and vice versa. If crossover occurs—if the origin and destination of the track are on opposite sides of the body—they are said to be *contralateral*. If the origin and destination of the track are on the same side of the body, they are said to be *ipsilateral*.

Spinal tracts are named based on the site of origin and termination. The first part indicates the origin, and the second part indicates the termination site. The major ascending tracts are spinothalamic (starts in the spine and ends in the thalamus), spinoreticular, fasciculus gracilis, fasciculus cuneatus, anterior spinocerebellar, and posterior spinocerebellar. Together, they are responsible for pain sensation, temperature, pressure, proprioception, fine touch, and vibration.

The major descending tracts are anterior corticospinal, lateral corticospinal, tectospinal, lateral and medial reticulospinal, and lateral and medial vestibulospinal. Together, they control the conscious movement of the skeletal muscles and subconscious movement and control of balance, muscle tone, and reflexes. They also control head turning in response to auditory or visual cues.

The motor neurons that carry impulses from the brain to the target muscles are divided into upper and lower motor neurons. **Upper motor neurons** originate in the motor area of the cerebral cortex or brainstem and carry motor information down a common pathway and terminate on a lower motor neuron in the spinal cord. The **lower motor neurons** carry the motor information directly to the muscle. Table 35.4 details the major ascending and descending tracts.

### Protective Mechanisms

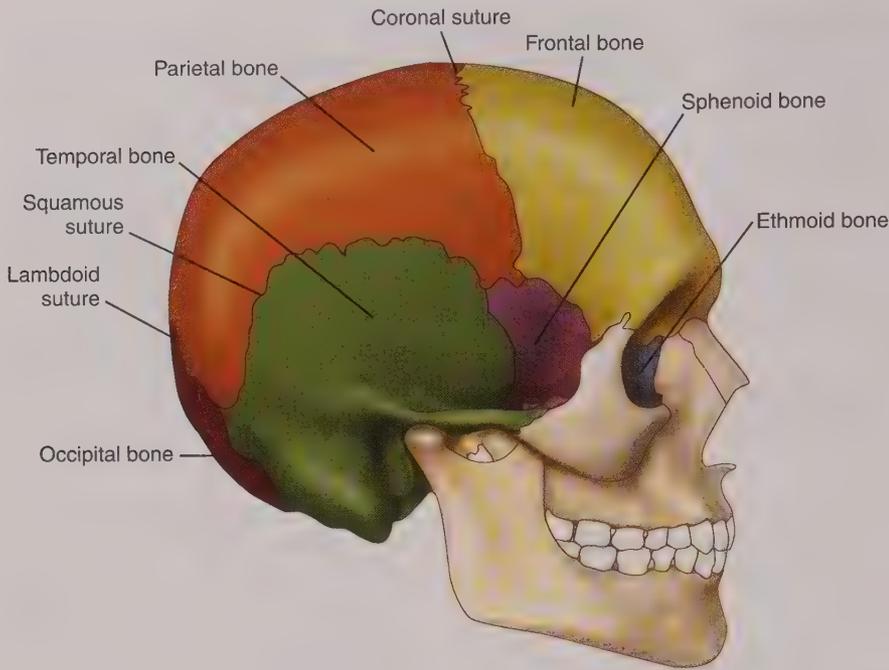

The skull or cranium, vertebrae, meninges, CSF, and blood-brain barrier are protective structures for the brain and spinal cord.

### Skull

The skull encases and protects the brain from injury. It is made up of eight cranial bones—two parietal, one occipital, two temporal, one sphenoid, one ethmoid, and one frontal—joined by fibrous joints or suture lines (Fig. 35.10). During infancy, fontanelles or “soft spots” exist to allow for brain growth during early infancy and provide flexibility during delivery for passage through the birth canal. These spaces are covered by a fibrous membrane. The bones gradually grow together, closing the fontanelles at approximately age 2. As discussed earlier, the foramen magnum, an opening in the occipital bone in the base of the brain, is located where the medulla

**Table 35.4 Ascending and Descending Tracts**

Tract	Function	Decussation
<b>Ascending</b>		
Spinothalamic	Temperature, light pain, pressure, or touch	Yes
Spinoreticular	Pain from injury	Yes
Fasciculus gracilis	Limited trunk position and motion, deep pain, vibration, or touch, level T6 and down	Yes
Fasciculus cuneatus	Limb and trunk position and motion, deep pain, vibration, or touch, level T6 and above	Yes
Anterior spinocerebellar	Proprioception (sensory information regarding position and movement)	Yes
Posterior spinocerebellar	Proprioception (sensory information regarding position and movement)	No
<b>Descending</b>		
Anterior corticospinal	Fine motor control of movement	No
Lateral corticospinal	Fine motor control of movement	Yes
Tectospinal	Reflexive head turning in response to stimuli	Yes
Lateral reticulospinal	Posture and balance, regulation of sensation of pain	No
Medial reticulospinal	Posture and balance, regulation of sensation of pain	No
Lateral vestibulospinal	Posture and balance	No
Medial vestibulospinal	Motor control of head position	Yes

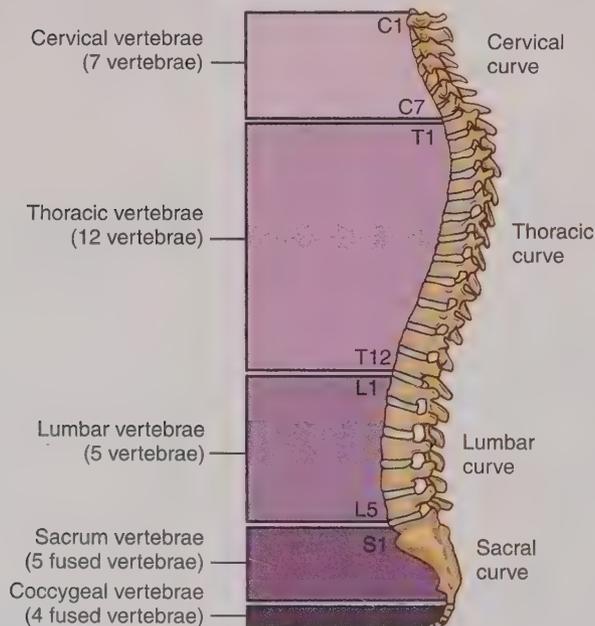

**FIGURE 35.10** Cranium. The cranium consists of two parietal, one occipital, two temporal, one sphenoid, one ethmoid, and one frontal bone, joined by suture lines.

oblongata, the lower portion of the brainstem, joins with the spinal cord.

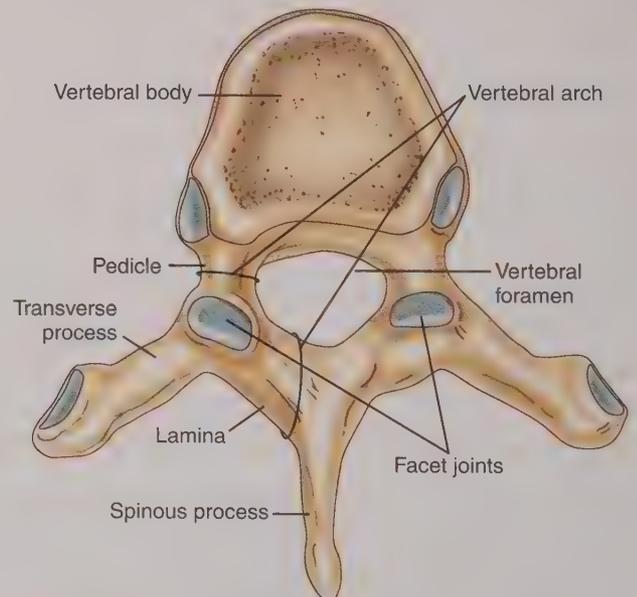

**Vertebrae**

The vertebrae are the skeletal structures that cover and protect the spinal cord. The vertebrae form a column that provides the head with support, allows flexibility and movement, and maintains the body in an upright position (Fig. 35.11). There are 33 vertebrae: 7 cervical, 12 thoracic,

5 lumbar, 5 sacral (fused), and 4 coccygeal (fused). The vertebrae consist of a body and a vertebral arch composed of a pedicle and a lamina (Fig. 35.12). Extending posteriorly from the vertebral arch are spinous processes. Extending laterally are the transverse processes. These are the points of attachment for ligaments and spinal muscles. The vertebrae are connected by facet joints that allow movement of the vertebral column. Ligaments provide stabilization. Each vertebra has a central canal, the vertebral foramen,

**FIGURE 35.11** The vertebral column. The vertebral column is the skeletal structure that covers and protects the spinal cord. There are 33 vertebrae. There are four curves of the vertebral column, the cervical and lumbar concave posteriorly, and the thoracic and sacral concave anteriorly.

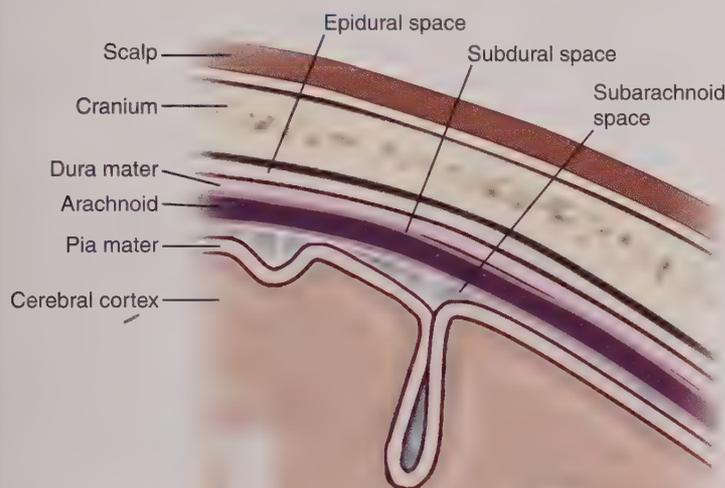

**FIGURE 35.12** Vertebral body and curvatures. The vertebrae consist of a body and a vertebral arch composed of a pedicle and a lamina. Vertebrae are connected by facet joints that allow movement of the vertebral column. Each vertebra has a central canal, the vertebral foramen, through which the spinal cord passes.

through which the spinal cord passes. In between the individual vertebrae are discs that act as shock absorbers. The discs are composed of a firm spongy material, the nucleus pulposus, surrounded by fibrous cartilage, the annulus fibrosus. The spinal column is able to support the weight of the body because it has a unique anatomical shape. There are four curves: the cervical and lumbar concave posteriorly, and the thoracic and sacral concave anteriorly.

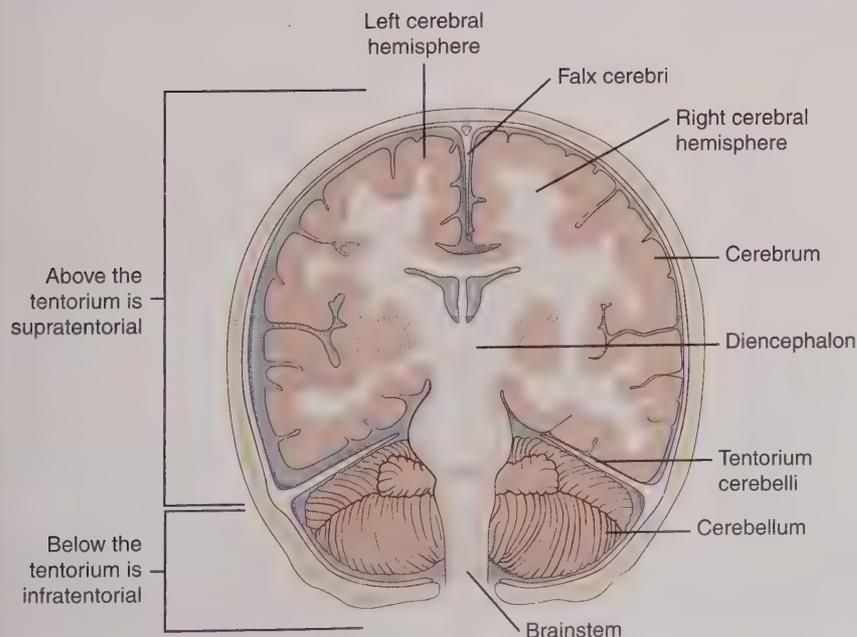

### Meninges

The meninges are fibrous membrane layers that protect the brain and spinal cord (Fig. 35.13). The outermost layer is called the **dura mater** and is a tough, fibrous membrane

that rests against the interior part of the skull. Within the skull, the dura mater consists of two layers: the outer periosteal layer and the meningeal layer. The outer layer stops at the base of the skull. The meningeal layer continues and covers the spinal cord. The meningeal layer folds inward in certain areas to separate portions of the brain. One fold, the **falx cerebri**, separates the right and left cerebral hemispheres (Fig. 35.14). Another fold, the tentorium cerebelli, separates the cerebellum from the cerebrum (see Fig. 35.14). This is sometimes used to define the location of certain structures within the brain. *Supratentorial* structures include the cerebrum and diencephalon (thalamus and hypothalamus). *Infratentorial* structures are the cerebellum and brainstem.

**FIGURE 35.13** Meningeal layers and spaces. The meninges protect the brain and spinal cord. The outermost layer is called the dura mater, which is a tough, fibrous membrane that rests against the interior part of the skull. The second layer of the meninges is the arachnoid, which is a very thin layer with a spider-web appearance. The inner membrane is the pia mater, which is a highly vascular membrane that lies in direct contact with the brain. The epidural space is a potential space that exists between the skull and the dura mater. The subdural space sits between the inner dura mater layer and the arachnoid layer. The third space is the subarachnoid space. This is between the arachnoid membrane and the pia mater.

**FIGURE 35.14** Falx cerebri and tentorium cerebelli. The falx cerebri separates the right and left cerebral hemispheres. The tentorium cerebelli separates the cerebellum from the cerebrum. Supratentorial structures include the cerebrum and diencephalon (thalamus and hypothalamus). Infratentorial structures include the cerebellum and brainstem.

The second layer of the meninges is the arachnoid. This is a very thin layer with a spider-web appearance. Within this layer are the arachnoid villi, small extensions that protrude through the meningeal layer of the dura mater that facilitate CSF reabsorption (discussed later in the chapter). The inner membrane is the pia mater, which is a highly vascular membrane that lies in direct contact with the brain.

### Meningeal Spaces

The meningeal spaces are real or potential spaces between the membrane layers. The epidural space is a potential space that exists between the skull and the dura mater. The middle meningeal artery is located here, and if this artery is torn or damaged by trauma, a hemorrhage can occur. This is called an epidural bleed or hematoma, which is recognized by its rapid accumulation and the onset of neurological symptoms. The subdural space lies between the inner dura mater layer and the arachnoid membrane. If a bleed occurs here, it is more commonly a venous type of hemorrhage. Because of the venous origin, blood accumulates slowly, and clinical manifestations may also develop more slowly. The third space is the **subarachnoid space**. This is between the arachnoid membrane and the pia mater, and much of the CSF flows through this space around the brain and spinal cord. Aneurysmal ruptures often cause bleeding into this space.

### Cerebrospinal Fluid

Cerebrospinal fluid is a colorless and odorless fluid that circulates through the ventricles in the brain and into the subarachnoid space. (See Table 35.5 for the characteristics of CSF.) The brain contains four ventricles or chambers: two lateral ventricles, the third ventricle, and the fourth ventricle.

Within each ventricle is a collection of capillaries, the *choroid plexus*. Cerebrospinal fluid is produced in the choroid plexus of the ventricles. Starting in the lateral ventricles, the choroid plexus produces CSF (Fig. 35.15). From there, it flows into the third ventricle, where the choroid plexus adds more fluid. It then flows into the fourth ventricle, with the choroid plexus again adding more fluid. From there, it flows into the central canal that houses the spinal cord or into the subarachnoid space to circulate around the brain, brainstem, and spinal cord, providing cushioning, protection, and nutrition. Approximately 500 mL of CSF is produced daily. CSF is constantly reabsorbed via the arachnoid villi, avenues allowing movement of CSF from the subarachnoid space into the venous system, resulting in only approximately 125 to 150 mL of circulating CSF volume present at any one time. **Hydrocephalus** results when CSF is unable to drain adequately into the venous system, for example, with bleeding in the subarachnoid space, causing the ventricles to enlarge with fluid.

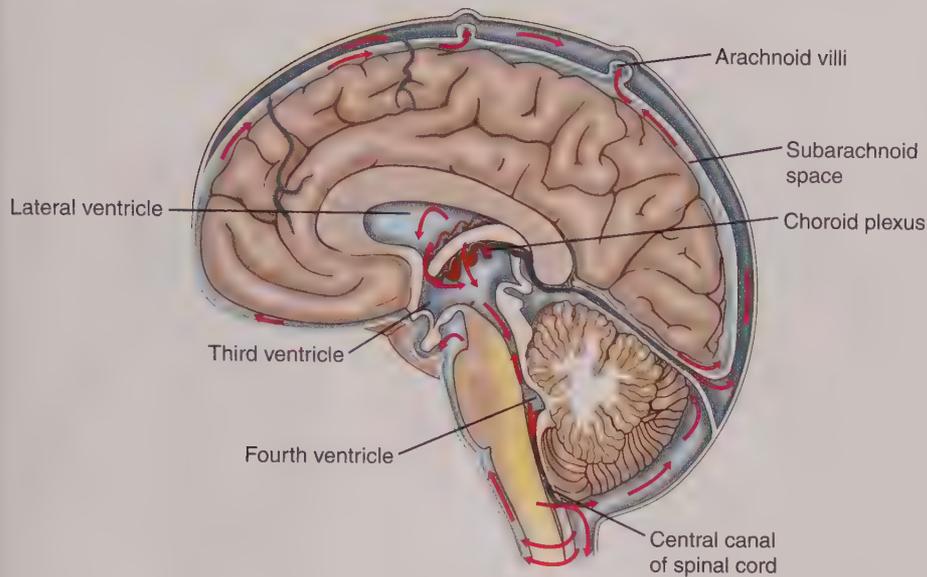

### Blood–Brain Barrier

The **blood–brain barrier (BBB)** is another protective structure of the brain. This barrier separates circulating blood volume from the extracellular fluid in the brain and prevents the passage of substances potentially damaging to the brain, such as antibodies, toxins, or macrophages. It is formed by tight junctions between the cells that form the capillaries not present in the general circulation. These tight junctions require substances to pass through the cell, not in between cells. The cells are “more selective” than the spaces between them, allowing for the exchange of nutrients and waste products while excluding toxins and other foreign substances.

**Table 35.5 Characteristics of Cerebrospinal Fluid (CSF)**

Characteristic	Normal Value	Abnormal Value	Possible Cause
<b>Volume</b>	125–150 mL	Increased with hydrocephalus	Communicating or obstructive hydrocephalus
<b>Pressure</b>	0–15 mm Hg	Increased intracranial pressure (ICP) greater than 20 mm Hg	Hydrocephalus, infection, cyst, cerebral edema
<b>Specific gravity</b>	1.007	Greater than 1.007	Presence of infection, RBCs due to a bleed
<b>Color</b>	Clear	Cloudy, turbulent Bloody	Presence of infection with increase in WBCs RBCs or breakdown of RBCs from hemorrhage
<b>Glucose</b>	Two-thirds of serum value	Greater or less than two-thirds of serum value	Decrease in meningitis, SAH; increase in severe infection
<b>Protein</b>	15–50 mg/dL	Greater than 50 mg/dL	Mild: meningitis, MS; high: tuberculosis meningitis, tumors, and Guillain–Barré syndrome
<b>Blood</b>	None	Slight or heavy blood content	Traumatic tap; SAH

MS, Multiple sclerosis; RBC, red blood cell; SAH, subarachnoid hemorrhage; WBC, white blood cell

**FIGURE 35.15** Flow of cerebrospinal fluid. Starting in the lateral ventricles, the choroid plexus secretes CSF. From there, CSF flows into the third ventricle, then into the fourth ventricle. CSF then flows into the central canal that houses the spinal cord or into the subarachnoid space to circulate around the brain, brainstem, and spinal cord, providing cushioning, protection, and nutrition.

### Connection Check 35.1

The nurse recognizes that patients with major changes in personality most likely have damage in which lobe of the brain?

- A. Frontal
- B. Occipital
- C. Parietal
- D. Temporal

## The Peripheral Nervous System

The peripheral nervous system (PNS) is composed of the spinal nerves, the cranial nerves, and the autonomic nervous system (ANS). It consists of sensory nerves that transport signals from organs and cells in the body to the CNS and motor nerves that transport signals back to the target organs. Both are divided into somatic and visceral divisions. The *somatic sensory division* transmits signals from receptors in muscles, bones, joints, and skin. The *somatic motor division* transports signals back to the skeletal muscles to produce a contraction. The visceral sensory division transmits signals from the heart, lungs, GI tract, and bladder. The visceral motor division transports signals back to smooth muscle, cardiac muscle, and glands at an unconscious level. This visceral motor division is also known as the autonomic nervous system (ANS) and is subdivided into the sympathetic and parasympathetic nervous systems.

### Spinal Nerves

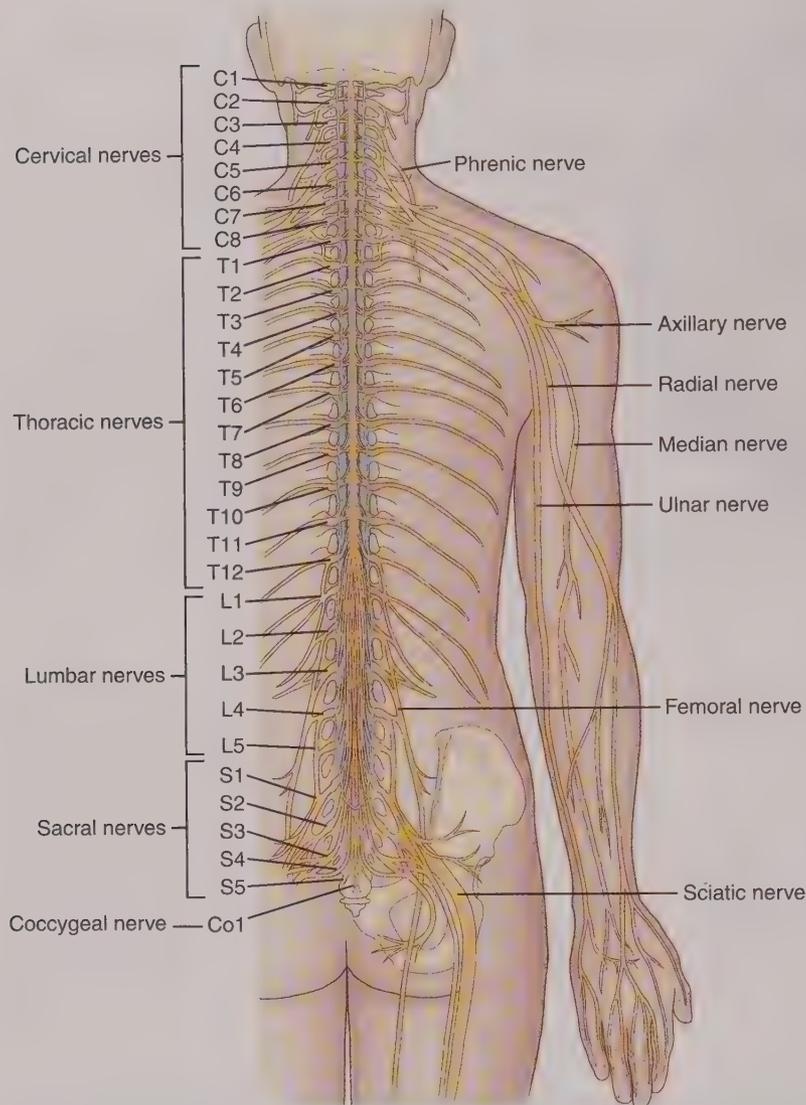

Spinal nerves transmit information to and from the spinal cord and receptors throughout the body. Because they transmit signals in both directions, they are referred to as *mixed nerves*. There are 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal (Fig. 35.16). As discussed earlier, proximal or close to the spinal cord,

each spinal nerve has two points of connection to the cord, the anterior, or ventral, root and the posterior, or dorsal, root. The ventral root transmits motor impulses to the muscle (efferent pathway). The dorsal root carries sensory information to the spinal cord (afferent pathway). Distal to the cord, the spinal nerves divide and form several large branches, which then subdivide further to form *nerve plexuses*—the cervical, brachial, lumbar, and sacral plexuses. The cervical plexus gives rise to nerves that innervate the head and shoulders and, most essential, the **phrenic nerve** that innervates the diaphragm to stimulate respiration. The brachial plexus gives rise to nerves that innervate the neck, shoulder, and arm. The lumbar plexus gives rise to nerves that innervate the thigh and leg. The sacral plexus gives rise to nerves that innervate the posterior thigh, lower leg, and foot. The largest nerve in the body, the sciatic nerve, arises from this plexus and travels down the posterior thigh.

A **dermatome** is an area on the skin that is supplied by a specific spinal nerve (Fig. 35.17) and maps where the nerve fiber provides sensation or feeling. It can be used to determine whether a sensory nerve root is damaged or injured. Dermatomes can be used for nursing assessment following spinal surgery or injury to detect changes in sensation.

### Cranial Nerves

The cranial nerves (CN) originate in the brain, except for the olfactory and optic nerves, and transmit signals to receptors in the body. They are identified by Roman numerals and are named in order according to where they arise in the brain, beginning with the anterior or rostral segments, the cerebrum, and working down the brainstem (Fig. 35.18). There are three sensory, five motor, and four mixed (both sensory and motor functions) nerves. Table 35.6 details the cranial nerves and functions. Evaluation of the cranial

**FIGURE 35.16** Spinal nerves. Spinal nerves transmit information to and from the spinal cord and receptors throughout the body. There are 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The phrenic nerve innervates the diaphragm.

nerves is a critical component of nursing assessment in the patient with disease, injury, trauma, or hemorrhage in the brain.

### Autonomic Nervous System

The ANS consists of the sympathetic and the parasympathetic nervous systems. Working in opposition and at an unconscious and involuntary level, the sympathetic and parasympathetic nervous systems regulate the activity of cardiac muscle, smooth muscle, and glands. The effect of each system is regulated by the type of neurotransmitter released at the synapse site and the type of receptor on the target cell.

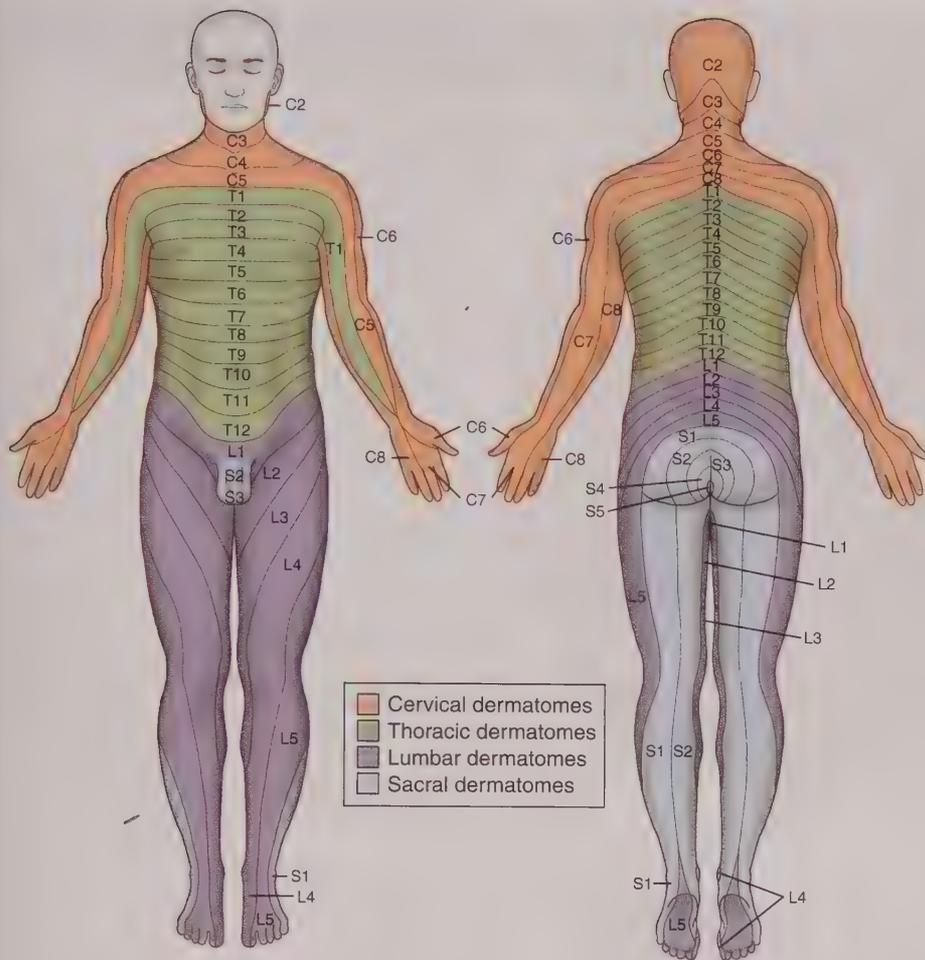

#### Sympathetic Nervous System

The sympathetic nervous system is known as the thoracolumbar system because it receives information from the thoracic and lumbar areas in the spinal cord. This system prepares the body for stress or physical activity and is known as

eliciting the “fight-or-flight” response. The neurotransmitter released at the synapse site is typically norepinephrine, and the fibers that secrete norepinephrine are adrenergic fibers. The receptors on the target cells are called *adrenergic receptors*. There are two types of **adrenergic receptors**: alpha and beta. **Alpha receptors** typically have an excitatory effect, producing vasoconstriction that increases blood pressure. **Beta receptors** are usually inhibitory and dilate the bronchioles, which enhances airflow. Beta receptors can also have excitatory effects on cardiac muscle, producing a stronger cardiac contraction and increased heart rate. Both the excitatory effects of increasing heart rate and blood pressure and the inhibitory effect facilitating airflow are necessary for “fight or flight.”

#### Parasympathetic Nervous System

The parasympathetic nervous system is known as the craniosacral system because it receives information from the brainstem and sacral region of the spinal cord. The

**FIGURE 35.17** Dermatome chart.

Dermatomes correlate to an area on the skin that is supplied by a specific spinal nerve and maps where the nerve fiber provides sensation or feeling.

neurotransmitter released at the synapse is acetylcholine. The nerve fibers that secrete acetylcholine are called **cholinergic fibers**. There are two types of cholinergic receptors: muscarinic and nicotinic. **Muscarinic receptors**, located on cardiac muscle, smooth muscle, and gland cells, can have excitatory or inhibitory responses depending on the target organ systems. Acetylcholine has an excitatory effect on intestinal smooth muscle but has an inhibitory effect on cardiac muscle. **Nicotinic receptors**, located on skeletal muscle and cells of the adrenal medulla, always have an excitatory effect. See Table 35.7 and Figure 35.19 for the contrasting actions of the sympathetic and parasympathetic nervous systems.

### Connection Check 35.2

The nurse correlates which responses as associated with the sympathetic nervous system? (Select all that apply.)

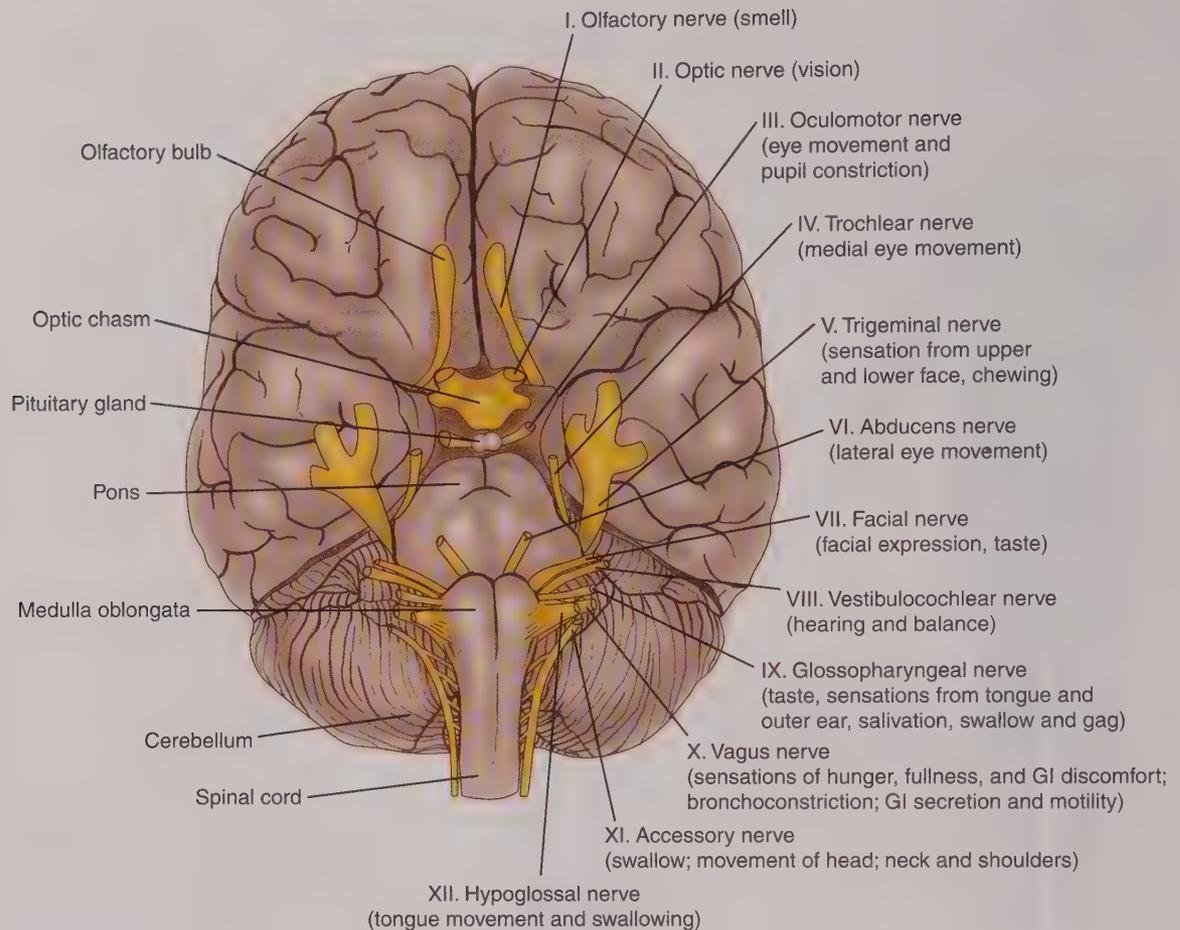

- A. Increased heart rate
- B. Decreased respiratory rate
- C. Increase in peristalsis
- D. Dilated bronchioles
- E. Decreased heart rate

### CASE STUDY: EPISODE 2

Mr. Smith continues to have headaches that are not relieved by over-the-counter (OTC) medications. His headaches are intermittent but daily. He has no other symptoms but is experiencing GI upset that he thinks is most likely due to anxiety. He is worried about the headaches and is anxious to have his appointment with the neurologist...

### ASSESSMENT

The nurse's ability to perform an accurate neurological assessment requires knowledge of the anatomy and physiology of the nervous system. Neurological changes can happen rapidly and subtly. **Early observation, detection, and reporting of changes in the patient's condition are critical in creating positive outcomes for patients.** Early detection can promote prompt medical intervention. Due to growing concerns about the potential neurological damage associated with sports injuries, greater attention is being paid to

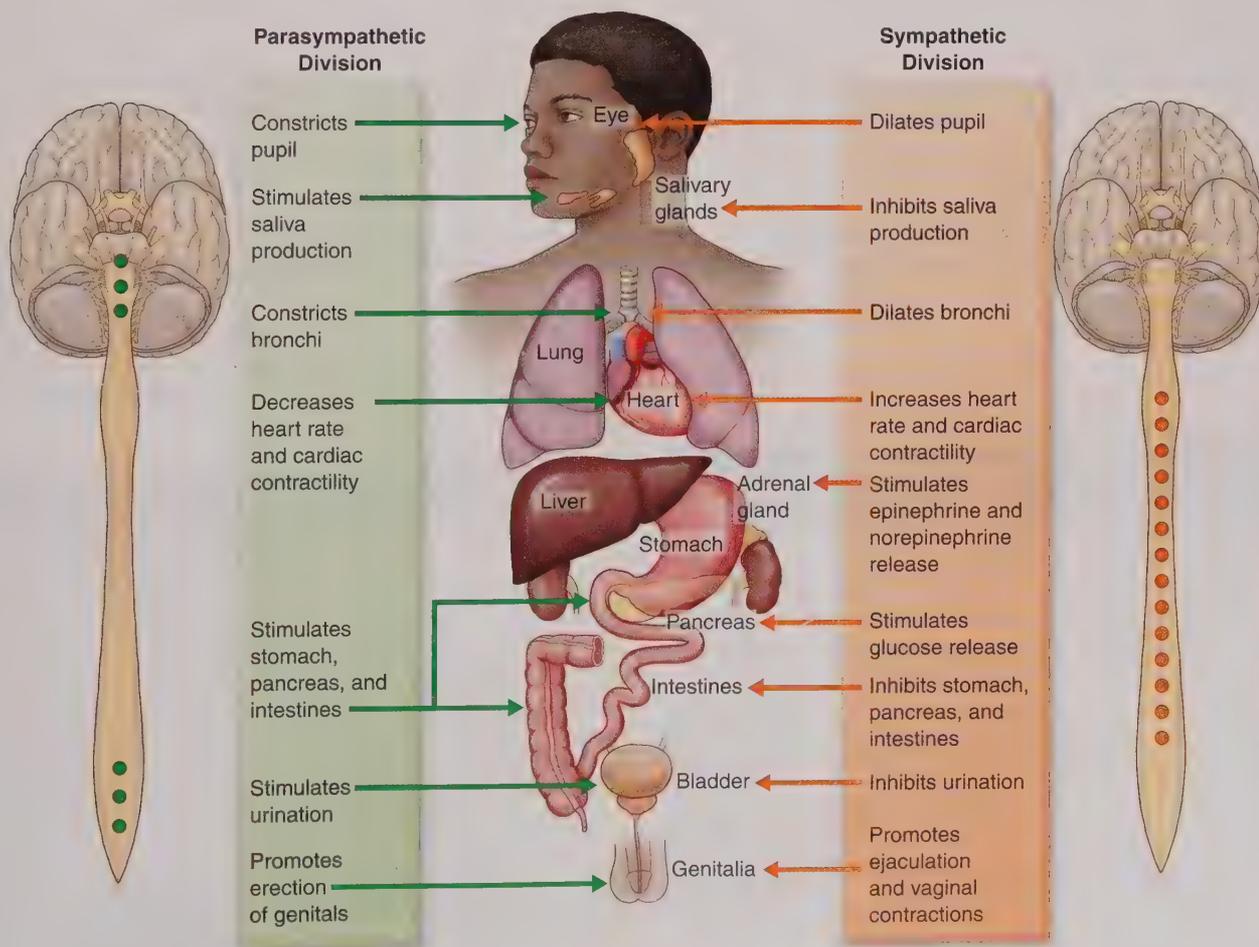

**FIGURE 35.18** The cranial nerves. Cranial nerves are identified by Roman numerals and are named in order according to where they arise in the brain, beginning with the anterior segments, the cerebrum, and working down the brainstem.

**Table 35.6** Cranial Nerves and Functions

Number	Name	Composition	Function
<b>I</b>	Olfactory	Sensory	Smell
<b>II</b>	Optic	Sensory	Vision
<b>III</b>	Oculomotor	Motor	Eye movement up, down, lateral, opening of eyelid, pupil constriction
<b>IV</b>	Trochlear	Motor	Medial and downward medial eye movement
<b>V</b>	Trigeminal	Mixed	Touch, temperature, and pain sensations from upper and lower face, chewing
<b>VI</b>	Abducens	Motor	Lateral eye movements
<b>VII</b>	Facial	Mixed	Taste, facial expressions
<b>VIII</b>	Vestibulocochlear (acoustic)	Sensory	Hearing and balance
<b>IX</b>	Glossopharyngeal	Mixed	Taste, touch, pressure, pain, and temperature; sensations from tongue and outer ear; regulation of blood pressure and respiration; salivation, swallow, and gag
<b>X</b>	Vagus	Mixed	Taste; sensations of hunger, fullness, and gastrointestinal discomfort; bronchoconstriction; gastrointestinal secretion, and motility
<b>XI</b>	Accessory	Motor	Swallow; head, neck, and shoulder movements
<b>XII</b>	Hypoglossal	Motor	Tongue movement with speech; food manipulation and swallowing

## Evidence-Based Practice

### Clinical Evaluation of Concussion in Athletes

Due to the incidence of concussive injuries associated with sports injuries, particularly in high school and college male athletes playing football, sideline assessments are often indicated when a player is potentially injured. This literature review included articles identified through searches using PubMed and MEDLINE and initially identified 1,492 articles published between 1965 and 2019 that were further refined to yield a total of 96 papers that included systematic reviews, consensus guidelines, and position statements. Findings revealed some of the complexities related to sideline assessments, particularly in relation to the time-pressured environment that requires rapid evaluation and decision making about the degree of injury and whether the student athlete should be removed from the game. Recommendations focus on the importance of symptom assessment, with priority given to potential cervical spine injury, intracranial bleeding, or other injuries that can present with clinical manifestations associated with a concussive injury. Specific recommendations relate to the use of a standardized assessment approach and decisions based on knowledge of the student athlete in comparison with clinical presentation. When the student seems “not right” after a possible concussive injury, the practitioner, often an athlete trainer, is encouraged to err on the side of caution when determining whether to remove the player or allow him or her to remain in the game.

Putukian, M. (2017). Clinical evaluation of the concussed athlete: A view from the sideline. *Journal of Athletic Training*, 52(3), 236–244.

Prior to the development of sophisticated diagnostic tools such as computed tomography (CT) and magnetic resonance imaging (MRI), physicians and nurses were dependent on accurately obtaining a history and completing a physical assessment, and these assessments were used to make an appropriate diagnosis and plan of care. The history and physical are still extremely important components of the assessment of the patient, and much can be learned by close observation and interaction with the patient. While interviewing the patient, the nurse makes observations about individual behavior and the responses to people and the environment. Data collection begins the moment a nurse initiates contact with the patient.

## History and Physical

### History

The history is best provided by the patient, but if the patient is unable to provide information, friends or family may be needed. When interviewing, the nurse treats the patient with respect and dignity by conducting the interview process in a nonjudgmental and caring manner, which facilitates establishing a trusting relationship between the nurse and the patient. It is important to be attentive to any subtle cues the patients may provide. The history includes information on regular healthcare, the medical history of the patient and family, chief complaint, allergies, medications, and social history.

*Regular healthcare* includes:

- Name of the primary healthcare provider
- History of routine health screenings, such as lipid screen, colonoscopy, and mammography
- Status of vaccines, such as tetanus, hepatitis, influenza, and pneumonia
- Alternative healthcare, such as acupuncture and herbal medicines

*Medical history* includes:

- Chronic illnesses such as diabetes, hypertension, or renal disease
- Treatment for chronic diseases or current problem
- Past trauma/injury
- Recent treatments or diagnostic studies
- Past surgical procedure/treatments

*Medical history of the immediate family* includes:

- Father, mother, and siblings
- If deceased, include cause of death.
- History of chronic illness such as diabetes, obesity, or hypertension

*Allergies:*

- List all medication, food, or environmental allergies.
- Allergic response
- Allergy treatment

*Medications:*

- Medications taken on a regular basis, including name, dose, frequency, and time of administration
- Length of time on the medication
- Last time the medication was taken
- Knowledge and presence of side effects
- Routine monitoring of the medication by a healthcare provider
- Self-administration of OTC products, vitamins, minerals, and alternative medications

*Social history:*

- Age and gender
- Marital status

- Religion
- Social support networks
- Work history and any environmental risk factors or exposures
- Smoking, alcohol use/abuse, or drug (legal and illegal) abuse

#### Current history of chief complaint:

- Description of current symptoms that brought the patient to the hospital/clinic, including:
  - Review of time of onset and presentation of symptoms
  - Current treatment of symptoms

### Connection Check 35.3

A nurse is performing the initial interview of a patient presenting to the clinic because of neurological complaints. Which actions by the nurse are appropriate? (Select all that apply.)

- A. Assessment of physical appearance
- B. Comprehensive medication list review
- C. Reassurance that all will be okay
- D. Review of alcohol and drug use
- E. Review of risks

### Physical

A physical assessment of the neurological system includes establishing the level of consciousness (LOC); determining cognitive function; evaluating mental status; and assessing cranial nerve, motor, cerebellar function, and reflex activity.

#### Level of Consciousness

The best indicator of neurological deterioration is a change in LOC. Assessing LOC involves identifying patient responsiveness and orientation to person, place, and time. There are different categories that describe LOC: conscious,

confused, lethargic, stuporous, obtunded, or comatose (Table 35.8).

Level of consciousness can be assessed using the **Glasgow Coma Scale (GCS)**. The GCS assigns a score for eye-opening, best motor response, and verbal response. The highest possible score is 15, with a score of 8 or less indicating severe neurological issues. When attempting to elicit a response, always begin with the least noxious stimulation, working from central to peripheral. First, call the patient by name. If there is no response, raise the voice to a higher level. If there is still no response, gently shake the patient. If there is no response, a sternal rub can be applied. If there is no response, apply a painful stimulus such as a pinch to the inner arm or nailbed pressure. Be cautious if the patient has other conditions that might make these techniques inappropriate. Table 35.9 details the components of the GCS.

**Safety Alert** In order to get an accurate assessment of the patient's response to a stimulus, the command needs to be clear and definitive, such as:

- Hold up two fingers on your left hand.
- Wiggle the toes on your right foot.

Avoid commands such as "squeeze my fingers." Hand grasps may be reflexive and may not represent a true response.

### Cognitive Function

The **Mini-Mental Status Examination (MMSE)** is a tool that can be used to assess cognitive function. It is a tool that assesses the patient's orientation, attention, calculation, memory, and language abilities. Patients are asked to answer questions, and a correct answer scores 1 point, with a total of 30 points available. A score below 20 is an indication of cognitive impairment (Table 35.10).

**Table 35.8 Levels of Consciousness**

Level of Consciousness	Definition
<b>Conscious</b>	Awake with appropriate speech and behavior
<b>Confusion</b>	Disorientation, bewilderment, difficulty following commands
<b>Lethargic</b>	Sleepiness; slow and delayed response to stimulus
<b>Obtundation</b>	Somnolence with drowsiness between sleep states, lessened interest in environment, slowed responses to stimulation
<b>Stupor</b>	Minimal movement without stimulus; requires strong vigorous stimulus and then drifts back to unresponsiveness
<b>Coma</b>	Not arousable and unresponsive

**Table 35.9 Glasgow Coma Scale (GCS)****Best Eye Opening**

Spontaneous	4	Spontaneous, not necessarily to command
To speech	3	Opens eyes only to verbal stimuli
To pain	2	Opens eyes only to painful stimuli
None	1	Does not open eyes

**Best Motor Response**

Obeys commands	6	Obeys commands
Localizes	5	Purposeful movement to pain
Withdraws (flexion)	4	Withdraws from painful stimuli
Abnormal flexion	3	Flexion in response to pain
Abnormal extension	2	Extension in response to pain
Flaccid	1	No response to pain

**Best Verbal Response**

Oriented	5	Oriented to person, place, and time
Confused	4	Confused conversation
Inappropriate words	3	Disorganized or random speech
Incomprehensible sounds	2	Moans, mumbles
None	1	No speech

\*A patient may be oriented, but if unable to speak because of an artificial airway, T is assigned to the score. For example, a patient who opens eyes spontaneously and obeys commands scores 11 T.

**Cranial Nerve Assessment**

Cranial nerve assessment is a critical component of the nursing assessment of the patient. It can identify neurological impairment due to disease or trauma to the brain. Table 35.11 details the components of the cranial nerve assessment.

**Motor Assessment**

A motor assessment is performed to inspect and assess muscle mass and tone as well as strength and equality between the left and right and to note any abnormalities (Box 35.1). The muscle strength of both the upper and lower extremities is assessed. The patient is asked to grasp the hands and squeeze bilaterally. The biceps and triceps are tested by the practitioner grasping the wrists and asking the patient to “pull me toward you” and “push me away.” The quadriceps are tested by asking the patient to lift the legs against gravity and then resistance. Plantar flexion is tested by grasping the

**Table 35.10 Mini-Mental Status Examination (MMSE)**

Parameter	Questions/Tasks
<b>Orientation</b>	Who are you? What is today? Where are you?
<b>Attention and calculation ability</b>	Count backward by seven. If this is too difficult, spell a word backward.
<b>Memory</b>	<ul style="list-style-type: none"> <li>● Immediate</li> <li>● Recent</li> <li>● Remote</li> </ul> <ul style="list-style-type: none"> <li>● Repeat these three words . . .</li> <li>● What did you have for breakfast?</li> <li>● Where did you attend high school?</li> </ul>
<b>Language</b>	<p>What is this object in my hand?</p> <p>Repeat this phrase: “No ifs, ands, or buts.”</p> <p>Perform this three-stage command: “Take this paper in your right hand, fold it in half, and place it on the floor.”</p> <p>Follow this written command: Write “close eyes” on a paper; the patient should close his or her eyes.</p> <p>Ask the patient to write a sentence. It should contain a noun and verb.</p> <p>Ask the patient to copy a design.</p>

These are sample questions. Actual questions will vary from test to test and per facility/agency.

foot and asking the patient to “step on the gas,” and dorsiflexion is tested by asking the patient to pull the “toes to the nose.” The practitioner uses the 0-to-5 scale to document the assessment findings. Table 35.12 illustrates scoring of motor strength. Another motor parameter that is assessed is *pronator drift*. This is done by asking the patient to extend both arms out in front of the body, turn the palms upward, and close the eyes. If one arm is weak, the patient’s hand pronates and begins to drift downward. This is a positive pronator drift and is a sign of subtle motor weakness.

**Sensory System**

The sensory system is assessed to determine if the patient can feel or identify specific sensations such as temperature, vibration, superficial or deep pain, proprioception or position sense, and cortical sensory interpretation. This is particularly important when performing a spinal cord assessment. Using the dermatome chart can help determine the area of injury or damage if sensory function has been altered. The patient is instructed to close the eyes while these tests are completed. The practitioner compares findings right to left and proximal to distal.

**Table 35.11 Cranial Nerve Assessment**

Number and Name	Testing
<b>I Olfactory</b>	Smell aromatic items such as coffee, oranges, vanilla, chocolate
<b>II Optic</b>	Visual acuity—use a Snellen’s chart, or ask the patient to read from a book or a newspaper. Assess for peripheral vision (visual fields): The examiner stands 2 feet from the patient. Have the patient cover one eye. With the examiner holding both arms up, the examiner wiggles fingers and moves in from the side, up, down, and toward the patient’s nose. The patient states when he or she can see the fingers. Both patient and examiner should see the fingers at the same time.
<b>III Oculomotor</b>	Darken the room. Check pupils by using a flashlight. Ask the patient to look at a stationary object. Bring the light in from the lateral position and shine it directly into the eye (direct reaction). Normal response is constriction. The response should be rapid and the pupils equal in size, shape, and symmetry. After checking both pupils, shine the light into one and look at the opposite eye; that eye should also constrict (consensual reaction). Observe for ptosis (eyelid drooping). Extraocular movements (EOMs) are checked by having the patient follow the examiner’s finger while drawing an “H” in the air. The patient should look up, down, laterally, and diagonally.
<b>IV Trochlear</b>	Part of EOM examination: The examiner asks the patient to follow the examiner’s finger as it is moved toward the patient’s nose (patient appears cross-eyed).
<b>V Trigeminal</b>	Assesses facial sensation for light touch, sharpness, and dullness. The examiner should use fingertips or soft cotton to determine facial feeling, moving to different areas of the face, including the forehead, cheeks, and jawline. Assess motor function by having the patient clench the teeth and then attempt to move the mouth side to side. Ask the patient to open the mouth while the examiner tries to close it.
<b>VI Abducens</b>	Part of the EOM examination: The examination involves asking the patient to follow the examiner’s finger by moving the eyes laterally.
<b>VII Facial</b>	Ask the patient to smile, frown, puff cheeks, raise eyebrows, and close eyes tightly and not let the examiner open them.
<b>VIII Vestibulocochlear (acoustic)</b>	Check for hearing by rubbing fingers close to the ear or by whispering. Check balance and ability to walk straight. Check for nystagmus (involuntary and rapid eye movement, generally side to side), usually detected during EOM examination.
<b>IX Glossopharyngeal</b>	Check gag reflex by applying a tongue depressor to the back of the throat. Ask the patient to swallow.
<b>X Vagus</b>	Assess gag and ability to swallow. Check voice for weakness and quality; ask the patient to say “Ah.”
<b>XI Accessory</b>	Ask the patient to shrug the shoulder against resistance. Ask the patient to turn the head side to side with resistance. Patient will push while examiner applies pressure.
<b>XII Hypoglossal</b>	Ask the patient to stick out the tongue and move it side to side.

### Box 35.1 Abnormalities of the Motor System

- Atrophy: decrease in muscle mass
- Paresis: slight or incomplete paralysis
- Plegia: complete loss of muscle function
- Contraction: shortening or tightening of the muscles
- Involuntary movements: uncontrolled movements
- Spasm: involuntary muscle contraction
- Spasticity: increased muscle tone that creates stiff movement

Light touch and superficial pain are assessed by starting at the feet and working upward. Using a cotton swab snapped in two (the broken tip is used to assess sharp sensation, the soft end to assess dull), the practitioner lightly touches the patient and then asks the patient to state when

**Table 35.12 Motor Strength**

Score	Description
<b>5</b>	Strong, full ROM against gravity and full resistance
<b>4</b>	Slight weakness, full ROM against gravity and moderate resistance
<b>3</b>	Moderate weakness, full ROM against gravity but not resistance
<b>2</b>	Severe weakness, full ROM but without gravity or resistance
<b>1</b>	Very severe weakness, muscle contraction only
<b>0</b>	No movement

ROM, Range of motion.

he or she feels the stimulus and where he or she feels it. The patient should be able to distinguish between dull and sharp. An open safety pin can be used to assess sharp sensation, but caution must be used to not break the skin. Deep pain is tested only when the patient does not respond to the superficial pain stimulus. Temperature is tested only if peripheral pain is not detected because the same sensory pathways carry pain and temperature. Test tubes filled with hot and cold water or the cool tuning fork can be used to assess this function. The patient's skin is lightly touched while being asked what is being felt.

Vibration is tested by using a tuning fork. Using a 128-Hz tuning fork, the practitioner strikes the forked ends against the heel of the hand, holds the stem, and applies it to the distal extremities such as the toes or feet. Both sides are always compared. The patient is asked to tell the practitioner if the vibrations are felt and when the vibration stops. The tuning fork can also be used to test hearing (acoustic nerve, CN VIII). One technique to assess hearing with a tuning fork involves applying the stem of the vibrating tuning fork to a spot on the mastoid process (prominence of the temporal bone behind the ear) equidistant from both ears. The bones of the skull transmit the impulse to CN VIII, which then transmits the signal to the brain. The sound should be heard in both ears at the same time.

Proprioception is the patient's ability to recognize position with the eyes closed. The examiner holds a digit, toe, or finger on the lateral aspect and then gently moves the digit upward or downward. With eyes closed, the patient should be able to identify whether the position is up or down.

Cortical sensory interpretation is a function of the parietal lobe and involves several tests (Table 35.13). Abnormalities in the sensory system are noted in Table 35.14. Abnormalities in the sensation of pain are noted in Table 35.15.

## Cerebellar Assessment

Cerebellar assessment involves evaluating the patient's balance, coordination, gait, and posture. The *Romberg* test is performed to assess balance and involves asking the patient to stand with the feet together, arms at the sides, with the eyes open. The examiner then checks that the patient can do this without swaying. The patient is then asked to close the eyes. If the patient is unable to maintain balance, this is a positive Romberg test and may indicate vestibular or proprioceptive problems. A patient with cerebellar damage may not be able to balance with the eyes open or closed.

Testing for coordination is completed in a variety of ways. A general assessment is done by observing basic activities such as walking, getting up or down from a chair, or reaching for objects. A specific test involves asking patients to move a finger from the nose to the practitioner's finger while the practitioner quickly moves his or her finger to different locations far enough away but close enough so that it can be reached by the patient. Another test of cerebellar coordination involves asking the patient to run the heel of one foot down the shin of the other leg. Assessing gait and posture is another important component of cerebellar testing, and the patient should be able to stand and walk erect, with a steady gait. The practitioner also assesses for length of stride, arm movement, base of gait (how far apart feet are placed), and the ability to turn steadily.

## Reflexes

Reflexes are involuntary and automatic responses to stimuli that provide the body with protection and help to adjust to an ever-changing and sometimes dangerous environment. The reflex arc occurs when sensory (afferent) neurons carry a stimulus to the motor neurons in the spinal cord. Motor (efferent) neurons carry the stimulus from the spinal cord to the muscle (a response). A complete neurological

**Table 35.13 Cortical Sensory Interpretation**

Name	Definition	Testing
<b>Stereognosis</b>	The ability to identify an object by its shape by simply holding the object	Place a common object (key or coin) in the patient's hand and ask him or her to identify it.
<b>Two-point discrimination</b>	The ability to distinguish two points separately	Test by using an opened paper clip to provide two points. The points should be about 2 cm apart. The patient should be able to distinguish the two points separately. Use the palms, lips, forearms, shins, soles, and top of the foot. If the patient is unable to distinguish two points, move the paper clip farther apart. Continue to test until the patient states that two points can be felt. The distance is measured. Charts are available that explain acceptable distances for each body part.
<b>Graphesthesia</b>	The ability to identify letters or numbers when drawn on the skin	Ask the patient to close eyes while the examiner draws a letter or number in the patient's palm. The patient should be able to identify it. Neglect of or failure to recognize one side of the body may be noted with patients with issues in cortical sensory function.

**Table 35.14 Abnormalities of the Sensory System**

Abnormality	Definition
<b>Anesthesia</b>	Absence of sensation; sensations are blocked
<b>Hypoesthesia</b>	Decreased sense of touch or sensation; numbness
<b>Hyperesthesia</b>	Increased sensitivity to touch
<b>Paresthesia</b>	Abnormal feeling of pins and needles; itching, numbness, and tingling

**Table 35.15 Abnormalities of the Sensation of Pain**

Abnormality	Definition
<b>Analgnesia</b>	Complete lack of pain sensation
<b>Hypalgesia or Hypoalgesia</b>	Decreased ability to feel the pain sensation
<b>Hyperalgesia</b>	Hypersensitivity to a painful stimulus

assessment includes evaluating the major deep tendon reflexes. Two major deep tendon reflexes are the biceps and triceps reflexes (Fig. 35.20). The major deep tendon reflexes to be checked are listed in Table 35.16, and the association of reflexes with a cranial nerve assessment is shown in Table 35.17.

Another important reflex to assess is plantar reflex, or the **Babinski sign**. This reflex is noted to have either upward-moving, downward-moving, or mute toes. To test this reflex, the practitioner takes the heel of the reflex hammer, or a sharp object, and stimulates the outside of the sole of the foot (Fig. 35.21), moving inward over the anterior aspect. If the patient's toes flare upward, this is a *positive Babinski*. A negative response is when the toes curl downward.

A positive Babinski is an indication of an upper motor neuron lesion, which indicates damage to the corticospinal tract of the spinal cord. This abnormal reflex finding can occur in patients with multiple sclerosis and traumatic brain injury. Alcohol can cause neuropathy that may elicit mute toes. A negative response is normal in an adult. In an infant, a positive response is elicited and is considered a normal finding because it is a primitive reflex in infants that disappears with the maturation of the CNS.

**Safety Alert** When caring for hospitalized patients who have neurological deficits, it is important to compare assessments between oncoming and off-going nurses through bedside rounds or reports to establish a baseline. If a change is noted later in the shift, the nurse can be confident of the timing of the change and report it accurately.

## Vital Signs and Increased Intracranial Pressure

The heart rate, blood pressure, and respirations are regulated in the brain and brainstem. Changes in vital signs may develop as a result of alterations in cerebral perfusion, disease, trauma or swelling. These vital sign changes are usually late signs of increased intracranial pressure (ICP) or neurological deterioration.

The skull is a hard, bony structure with no ability to expand. Increased ICP occurs when there is a disturbance in the balance of volumes within the brain: brain tissue, CSF, and blood. This can occur because of a mass or lesion, increased blood volume due to a hemorrhagic event, or an increase in CSF due to a blockage or buildup within the CSF drainage system. The **Monro-Kellie hypothesis** states that the sum of the volumes of the brain—brain tissue, CSF, and intracranial blood—is constant. A change or increase in one should cause a compensatory decrease in one or both of the other two. If the increase in the volume of one of the

**Biceps Reflex****Triceps Reflex****FIGURE 35.20** Technique for assessment of biceps and triceps reflexes.

**Table 35.16 Reflexes**

Reflex	Dermatome	Testing
<b>Biceps</b>	C5–C6	Arm flexed, palm down  Nurse puts finger on tendon and taps finger with hammer  Normal: elbow flexion
<b>Triceps</b>	C7	Arm flexed, palm toward body  Tap tendon above elbow  Normal: elbow extension
<b>Brachioradialis</b>	C5–C7	Arm at rest on thigh  Tap tendon on forearm between wrist and elbow  Normal: forearm flexion
<b>Patellar</b>	L3–L4	Flex leg at knee  Tap tendon below patella  Normal: knee extension
<b>Achilles</b>	S1–S2	Flex leg at knee  Tap tendon above heel  Normal: plantar flexion

**Table 35.17 Reflexes Associated With Cranial Nerve Assessment**

Reflex	Sensory	Motor	Response
<b>Corneal</b>	V	VII	Blink
<b>Gag</b>	IX	X	Gag
<b>Cough</b>	X	X	Cough
<b>Pupillary</b>	II	III	Pupil constriction

components exceeds the brain's compensatory ability, the ICP increases. This is a medical emergency and requires immediate intervention.

Normal ICP is 0 to 15 mm Hg; measurements greater than 20 mm Hg indicate increased ICP and often require intervention. Patients with increased ICP may demonstrate symptoms of changes in LOC, vomiting, headaches, and seizures. Changes in vital signs are usually late signs of increased ICP. The classic signs of increased ICP are known as Cushing's triad, which is characterized by an elevated blood pressure with a widening pulse pressure, bradycardia, and irregular respirations. In addition to increased ICP, abnormal respiratory patterns can be caused by other brain abnormalities or metabolic disturbances and are described in Table 35.18. Increased ICP is discussed in detail in Chapter 39.

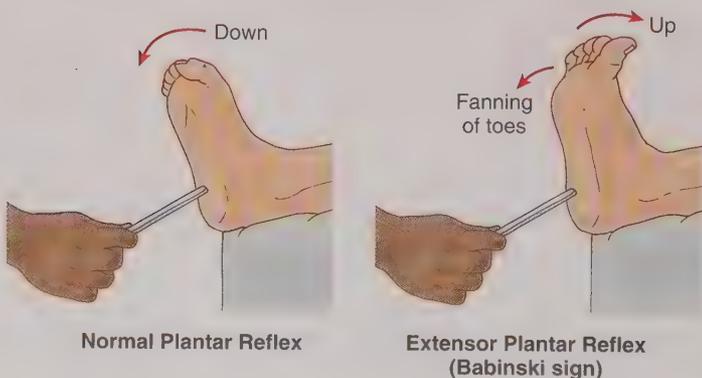

**Safety Alert** Changes in the neurological assessment can be very subtle. The patient must be monitored closely for any changes in LOC in an attempt to recognize and intervene appropriately before changes in vital signs occur. Vital sign changes related to increased ICP are late signs of neurological deterioration and may be irreversible.

## DIAGNOSTIC STUDIES

### Radiographic Procedures

X-ray studies or routine radiographical procedures are non-invasive studies done to assess the skull and spinal column for fractures, compression, stenosis, and malformation and can identify areas of injury or trauma. Patient preparation includes explaining the rationale and expected results of the procedure. The nurse assists the patient with appropriate safe positioning. Close monitoring of the patient who has a suspected cervical–spinal cord injury is essential because of the potential of devastating injury and paralysis if damage to the spinal cord occurs. The patient should be immobilized with a hard collar until a spinal cord injury is ruled out.

**FIGURE 35.21** Assessment of Babinski sign.

**Table 35.18 Abnormal Respiratory Patterns**

Pattern	Description	Location of Lesion/Injury
<b>Cheyne–Stokes respiration</b>	An increase in rate followed by short periods of apnea	Metabolic disorder; bilateral cerebral or cerebellar lesions
<b>Central neurogenic hyperventilation</b>	Deep, rapid breathing; increase in rate and depth; greater than 25 per minute (can be 40–70 per minute)	Midbrain and upper pons disorder
<b>Apneustic breathing</b>	Slow, deep breathing, then a pause; breath held and released	Disorder of midbrain to lower pons
<b>Cluster breathing; Biot’s</b>	Irregular breathing with periods of apnea	Lower pons or upper medulla disorder
<b>Ataxic respiration</b>	Irregular rate and depth with irregular periods of apnea	Upper medulla disorder
<b>Kussmaul’s breathing</b>	Rapid and shallow, then deep and labored	Severe metabolic acidosis; diabetic ketoacidosis; renal failure

### Computed Tomography

Computed tomography takes cross-sectional images that are viewed as cuts or slices that allow the provider to view the brain, spine, and orbits in a quick, noninvasive manner. A CT scan is used to assess for bleeding, edema, or masses. It is a required screening test for a patient with a suspected ischemic stroke to rule out hemorrhagic stroke prior to receiving thrombolytic (clot-buster) therapy; the presence of a bleed is a contraindication for the administration of thrombolytics. A CT scan is also used to evaluate treatment and monitor for the resolution of injuries. Typically done as a first-step screening procedure prior to MRI or if MRI is contraindicated, the CT scan can be performed with or without contrast. If contrast is necessary, it is given intravenously to help with visualization.

Nursing implications for a CT scan include:

- Providing preprocedure care, including:
  - Explaining the procedure
  - Assessing the potential need to medicate the patient for anxiety (During the examination, the patient is required to lie still on a hard table with the head secured, which may cause feelings of claustrophobia.)
  - Ensuring a patent IV line is in place
  - Checking for allergies to iodine, such as shellfish or dyes, because contrast contains iodine
  - Monitoring blood urea nitrogen (BUN) and creatinine to assess kidney function prior to receiving contrast because it is toxic to the kidney and can impair renal function
  - Assessing for diabetes mellitus and the use of the medication metformin in the management of type 2 diabetes (see Safety Alert)
- Providing postprocedure care, including:
  - Administering IV fluids or increasing the intake of oral fluids to clear contrast medium from the system

- Monitoring for allergic reactions if contrast is administered

**Safety Alert** Contrast dye is nephrotoxic and can impair renal function. Metformin is cleared primarily through the kidneys, and if it is administered prior to the examination and the administration of contrast, this medication may result in renal impairment. Additionally, metformin levels will remain elevated, potentially resulting in lactic acidosis. Because of this rare and potentially dangerous consequence, metformin must be held 48 hours prior to and after the CT scan or until renal function is determined to be normal via normal BUN and creatinine levels.

### Positron Emission Tomography

Positron emission tomography (PET), involves the administration of the radioactive glucose tracer fluorodeoxyglucose (FDG), which detects areas of increased metabolic activity in the body. A PET scan is a very sensitive test for detecting cancer because rapidly dividing cancer cells absorb the tracer (FDG), making them detectable with this imaging. Acute infection can also be identified with the PET scan. Immediately prior to the test, an IV line is inserted, and the tracer is administered.

Nursing implications include:

- Providing preprocedure education, including:
  - No food or drink by mouth is allowed for at least 6 to 12 hours prior to the test to limit metabolic activity related to digestion.
  - No caffeine, alcohol, or tobacco for 24 hours prior to the test because they can interfere with the scan results.

- The patient is instructed to lie very still during the examination to minimize metabolic activity.
- After the tracer has been administered, the patient is instructed to remain quiet in a dark room to allow the tracer to be distributed throughout the body while minimizing metabolic activity.
- Providing postprocedure education, including:
  - Encouraging adequate fluid intake to clear the tracer from the circulation

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive and painless imaging study that uses magnetic fields to obtain images. The MRI scan provides three-dimensional images and offers clear visualization and detail of small structures. Images can be obtained with or without contrast, but if used, the contrast is noniodine based, thus limiting issues with allergies and nephrotoxicity. An MRI can be used to assess injuries of the brain and spinal column, as well as to diagnose tumors, infections, and bleeding. It is very useful in the diagnosis of a cerebrovascular accident (CVA), more commonly referred to as stroke.

Nursing implications include:

- Providing preprocedure care, including:
  - Providing patient education about the procedure
  - Screening the patient for the presence of any metal objects, such as keys, watches, credit cards, or phones, prior to the examination. Metal may interfere with the magnetic field and may also be a safety hazard. An implanted device that contains metal, such as a pacemaker, may make the MRI contraindicated because the magnetic field may disable the device.
  - Assessing the potential need to medicate the patient for anxiety. The test requires that the patient lie quietly in a tunnel-like chamber for up to 50 minutes. Velcro straps may be used to hold the patient in position, and the patient may hear loud pounding or pulsating noises because of the operation of the scanner. Patients who are claustrophobic may require sedation. Headsets are typically supplied to provide distracting music.
- Providing postprocedure care, including:
  - Encouraging adequate hydration after the test if contrast is used to facilitate clearance through the kidneys

### Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is a type of MRI that uses the radio-wave signal characteristics of flowing blood to get images of the body's blood vessels. Used to determine the presence of aneurysms, clots, dissections, or vessel stenosis, the MRA is performed in the same fashion as an MRI with the same patient preparation and nursing implications. Contrast may be used in some circumstances. Pre- and postprocedure care is similar to that for the patient undergoing MRI.

### Cerebral Angiography

Cerebral angiography is an invasive, intra-arterial, radiological procedure that involves the administration of radiopaque dye through a catheter inserted in an artery, typically the femoral artery. Continuous imaging (fluoroscopy) is done to visualize the cerebral circulation because angiography is an excellent diagnostic test to evaluate cerebral and ocular vessel occlusion, carotid disease, aneurysms, arteriovenous malformations, and other vascular disorders.

Nursing implications include:

- Providing preprocedure education, including:
  - Instructing the patient not take anything by mouth after midnight before the procedure
  - Explaining that the procedure takes approximately 60 to 120 minutes
  - Describing that an IV catheter will be inserted prior to the procedure to provide hydration during and after the procedure to help clear the contrast
  - Teaching that the administration of IV contrast may cause a warm, flushed feeling
- Providing preprocedure care, including:
  - Ensuring informed consent has been obtained
  - Completing a neurological, peripheral pulse, and vital signs assessment before the procedure to establish a baseline from which to evaluate any changes. Ensuring that the patient and family understand that there are risk factors, including the risk for stroke due to the potential for thrombus dislodgement and the risk for impaired peripheral circulation distal to the arterial catheter placement.
  - Assessing for allergies to contrast dye, iodine, and seafood because contrast dye contains iodine. Seafood typically contains iodine.
  - Evaluating renal function parameters (BUN and creatinine) prior to IV contrast administration because contrast is nephrotoxic
  - Assessing for the use of anticoagulants because they place the patient at risk for bleeding during and after the angiogram
  - Administering IV sedation as ordered
- Providing postprocedure care, including:
  - Monitoring vital signs, monitoring neurological status, and assessing puncture site and pulses distal to the catheter insertion site every 15 minutes for the first hour, then every hour as ordered. (It is important to follow agency-specific postprocedure policies.)
  - Maintaining pressure on arterial puncture site for 15 to 20 minutes after removal to avoid bleeding or hematoma formation at the site. Closure devices are now available that eliminate the need for manual pressure to be applied; however, they may not be appropriate for every patient.
  - Ensuring that the patient keeps the leg straight and maintains bedrest for 3 to 12 hours as ordered postprocedure and after catheter removal to avoid bleeding or hematoma formation at the catheter

insertion site. Bedrest time will be dependent on the ability to utilize a closure device versus manual pressure. (It is important to follow agency-specific postprocedure policies.)

- Maintaining IV fluid hydration postprocedure to help clear contrast dye from the circulation
- Monitoring for bleeding, hematoma formation, or infection at catheter-insertion site
- Monitoring renal function (BUN and creatinine levels) postprocedure

### Computed Tomography Angiography

Computed tomography angiography is a diagnostic test that combines the technology of a CT scan (cross-sectional images of the brain) and traditional cerebral angiography (enhanced visualization of cerebral vasculature through the IV injection of contrast dye). It is a tool to evaluate cerebral vasculature. Computed tomography angiography is considered less invasive because the contrast is injected into a vein rather than an artery. It is sometimes used if an MRA is contraindicated. The patient preparation and nursing implications are the same as for a CT scan.

### Connection Check 35.4

A patient is scheduled for an emergency CT scan because of clinical manifestations of a CVA/stroke. The nurse recognizes which statement as true about the findings of the CT scan?

- Thrombolytics are contraindicated if the scan identifies a bleed.
- Thrombolytics are indicated if the scan is positive for a bleed.
- Thrombolytics are contraindicated if the scan identifies an occlusion.
- Thrombolytics are indicated if the scan identifies an occlusion.

### Electroencephalography

Electroencephalography is an inexpensive, noninvasive procedure that uses 8 to 24 scalp electrodes to trace the spontaneous electrical activity of the brain. It is a diagnostic test for seizure activity and other abnormalities in electrical activity. It can also be used as a part of sleep studies, to evaluate the unconscious patient, or to determine brain death.

Nursing implications include:

- Providing preprocedure education, including:
  - No caffeine consumption for 8 to 12 hours prior to the test; caffeine may alter the results.
  - Wash hair the night before and morning of the test, and avoid the use of hair products prior to the test, to aid in scalp electrode attachment.
- Providing patient support as necessary during the test

### Evoked Potentials

An evoked potential is a painless, noninvasive test that measures the speed and size of nerve conduction generated by the nervous system in response to stimuli. Electrodes are attached to the scalp and to different areas of the body depending on the type of test being conducted. The stimulus also varies depending on the test. Visual evoked potentials use visual test patterns as stimuli and are indicated for optic neuritis, masses, or tumors. Auditory brainstem evoked responses are stimulated by sounds and are used to test for CN VIII (acoustic nerve) damage. A somatosensory evoked potential focuses on nerve conduction in the arms and legs and is done with mild electrical stimulation. Somatosensory evoked potential electrodes are typically placed on the wrist (medial nerve) or knee (perineal nerve) and are used for disorders such as multiple sclerosis. Sedation is often required for somatosensory evoked potentials because the electrical stimulus may be painful and to ensure a reliable result.

Nursing implications include:

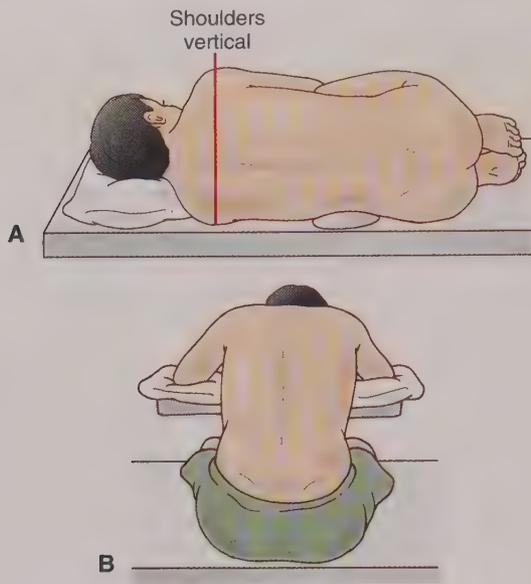

- Providing preprocedure patient education, including:
  - Wash hair the night before and the morning of the test, and avoid hair products prior to the test, to aid in scalp electrode attachment.
- Offering patient support as necessary during the test

### Lumbar Puncture

A lumbar puncture is the most common procedure done to obtain a sample of cerebrospinal fluid (CSF) for analysis and to measure intracranial pressure. Increased pressure may indicate CSF obstruction or overproduction. The presence of abnormalities in glucose or protein as well as a cloudy color may represent infection. The presence of breakdown products of red blood cells, termed xanthochromia, or frank blood may indicate subarachnoid hemorrhage or a traumatic tap, respectively. A lumbar puncture can also be used for the administration of spinal anesthesia and intrathecal medications or to remove CSF to reduce pressure. An invasive procedure, a lumbar puncture requires the insertion of a spinal needle into the L3 to L4 space of the spinal column below the level of the spinal cord. The patient is typically positioned laterally (on the side) in bed, drawing the knees up toward the chest (Fig. 35.22A). This procedure can also be done with the patient leaning across a bedside table with the back arched (Fig. 35.22B).

Nursing implications include:

- Providing preprocedure education explaining the lumbar puncture
- Providing preprocedure care, including:
  - Ensuring that antiplatelet or anticoagulation medications are held prior to the test to reduce the risk of bleeding
  - Checking coagulation studies prior to the test
  - Ensuring that informed consent is obtained
- Providing supportive care as necessary during the test

**FIGURE 35.22** Positioning for lumbar puncture. A, Patient positioned on side. B, Patient leaning across bedside table.

- Providing postprocedure care, including:
  - Ensuring flat bedrest for 4 to 6 hours after the test to help prevent CSF leakage, which can cause severe headache (see Safety Alert)
  - Encouraging fluids postprocedure to decrease headache intensity if present

**Safety Alert** To avoid post-lumbar puncture headaches, the patient is instructed to lie flat for 4 to 6 hours and stay hydrated. If a headache is severe and prolonged, a “blood patch” can be performed to help seal a CSF leak if present. In this procedure, a small amount of the patient’s blood is injected into the site of the puncture, and the resultant clot seals the leak.

### Myelography

Myelography/myelogram is an invasive radiographic procedure that involves a lumbar puncture and injection of contrast medium into the subarachnoid space around the spinal cord. X-rays are taken that enable visualization of the entire spinal column to evaluate for lesions, cysts, injury, herniated discs, and masses/tumors. This test is not as commonly performed with the advent of MRI because the MRI can provide similar data.

Nursing implications are similar to those for the lumbar puncture, with the addition of:

- Checking for allergies to contrast dyes, iodine, or seafood because of the administration of contrast during the test
- Ensuring that informed consent has been obtained

- Educating the patient to take nothing by mouth for 4 hours prior to the test
- Ensuring hydration after the test to promote the excretion of contrast dye

### Biopsy

Brain biopsies are invasive procedures done to obtain tissue samples for examination and are indicated to rule out or identify infections or abscesses or to identify tumor tissue. Types of biopsies include needle, stereotactic, and open. A needle biopsy involves drilling a small hole into the skull, inserting a needle, and withdrawing a tissue sample. A stereotactic procedure involves the use of specialized computer imaging that utilizes a three-dimensional coordinate system to pinpoint the area to be biopsied. The needle is inserted at the precise location identified through the imaging, and tissue is withdrawn. An open biopsy involves removing bone from the skull in an operative procedure, exposing the tumor or tissue to be biopsied. These procedures are performed in the operating room under sedation or anesthesia. Nursing implications for operating room procedures are discussed in detail in Chapters 15, 16, and 17.

### Connection Check 35.5

Which question by the patient having cerebral angiography indicates that teaching has been effective?

- “This is a fairly simple x-ray test, right?”
- “Is it unusual if I get hot and flushed when you inject the dye?”
- “My kidneys have to be in good shape to get this dye, right?”
- “Is this test to see if an infection is causing my problem?”

### PSYCHOSOCIAL CONSIDERATIONS

Neurological events can happen to patients suddenly and without warning, and these occurrences can be devastating to both patients and families. Disease, metabolic disorders, injury/trauma, tumor, hemorrhage, infection, and congenital disorders are all examples of potentially life-altering conditions that affect the neurological system. Deficits can be related to motor, sensation, cognition, and/or speech. Effects can be permanent or temporary, and deficits can be slight or extreme. Aggressive and prolonged rehabilitation may be necessary, and outcomes cannot always be predicted during the early course. Patients and families at first are stunned and confused, and because outcomes are not always predictable, anxiety may develop that can ultimately lead to depression.

Many factors influence how patients and families respond to an event. Age, general health, social status, history of chronic illness, previous life experience, job, and home responsibilities can all affect how a person responds. The

event may interfere with life goals (e.g., college, a planned move), future plans, employment and employment opportunities, finances, and social and sexual interactions. Patients may experience altered social roles and body image issues. The nurse must approach the patients and families with a calm and realistic demeanor and may serve as the advocate for the patient and family as they work through the many challenges of the event.

## AGE-RELATED CHANGES

Specific age-related changes in the nervous system include motor and sensory changes and alteration of thermoregulation (see Geriatric/Gerontological Considerations). These changes can be subtle and occur over time. Changes in the CNS occur as the brain weight and mass decline with a loss of neurons.

### Geriatric/Gerontological Considerations

#### Neurological Changes

1. Slowed body movements
2. Decreased reaction time
3. Decreased muscle strength and flexibility
4. Decreased sense of touch, smell, temperature, and pain sensations
5. Possible cognitive impairment, such as confusion and/or memory loss—care must be taken to carefully evaluate for other causes of cognitive issues, such as infection.

With aging, there is a natural decline in the availability of neurotransmitters and postsynaptic receptors, which causes a slowing of signal transmission. Voluntary motor movements have decreased functioning. Vascular changes, such as loss of elasticity and stenosis, alter the delivery of oxygen to the brain. The older patient may have compromised thermoregulation because of changes in the ANS, skin, and vasculature. The body temperature may be lower than normal, and therefore a febrile response to infection may not occur.

These changes impact older adults in many different ways. Body movements are slowed, and there is a decreased reaction time to environmental changes. Balance and coordination are impaired and can lead to an increase in falls. There is a decrease in muscle strength, flexibility, and joint function, which may also increase the risk of falls. Polypharmacy, orthostatic hypotension, osteoporosis, and arthritis further complicate the issue. Older adults may need assistive devices to help with safety, and canes and walkers may be used to help stabilize the gait.

Age-related changes also occur in the sensory system, resulting in a decreased awareness of the sense of touch,

smell, temperature, and pain sensations. These changes make the older adult more vulnerable to injury. Hearing and eyesight may be impaired, and the loss of smell can lead to a decreased appetite.

Cognitive impairment can occur as a result of the aging process, disease, medications, poor nutrition, and changes in the nervous system. Clinical manifestations range from confusion to disorientation, impulsive behavior, and poor judgment. Memory can also be affected. Caution should be taken in assuming the changes are a “normal” part of aging because these changes can also occur as a result of disease, such as Alzheimer’s, uncontrolled diabetes, or even infection. A urinary tract infection left untreated can cause subtle changes in mental status in older patients. A clear diagnosis needs to be made to ensure the best outcome for the patient. Rapid or sudden changes in mental status or cognition should always be evaluated by a provider.

It is critical for the older adult to maintain a healthy lifestyle. Treatment and control of chronic illness, staying active, and participating in new and challenging activities can help maintain a healthy state during the older years. Smoking cessation, healthy eating habits, and exercise can also help. Prevention is the real key for health in this patient population.

### Connection Check 35.6

The nurse correlates which clinical manifestations with age-related changes of the nervous system? (*Select all that apply.*)

- A. Decreased visual acuity
- B. Increased pain sensation
- C. Balance problems
- D. Dementia
- E. Decreased pain sensation

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Smith keeps his appointment with his neurologist. Upon his arrival, the first part of the assessment process is to complete a comprehensive history and physical examination. Mr. Smith has no significant health history. He exercises regularly, has a healthy diet, and drinks alcohol in moderation. The neurologist next obtains a thorough history of Mr. Smith’s chief complaint of headaches, which have been frequent and severe for several weeks and unrelieved with aspirin or Tylenol. There does not seem to be a precipitating event such as diet or exercise, but after close questioning, it seems eating certain foods may be connected. The neurologist continues with the neurological assessment.

### Case Study Questions

- The nurse recognizes which parameter as an important component of the neurological examination for Mr. Smith?
  - Cranial nerve assessment
  - Glasgow Coma Scale assessment
  - Assessing the Babinski sign
  - Assessing cerebral perfusion pressure
- The nurse anticipates which as the next step in the assessment process after the neurological examination?
  - MRI
  - Evoked potentials
  - Lumbar puncture
  - CT scan
- What information from Mr. Smith's history may make him ineligible for magnetic resonance imaging (MRI)?
  - History of cerebrovascular accident with residual hemiplegia
  - History of cardiac dysrhythmias requiring pacemaker
  - History of seizure disorders controlled by antiepileptic medications
  - History of deep vein thrombosis requiring anticoagulant therapy
- Due to Mr. Smith's complaints of persistent headaches, the nurse assesses for other signs of increased intracranial pressure. Which finding may also be associated with increased intracranial pressure?
  - Change in level of consciousness
  - Tachycardia
  - Diaphoresis
  - Hypotension
- The nurse's role in the overall patient assessment process includes which of the following actions? (*Select all that apply.*)
  - Patient education about the process
  - Assessing for allergies to seafood
  - Explaining CT scan test results
  - Providing reassurance that all will be okay
  - Checking renal function laboratory values

### CHAPTER SUMMARY

The nervous system consists of specialized cells for communication, neurons, and specialized cells for support, neuroglial cells. Transmission of information takes place at the synapse through the action of neurotransmitters. The central nervous system consists of the brain and spinal cord. The brain is divided into three parts: the cerebrum, the cerebellum, and the brainstem. The cerebrum is divided into four major lobes: frontal, parietal, temporal, and occipital, each having a separate and unique function. The cerebellum coordinates muscle activities, controls fine motor movement, and is responsible for balance and equilibrium. The brainstem consists of three areas, medulla oblongata, pons, and midbrain, which are responsible for basic functions such as heart rate and respiration. The spinal cord begins at the brainstem and extends to the level of L1 to L2 in adults. Information is transmitted through ascending and descending tracts to and from the brain to target organs or cells.

The peripheral nervous system (PNS) includes cranial nerves originating in the brain and spinal nerves originating in the spinal cord. The PNS includes the autonomic nervous system that is divided into the sympathetic and parasympathetic systems. The sympathetic nervous system prepares the body for physical activity and is known as eliciting the "fight-or-flight" response. The parasympathetic nervous system prepares the body for rest.

Evaluation of neurological function starts with a complete history and physical examination that is followed by a full neurological head-to-toe assessment, including level of consciousness, mental status, cranial nerves, motor and sensory function, coordination, and reflex activity. Diagnostic studies include computed tomography (CT), CT angiography, positron emission tomography, magnetic resonance imaging, magnetic resonance angiography, cerebral angiography, electroencephalography, evoked potentials, myelography/myelogram, lumbar puncture, and biopsies as indicated.

## Coordinating Care for Patients With Brain Disorders

*Elizabeth Zink*

### LEARNING OUTCOMES

Content in this chapter is designed to support the learner in:

1. Describing the epidemiology of disorders of the brain
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Headaches
  - b. Brain tumors
  - c. Seizures
  - d. Meningitis
  - e. Encephalitis
  - f. Parkinson's disease
  - g. Alzheimer's disease
3. Describing the diagnostic results used to confirm disorders of the brain
4. Discussing the management of:
  - a. Headaches
  - b. Brain tumors
  - c. Seizures
  - d. Meningitis
  - e. Encephalitis
  - f. Parkinson's disease
  - g. Alzheimer's disease
5. Developing a comprehensive plan of nursing care for patients with disorders of the brain
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with disorders of the brain
7. Explaining the clinical presentation and management of complications associated with disorders of the brain

### CONCEPTS

- Assessment
- Cellular Regulation
- Cognition
- Comfort
- Mobility
- Neurological Regulation
- Nutrition
- Oxygenation
- Safety

### ESSENTIAL TERMS

Acoustic neuroma  
Agnosia  
Auras  
Automatisms  
Bradykinesia  
Brudzinski's sign  
Carcinomatosis  
Cephalalgia

Postictal  
Preictal  
Status epilepticus  
Supratentorial  
Trigemino-cervical complex  
Vasogenic edema

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

James Johnson is a 52-year-old male with a history of hypertension (HTN), type 2 diabetes mellitus (DM), and obesity who has a smoking history of one pack per day for 25 years. Mr. Johnson comes to his provider with a complaint of intermittent headaches that occur in general first thing in the morning. Mr. Johnson tells the provider that his job is very stressful. He says that he generally takes his medication for DM, including metformin (Glucophage) 750 mg, every day regularly but only takes his amlodipine (Norvasc), 10 mg every day, when he can afford the medication. He does not take his furosemide (Lasix), 20 mg every day, because it makes him use the bathroom too often.

Mr. Johnson's blood pressure is 188/92 mm Hg with a heart rate of 95 bpm. He is counseled on the need to take his BP medication, given guidelines for diet and exercise, and prescribed medication to assist with smoking cessation. Mr. Johnson is also given a return appointment in 1 month...

## INTRODUCTION

Disorders of the brain impact patients in a variety of ways, and a diagnosis is often frightening depending on how the disorder affects cognition, personality, mobility, and activities of daily living. Many of these disorders are chronic in nature, including primary headaches, seizure disorders, Parkinson's disease, and Alzheimer's disease, requiring lifelong management and coping with exacerbations. Others are more emergent, including primary or metastatic brain tumors, meningitis, and encephalitis, and may be life-threatening emergencies. These patients may present in the emergency department with new onset of complaints or in general medical-surgical settings, outpatient settings, or neuroscience units. This chapter addresses the management of these disorders, with a focus on correlating the pathophysiology of the disorders to the clinical presentations, as well as the rationales for medical and nursing management.

## HEADACHE

Headache, also referred to as **cephalalgia**, is the most common manifestation of pain, accounting for more missed days of work and school, and more visits to healthcare providers. Headache also has vast implications in the performance of activities of daily living (ADLs). Headache is classified into two categories: primary and secondary. Primary headaches are not associated with other underlying causes, and the major types of primary headache are tension

type, migraine, and cluster headaches. Secondary headaches are caused by an underlying pathology such as infection, neoplasms (tumors), vascular (blood vessel) abnormalities, medication-induced disorders, or idiopathic causes, and typically present with a sudden onset of severe pain.

## Epidemiology

Studies indicate that at least 4% of the general population experience chronic daily headaches. One-year prevalence data suggest that 46% to 64% of the population report some type of headache during a lifetime. In the United States, 20% to 40% of the population, 5% to 9% of males, and 12% to 25% of females experience migraine headaches. Ranking of disabilities by the World Health Organization (WHO) places headaches in the top ten ranking for disabling conditions, ranking headaches in the top five for women. The prevalence of tension headaches is in excess of 42%, whereas migraine headaches have been reported in 11% of the population. Cluster headaches, found predominantly in males, with an onset of 30 to 50 years, show an overall prevalence of 0.4% of the population. Of all cluster headaches, 80% are reported as episodic, whereas 20% are classified as chronic.

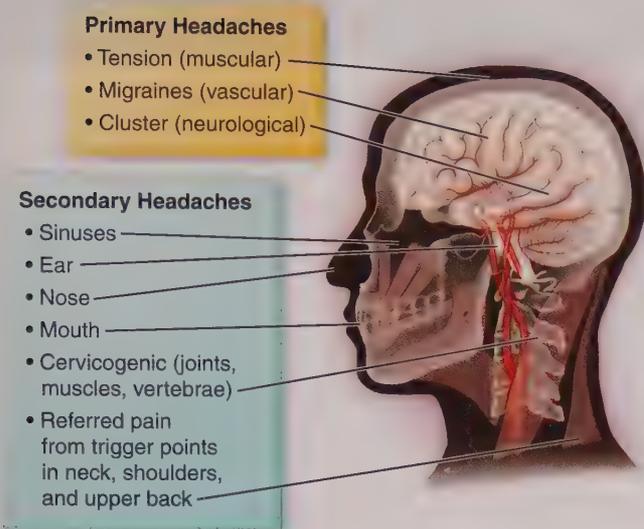

## Pathophysiology

Headaches are the result of the reaction of **nociceptors** (pain-sensitive nerve endings) to triggers, sending messages to the thalamus via the trigeminal nerve (CN V). Headaches (Fig. 36.1) are classified into one of two categories. Primary headaches are those not associated with other underlying disease or organic causes, and secondary headaches are caused by an underlying structural problem such as stroke, tumor, meningitis, or encephalitis (Table 36.1). The **trigemino-cervical** complex is a network of neurons relaying pain signals (messages) from the cervical spinal and from the meninges through the trigeminal nerve. This complex has been identified as a potential target for pain-modifying therapies, particularly for migraine headaches.

## Clinical Manifestations

Tension headaches may be episodic or chronic in nature. Episodic tension headaches typically occur 10 to 15 days per month, lasting 30 minutes to several days. Chronic tension headaches occur more than 15 days per month during a 3-month period and are generally more severe than episodic headaches. Clinical manifestations include mild to moderate pain that is typically bilateral in the occipital area. Patients often describe the pain as constant pressure to the face, head, and neck, often with sensitivity to light.

Cluster headaches are considered neurovascular headaches. The clinical presentation typically includes severe, unrelenting, unilateral pain in and around the eye. Peak pain is usually within 5 to 10 minutes after onset, continuing in intensity for 1 to 3 hours. They generally occur around the same time for several weeks, more often at night, and reoccur

**FIGURE 36.1** Classifications and causes of headache.

daily to near daily for weeks to months followed by periods of remission.

Migraine headaches are isolated into four phases. The premonitory phase can occur 24 hours before the headache develops. Clinical manifestations include mood changes, fluid retention, increased urine output, excessive and uncontrolled yawning, and food cravings. Just prior to the migraine, many patients perceive particular sensations referred to as **auras**. Symptoms of auras include but are not limited to flashing lights and muscle weakness. Followed by the headache phase, the pain starts gradually, building in intensity. For some, there is a migraine without the headache pain. Following the headache is the postdromal phase, and during this time, many patients experience confusion and exhaustion. This final period can last for as long as 24 hours before patients feel that they are back to their baseline health. Many of the medications used for the treatment of migraines target specific phases of the migraine headache.

**Table 36.1** Pathophysiology of Headaches

	Pathophysiology	Etiology	Manifestations
<b>Tension Headaches</b>			
<b>Episodic:</b>	Common anatomical and physiological mechanism: Pain messages are transmitted from the meninges of the brain to the cortex through a mechanism called the trigeminocervical complex	<ul style="list-style-type: none"> <li>• Jaw clenching</li> <li>• TMJ (temporomandibular joint dysfunction)</li> <li>• Degenerative arthritis of the neck</li> <li>• Forceful/intense</li> </ul>	<ul style="list-style-type: none"> <li>• Most common location is frontal and temporal (sides of head)</li> <li>• Generally bilateral</li> <li>• Occipital (posterior base of head), either one or both sides</li> </ul>

### Connection Check 36.1

The nurse correlates which clinical manifestation to a secondary headache?

- Sudden severe onset
- Tense neck muscles
- Nausea
- Tingling scalp sensation

## Management

### Medical Management

#### Diagnosis

Diagnosis of the specific type or etiology underlying a headache complaint consists of excluding potential causes and depends on the time course of headache occurrence. For example, patients presenting with sudden onset of headache are evaluated for clinical manifestations of meningitis, cerebrospinal fluid (CSF) leak (particularly in patients with a recent history of lumbar puncture or epidural

catheter removal), cerebral aneurysm, cerebral aneurysm rupture, or brain tumor, among other causes. When the time course of headache occurrence is prolonged, the following causes may be considered: sinusitis, opiate dependence and withdrawal, caffeine withdrawal, or over-the-counter medication overuse. One method of tracking and characterizing headache symptoms over a period of time is the use of a headache diary. Patients are instructed to record the time and date of headache occurrence as well as activities, foods, and medications taken in close proximity to the headache, to determine possible triggers and to examine patterns. An example of a diary for headaches is presented in Fig. 36.2.

Review of the headache diary is part of the detailed medical history obtained from the patient, followed by a complete neurological assessment (see Chapter 35 for a description of neurological assessment). In situations in which headaches are atypical, sudden and severe at the onset, or accompanied by neurological deficits, unusual precipitating factors, pain in the neck or jaw upon examination, and in patients older than 50 years of age on presentation, other diagnostic testing is often pursued to assess for a secondary etiology for the headache. Diagnostic tests such as blood

Content/Data:	Examples:
The time the headache started:	
The time the headache ended:	
Were there any auras prior to the start of the headache?	Spots in front of the eyes, odors, ringing in the ears
The location of the headache:	Behind the eyes, back of the neck, temporal
Description of the pain:	<ul style="list-style-type: none"> <li>• Throbbing</li> <li>• Pressure</li> <li>• Piercing</li> <li>• Stabbing</li> </ul>
Intensity of the pain:	Score of 1–10:
Other symptoms:	
Medication taken:	
Other interventions:	<ul style="list-style-type: none"> <li>• Ice pack</li> <li>• Bedrest</li> <li>• Dark room</li> <li>• Relaxation techniques</li> </ul>
Effects of treatment:	
Hours of sleep the previous night:	
Foods eaten before the headache started:	<ul style="list-style-type: none"> <li>• Caffeine</li> <li>• Artificial sweeteners</li> <li>• Aged cheese</li> <li>• Sweeteners</li> <li>• Chocolate</li> <li>• Ice cream</li> <li>• Salty foods</li> <li>• Nuts</li> </ul> <ul style="list-style-type: none"> <li>• Diet soda</li> <li>• Alcohol</li> <li>• Foods with preservatives: <ul style="list-style-type: none"> <li>– Bacon, hot dogs</li> <li>– Chinese food (MSG), cured meats</li> <li>– Processed foods</li> <li>– Citrus fruits</li> </ul> </li> </ul>
Skipped meals:	
Activities before the headache began:	<ul style="list-style-type: none"> <li>• Exercise</li> <li>• Strenuous activities</li> <li>• Naps</li> </ul>
Stressful events:	
Weather changes:	
Menstruation/birth control pills:	

**FIGURE 36.2** Headache diary.

tests to assess for infection (e.g., complete blood cell count, blood cultures) and inflammation (C-reactive protein, erythrocyte sedimentation rate), CSF testing, and imaging studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) assist in ruling out potential causes of headaches. Cerebrospinal fluid may be obtained via a lumbar puncture to measure pressure (high or low CSF pressures can cause headaches), signs of infection, and inflammation. A CT and/or MRI detects masses, cysts, and irregularities in the vessels or bones of the head. An electroencephalogram

(EEG) measures the electrical activity of the brain and can also assist in the diagnosis of seizures, tumors, inflammation, and brain injury, all of which can lead to headaches. Sleep studies might also be performed to diagnose sleep apnea if a history of obesity, snoring, or fatigue is present.

### Treatment

Treatment of tension headaches involves treating any underlying disorders or diseases. Depression and anxiety can cause tension headaches. Counseling and antianxiety

and antidepressant medications can aid in the relief of tension headaches. Causes of headaches related to poor posture can be relieved with physical therapy, those related to arthritis can be aided with the use of anti-inflammatory medications, and corrective devices can help alleviate tension headaches caused by temporomandibular joint dysfunction.

### Medications

NSAIDs, analgesics, muscle relaxants, and sedatives as well as antidepressants may also assist in alleviating pain for those who suffer from both tension and migraine headaches. Treatment for migraine headaches includes medications used to relieve the clinical manifestations of the migraine (abortive therapy) and those designed to prevent the migraine headache. The use of anti-inflammatory medications can reduce inflammation and ease the pain of migraines. Combination medications, such as those blending acetaminophen with caffeine, can also assist in alleviating symptoms of migraines.

Serotonin, a neurotransmitter, causes vasoconstriction and lowers the pain threshold. Triptan medications such as sumatriptan (Imitrex) increase the levels of serotonin and appear most beneficial during moderate to severe migraine pain. Ergot alkaloid medications such as dihydroergotamine (Migranal) bind to the serotonin receptors on the nerve endings, decreasing transmission of pain messages along the nerve fibers. These medications appear to be most effective during the early phases of migraine headaches.

Many of the medications used in preventive therapy for migraine headaches were initially used for several other conditions. Anticonvulsant medications used to treat seizure disorders, such as lamotrigine (Lamictal) and gabapentin (Neurontin), increase the levels of many neurotransmitters and diminish pain impulses. Antihypertensive medications such as beta blockers (e.g., propranolol [Inderal]) and calcium channel blockers (e.g., amlodipine [Norvasc]) are used for the prevention of migraines. These medications are thought to prevent vasoconstriction or vasodilation in the cerebral blood vessels. Antidepressants are used to treat migraine headaches by increasing serotonin and other chemicals in the brain, such as dopamine and norepinephrine. These medications include selective serotonin reuptake inhibitors such as citalopram (Celexa), paroxetine (Paxil), escitalopram (Lexapro), and fluoxetine (Prozac), as well as serotonin and norepinephrine reuptake inhibitors such as duloxetine (Cymbalta), venlafaxine (Effexor), and Tramadol (Ultram). Tricyclic antidepressants such as amitriptyline (Elavil) and imipramine (Tofranil) are also used in the treatment of migraine headaches.

### Lifestyle Modifications and Complementary and Alternative Medicine Therapies

Lifestyle modifications can reduce or prevent headaches. Identifying food triggers and eliminating them from the diet can reduce and prevent migraine headaches. Ensuring steady, regular meals as well as adequate fluid intake and

establishing consistent sleep habits can also assist in the relief and prevention of headaches. Riboflavin (vitamin B<sub>2</sub>), magnesium, and coenzyme Q10 are also used in the relief and reduction of headaches.

Alternative therapies for the treatment of headaches include biofeedback, massage and gentle exercise of the neck, cognitive behavioral therapy (stress-reduction techniques), meditation, relaxation training, and yoga. Acupuncture and acupressure have also been used in the treatment and prevention of headaches.

### Age-Related Considerations

Headaches in children appear to be of shorter duration and are more commonly bilateral in nature. Gastrointestinal disturbances are more prevalent in children with headaches. Dental care and treatment of dental caries, as well as ill-fitting dentures, can be a source of headache. Patients presenting with headaches after age 50 years should be carefully assessed for a vascular cause of headaches such as cerebral blood vessel abnormality (e.g., aneurysm) and stroke.

### Complications

#### Medication Overuse Headaches

Some patients develop chronic daily headaches as a result of excessive use of over-the-counter medications such as acetaminophen and ibuprofen. Daily or near daily use of over-the-counter medications begins a cycle resulting in frequent headaches that cannot be broken unless these medications are stopped. Treatment paradigms may include a sudden withdrawal of these medications while the provider places the patient on medication to prevent headaches or a more gradual withdrawal of the over-the-counter medication.

#### Status Migrainosus and Hemicrania Continua

Continuous headache syndromes such as status migrainosus and hemicrania continua are debilitating disorders in which patients are unable to experience headache relief and may need to be treated on an inpatient basis. Treatment for these continuous headaches may include IV hydration and pharmacological treatment with dihydroergotamine and antiemetics.

### Nursing Management

#### Assessment and Analysis

The clinical presentation of headache is largely dependent on the etiology and pattern of the clinical manifestations. Patients presenting frequently complain of acute head pain, **photophobia** (sensitivity to light), nausea, vertigo, and aura. A thorough patient history is essential in determining a patient's headache type, the potential causes, and an appropriate treatment plan.

#### Nursing Diagnoses

- **Acute pain** related to neurovascular dysfunction (vasodilation of cerebral vessels)
- **Knowledge deficit** related to concealment of triggers initiating migraine headache

- **Self-care deficit** related to inability to manage the headaches

## Nursing Interventions

### ■ Assessments

- Vital signs  
*Pain stimulates the autonomic nervous system, resulting in increases in heart rate, blood pressure, and respiratory rate.*
- Pain  
*Detailed pain assessment may assist in differentiating the type of headache as well as providing important data related to relief measures and pain medication.*
- Triggers  
*Identifying and managing triggers to headaches is important in decreasing the frequency and severity of headaches.*
- Abortive and preventive measures  
*Patient identification and management of symptoms at onset may help alleviate the severity of the headache as well as abort the headache.*
- Auras  
*In patients who experience an aura in advance of the headache, abortive interventions may be implemented earlier to decrease the severity of the headache.*

### ■ Actions

- Administer prescribed medications  
*NSAIDs are prescribed for their anti-inflammatory properties. Caffeine derivatives may be prescribed for patients because they block adenosine and lead to vasoconstriction of blood vessels. Antiemetics may be indicated when headache is complicated by nausea and vomiting.*
- Maintain calm, dark, quiet environment  
*Excessive noise and lights may trigger and exacerbate pain symptoms by stimulating the sympathetic nervous system.*

### ■ Teaching

- Importance of adequate sleep  
*Sleep and rest are associated with a decrease in headaches associated with stress.*
- Take pain medications as prescribed  
*Severity of headaches may be better controlled with a timely and appropriate medication regimen.*
- Food triggers  
*Identifying food triggers and eliminating them from the diet can reduce and prevent migraine headaches.*

## Evaluating Care Outcomes

Headaches can become a chronic debilitating disorder, and management of headaches requires proper diagnosis and management. Once the patient is familiar with the personal headache history, headache triggers, and best approaches to pain control, episodes of headache are better managed. Lifestyle changes may be required for the best control of headaches in some patients.

## Connection Check 36.2

When educating a patient with migraine headaches, the nurse includes which interventions? (*Select all that apply.*)

- Practice a healthy lifestyle (cease smoking, alcohol in moderation, exercise)
- Avoid triggers
- Use techniques such as relaxation and stress reduction
- Stop taking medications if symptoms subside to decrease tolerance
- Eliminate all salt and caffeine from the diet

## BRAIN TUMORS

### Primary Brain Tumors

Primary brain tumors are tumors that originate in the brain and range from slow-growing, benign tumors to highly malignant, aggressive tumors. Primary brain tumors originate from brain cells, brain **meninges** (membranes covering the brain), nerves, and glands (Fig. 36.3). Because of the diversity of these tumors, classification is difficult and is generally based on the type of brain cells involved and the location where the cancer evolves. Tumors are also classified on the basis of the WHO Classification System. They are classified from least aggressive (grade I) to most aggressive (grade IV) depending on the rate of growth and behavior of the cells.

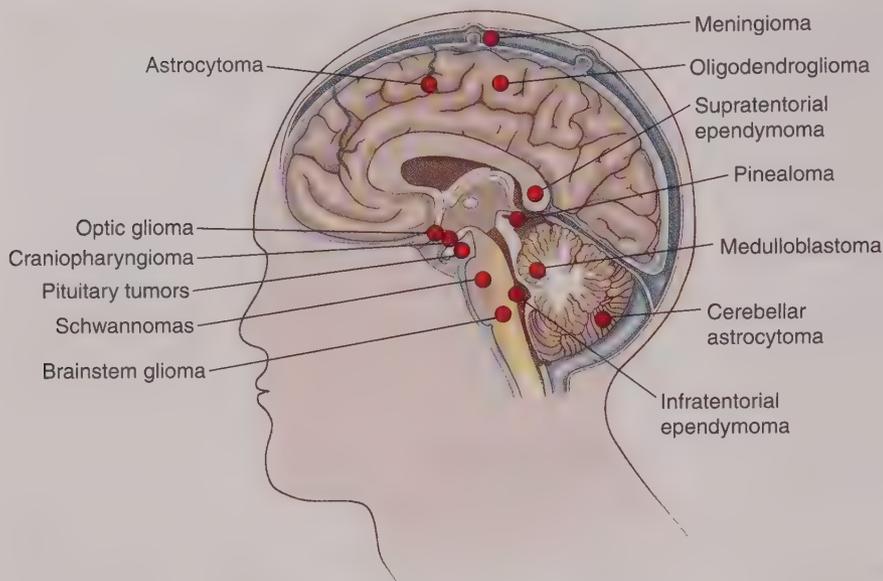

### Epidemiology

According to the American Brain Tumor Association, in 2017 approximately 80,000 men, women, and children were diagnosed with a primary brain tumor. This number includes both benign and malignant brain tumors. The American Cancer Society predicted that about 23,880 people (13,270 males and 10,160 females) were diagnosed with a malignant brain or spinal cord tumor in 2018, and approximately 70% of those with a malignant tumor will not survive as a result of their diagnosis. The risk of developing a brain tumor is very low, with the lifetime risk of 1% or less.

Males have a higher incidence, with poorer responses to therapy in comparison with women. The median age at diagnosis for brain tumors is 60 years.

### Pathophysiology

**Gliomas** generally originate in the cerebrum. Glial cells provide the physical structure of the brain and supports the endothelial cells of the blood-brain barrier. Glial cells also provide nutrients and ionic balance and are involved in the repair and scarring processes. Gliomas are inclined to develop along the curved areas of the brain, making the frontal lobes more susceptible. Most commonly found in patients between the ages of 20 and 50 years, gliomas are grade I and II and are slow-growing tumors. Anaplastic gliomas (grade III) are tumor cells out of control, lacking differentiation and/or orientation to one another and to

**FIGURE 36.3** Location of brain tumors.

surrounding vessels. Glioblastoma multiforme is a grade IV astrocytoma and is the most aggressive and lethal type of tumor, especially when located in or near the brainstem.

**Meningiomas** are the most common form of brain cancer arising in patients between the ages of 40 and 70 years, affecting females in larger numbers than males. Meningiomas arise from the meninges (layers of the brain). Although 90% of meningiomas are benign, they can still cause devastating damage because they are space-occupying lesions that can increase intracranial pressure (ICP). Additionally, damage may occur based on tumor size or location.

**Oligodendrogliomas** arise from oligodendrocytes, or oligodendroglia, and their main functions are to provide support and insulation to axons in the central nervous system (CNS), equivalent to the function performed by Schwann cells in the peripheral nervous system. These are slow-growing tumors that generally do not spread to surrounding tissue. Arising from the fatty covering that protects nerves, they generally occur in the cerebrum. Oligodendrogliomas are generally found in middle-aged patients.

**Acoustic neuromas** (CN VIII) are slow-growing benign tumors that generally do not invade other tissue; however, compression on other cranial nerves, (CN V, CN VII, CN IX, and CN X) and tissue (cerebellum and brainstem) can manifest in severe complications. Acoustic neuromas, also known as schwannomas, originate from the protective covering around nerve fibers (CN VIII) at the anatomical location of the cerebellopontine angle. Acoustic neuromas are generally found in adults age 40 to 60 years.

Pituitary tumors are generally found in the anterior lobe of the pituitary, the most common of which is the adenoma, typically a benign tumor. Clinical manifestations of pituitary adenomas are related to hypersecretion of hormones by the pituitary gland, including acromegaly from hypersecretion of growth hormone, amenorrhea-galactorrhea from prolactin

hypersecretion, changes in urine output secondary to changes in antidiuretic hormone secretion, and disorders of the adrenal cortex from hypersecretion of adrenocorticotrophic hormone. Pituitary tumors can be found within all age groups. (Management of pituitary tumors is presented in more detail in Chapter 41.)

## Metastatic Central Nervous System Disease

### Epidemiology

Metastatic tumors are the most common type of brain tumor and metastatic disease in the central nervous system (CNS) occurs in approximately 30% of patients with primary cancers outside of the brain. Primary cancers can spread to the CNS in three common locations, the brain tissue (parenchyma), the spinal cord and the cerebral spinal fluid (leptomeninges) and is then called a metastasis. Metastatic disease in the CNS is most commonly caused by the following primary cancer types: lung, melanoma, renal, breast and colorectal cancer, although other types of cancer may also produce metastases to the CNS.

### Pathophysiology

The precise mechanism for cancer cells of a different primary cancer to invade the CNS is not known. Some patients present with metastases to the CNS at the same time that a primary cancer is diagnosed, while other patients present with CNS metastases later in the course of their disease. Primary cancers such as lung cancer are typically a rapidly progressive type of cancer, and therefore it is common to diagnose metastases during the initial presentation.

### Clinical Manifestations

Clinical manifestations of brain tumors are dependent on their location in the brain. For example, a meningioma may be attached to the inside of the dura layer of the meninges

and may protrude several millimeters into the brain tissue in the frontal lobe, producing no clinical manifestations. A larger meningioma in the same area can cause changes in level of consciousness and cognition secondary to pressure on the frontal lobe. The same type of tumor can also be located in the posterior region of the brain between the cerebellum and pons placing pressure on CN VIII, causing decreased hearing on one side. Brain tumors are often referred to as space-occupying lesions that may cause increased ICP depending on the rate of tumor growth and location (Table 36.2). Malignant brain tumors in particular are associated with swelling as the rapid growth damages brain tissue. Clinical manifestations of increased ICP include **papilledema** (swelling of the optic disk), headache, nausea, and vomiting, decreased alertness, cognitive impairment, personality changes, ataxia, hemiparesis, abnormal reflexes, and cranial nerve palsies. Brain tumors may also be diagnosed during the diagnostic evaluation of patients presenting with new onset of seizure activity.

## Management

### Medical Management

Chemotherapy and radiation are used in place of or in conjunction with surgery, depending on the type and location of the tumor. The chemotherapeutic agents used to treat brain tumors must have the ability to cross the blood-brain barrier. Some of the chemotherapeutic agents used

include carmustine, lomustine, thiotepa, and high doses of methotrexate. Side effects of chemotherapy include fatigue, diarrhea, weight loss, nausea, vomiting (or both), mucositis, hair loss, and sterility. Chemotherapeutic agents also cause neutropenia (decreased white blood cell count), requiring special precautions aimed at increasing vigilance to prevent secondary infections that may be life threatening in the immune-compromised patient. Radiation therapy destroys both tumor and normal cells by damaging cellular DNA. A class of chemotherapeutic agents called *radiosensitizers* are administered to patients in combination with radiotherapy in order to create an environment where cancer cells are more susceptible to radiation. A common medication in this class is temozolomide (Temodar).

Radiation treatment is provided in divided doses, maximizing the recovery of normal cells. Radiation is delivered in a focused manner, concentrating on the affected area. Other technologies such as the CyberKnife are used to direct radiation to the tumor, avoiding healthy brain tissue. Side effects of radiation treatment include fatigue, reddening of the skin (sunburn appearance), headache, swelling, visual changes, neurological disturbances, hearing loss, and facial numbness (Table 36.3). See Chapter 13 for more detailed coverage about the management of patients with cancer. Treatment of brain tumors depends on the cell type of tumor as well as specific genetic characteristics. The

**Table 36.2 Presenting Clinical Manifestations of a Brain Mass**

Presenting Symptomology	Location of Tumor
Motor weakness	Frontal motor cortex
Sensory loss	Parietal sensory cortex
Speech	Left inferior frontal lobe (Broca's area) Left temporal lobe (Wernicke's area)
Loss of vision in one eye	Optic nerve
Bitemporal field cuts	Optic chiasm
Loss of visual field on the same side in both eyes	Optic tract Occipital lobe
Loss of upward gaze	Pineal gland
Loss of light reflex	Pineal gland
Bitemporal field cuts with abnormal endocrine function	Suprasellar
Loss of cranial nerves on one side with loss of motor or sensory on contralateral side	Brainstem

**Table 36.3 Nursing Interventions for Complications of Radiation Therapy**

Intervention	Rationale
Fatigue nutritional supplements (i.e., Boost, Ensure)	Fatigue following radiation therapy is common. Those patients experiencing weight loss are more susceptible; therefore, maintaining weight is important.
Skin utilization of sunscreens, sun-protective covering, skin emollients	Reddened, dry areas of the skin and hair loss are sometimes complications of radiation therapy. Ensuring proper sun protection and relief from dry, itching skin is essential.
Headache/Nausea and vomiting dexamethasone (Decadron), ondansetron (Zofran), dronabinol (Marinol)	Radiation therapy of the brain can cause swelling around the area of the tumor, thereby increasing intracranial pressure, causing headache, nausea, and vomiting. Medications such as dexamethasone (Decadron) are used to reduce swelling. Medications to reduce effects such as nausea and vomiting are important because they can cause dehydration and weight loss and negatively impact quality of life.

World Health Organization (WHO) changed the brain tumor classification system to include both cell type and genetic features.

### Surgical Management

Patients undergo biopsies of brain masses to sample the tissue within the mass so that the cells can be examined and a specific diagnosis can be made. Biopsies of brain tissue are performed using advanced radiological techniques that allow the neurosurgeon to map the location of the mass in multiple dimensions. Radiographic images are obtained using CT and MRI scans and are transferred to a computer system that integrates each image into a precise, well-defined coordinate of the area to be biopsied to define an exact location and path for retrieval of brain tissue. This procedure allows for the retrieval of specimens for identification and assists in the determination of an appropriate treatment regimen while minimizing the risk of injury to blood vessels and surrounding healthy brain tissue. The sample of tissue is then examined by a pathologist and a pathological or histological (cellular) diagnosis is made that guides further therapy and treatment planning.

The most common surgical procedure for all types of brain tumors is the craniotomy. During this procedure, a section of the skull is removed (known as a bone flap) to provide access to the brain. In some instances, this can be done to biopsy brain tissue or to excise (remove) a tumor. If the entire tumor cannot be removed, the tumor is debulked, removing as much of the tumor as possible. Following the procedure, the bone flap is then replaced with the use of small plates and screws. Should the bone flap not be returned, the procedure is called a *craniectomy*. When changes in neurological assessment are noted postoperatively and reported to the healthcare provider, they localize the findings to their reference areas in the brain and may order CT imaging to determine whether a structural change has occurred to produce the new findings. A patient's neurological assessment is performed in a serial manner so that the nurse is continually comparing the current assessment with the last one and with the most current baseline.

### Complications

#### Increased Intracranial Pressure

Increased ICP can severely hamper cerebral blood flow, causing decreases in cerebral perfusion pressure (CPP) and leading to secondary injury of the brain via cytotoxic and anoxic injury and herniation of the brain. See Chapter 39 for full coverage of increased ICP.

#### Bleeding

The risk of intracranial bleeding postoperatively is highly variable and dependent on features of the tumor, location in the brain, proximity of the tumor to blood vessels, and the surgical approach. Patients are typically cared for in high-acuity areas such as an intensive care unit or postanesthesia care unit to facilitate frequent neurological assessments, which are necessary to detect early signs of bleeding that

can cause increased ICP. When changes in the neurological assessment are detected, the healthcare team is alerted for further assessment and often radiographical assessment by CT scan is ordered to determine whether there has been a structural change such as bleeding. Bleeding can occur into the area where the tumor was resected, or it can occur above or below the dural covering while blood vessels are manipulated during the surgical approach, which can become disrupted or injured. If postoperative intracranial bleeding is identified, the surgical team determines whether an additional surgical procedure is required or whether medical management can be pursued. The neurological assessment is used to determine how a patient is responding to increased ICP.

#### Cerebral Edema

The most common type of cerebral edema occurring with neurosurgical procedures and brain tumors is called **vasogenic edema**, in which the blood-brain barrier becomes increasingly permeable. This type of edema is most common after brain tumor resection and is secondary to changes to the usually tightly controlled blood-brain barrier that becomes inflamed and more permeable in the area of the tumor and surgical resection. The time course for cerebral edema after brain tumor resection is variable and is associated with the type of tumor. Serial neurological assessments are used to monitor a patient's response to the surgical procedure, and deterioration of that assessment can be caused by cerebral edema. The edema can be located in and around the area where the tumor was resected or can be located along the path taken by the surgeons to expose and resect the tumor. Emergent treatment for cerebral edema includes osmotic diuretics, hyperventilation, and head positioning (head of bed elevated greater than 30 degrees) (see Chapter 39 for a description of treatment for increased ICP). Management of cerebral edema regarding brain tumors often includes increasing the dose of glucocorticoids as these medications decrease the inflammatory process associated with damage in and around the tumor.

#### Seizures

Seizures may occur as a presenting sign of a brain tumor and episodically thereafter, or they may occur postoperatively. Locations closer to the upper regions of the brain (**supratentorial**, or above the tentorium) are at greater risk for seizure activity when an abnormality such as a tumor occurs or when tissues are disrupted during a surgical procedure. Immediate treatment of seizures includes administration of benzodiazepines to stop the seizure and antiepileptic medications to prevent recurrence of the seizure (see the subsequent section on seizures for additional information).

#### Venous Thromboembolism

The occurrence of a malignancy (some brain tumors are malignant), surgical procedure, and immobility place patients with brain tumors at a higher risk of venous thromboembolism (VTE). The nurse ensures that preventive measures

such as mechanical VTE prevention devices (e.g., sequential compression devices) and pharmacological prevention (e.g., heparin administered subcutaneously) are applied and administered as ordered.

## Nursing Management

### Assessment and Analysis

Many of the clinical manifestations observed in the patient with a brain tumor are directly related to the location of the tumor, pressure on adjacent structures, and increased ICP. The clinical presentation often includes:

- Change in level of consciousness
- Headache
- Pupillary changes secondary to compression of CN III
- Vision changes
- Seizure activity
- Elevated blood pressure with widening pulse pressure
- Decreased heart rate
- Nausea and vomiting
- Numbness and tingling

### Nursing Diagnoses

- **Impaired tissue perfusion (cerebral)** associated with decreased cerebral circulation secondary to increased ICP
- **Self-care deficit** associated with decreased level of consciousness and neuromuscular dysfunction
- **Fear** associated with the surgical procedure (craniotomy) to remove the brain tumor
- **Risk for infection** associated with the surgical procedure and immunosuppression secondary to chemotherapeutic agents
- **Altered body image** secondary to potential hair loss secondary to chemotherapy, the surgical procedure, and radiation markings

### Nursing Interventions

#### ■ Assessments

- Neurological assessment including level of consciousness, orientation, motor strength, and sensation. Cranial nerve assessment may also be helpful in monitoring a patient's response to a craniotomy (see Chapter 35 for complete neurological assessment, including cranial nerve assessment).  
*Vigilant monitoring of the neurological assessment, observing for changes from the patient's preoperative and postoperative baseline, is essential for early identification of potentially life-threatening neurological deterioration. Changes in level of consciousness are the most sensitive indicator of increased ICP and can signal complications of brain tumor resection and craniotomy, such as intracranial bleeding and cerebral edema (swelling). Subtle changes in motor strength on one side of the body when compared with the other are significant when they occur during the recovery period after a craniotomy. The baseline neurological assessment after a surgical procedure should be determined and*

*agreed upon by the nurse and providers or nurse practitioners caring for the patient to facilitate future comparisons and interpretation. Pupil reaction to light is part of the assessment and changes in reaction are indicative to damage/compression to CN III (oculomotor nerve).*

- Vital signs including temperature, blood pressure, heart rate, respiratory rate, and pulse oximetry  
*Changes in vital sign measurements can signal pain (tachycardia), and **Cushing's triad** (decreased heart rate, increased systolic blood pressure, and irregular respiratory rate) occurs late in increased ICP signaling herniation syndrome, a medical emergency.*
- Estimated blood loss  
*Estimated blood loss is typically not large in a craniotomy; however, in particular situations, blood loss can be greater than expected, and this should be taken into account during a handoff from the operating room or recovery room.*
- Monitor serum electrolytes, particularly serum sodium and glucose  
*Serum sodium should be maintained within normal values, and possibly on the high end of normal to prevent fluid moving into cells or interstitium potentially raising ICP. Glucose needs to be monitored because dexamethasone may lead to elevated serum glucose levels.*
- Intake and urinary output  
*Strict intake and output measurements are necessary in patients who have undergone a craniotomy in which the pituitary gland has been manipulated. These patients are at risk for diabetes insipidus, in which the nurse observes a large urinary output per hour that can rapidly result in an intravascular volume deficit.*
- Urine specific gravity and osmolality; serum sodium and osmolality  
*In patients who have undergone pituitary surgery, diabetes insipidus can be diagnosed using a combination of conditions including increased urinary output, decreased urine specific gravity (<1.005), an increased serum sodium concentration (>145 mEq/L), and an increase in serum (>280 mOsm/kg) and urine osmolality (<200 mOsm/kg). Increased urine output may decrease blood pressure further, compromising CPP.*
- Pain  
*Patients may experience postoperative pain associated with the incision and positioning of the head and neck during surgery. Judicious use of opioid medications may be used to treat postoperative pain, balancing the importance of maintaining an adequate neurological assessment. NSAIDs are not preferred for pain control in the postoperative period because of concern for an increase in bleeding risk.*
- **Actions**
  - Administer glucocorticoids as ordered, dexamethasone (Decadron)  
*Postoperatively, patients are given glucocorticoids such as dexamethasone to treat and prevent further local cerebral edema. Dexamethasone has been shown to stabilize cell membranes to prevent the occurrence of cerebral edema.*

- Replace urine loss and electrolytes as ordered  
*Dehydration can lead to hemodynamic instability (hypotension, tachycardia, dysrhythmias) and decreased cerebral perfusion.*
- Elevate head of bed 30 to 45 degrees and maintain head in good alignment  
*Promotes venous outflow of blood from the head through the jugular veins in the event of increased ICP*
- Administer stool softeners  
*Decrease Valsalva and straining, which can increase ICP.*
- Administer antiepileptic medications as ordered  
*Patients may be administered antiepileptic medications based on tumor location and a history or risk of seizure activity. Some healthcare providers choose to administer antiepileptic medications for a period of time postoperatively with the goal of preventing seizures, which can occur as a result of tissue disruption during the surgical procedure.*
- Apply mechanical devices and administer pharmacological prophylaxis of venous thromboembolism as ordered  
*The presence of cancer as well as tissue injury during surgery increase a patient's risk of VTE. Pharmacological prophylaxis may not be administered immediately after surgery because of a concern for bleeding risk; however, medication may be initiated further into the patient's hospital course.*

### ■ Teaching

- Tapering of steroids  
*It is important to provide clear direction to the patient and family regarding the tapering of the steroid dose during the prescribed number of days. Rapid withdrawal of glucocorticoids can cause an adrenal crisis.*
- Monitoring of glucose  
*Some patients become hyperglycemic as a result of steroid administration and require home testing of glucose levels while they are receiving glucocorticoids. Typically, this monitoring is temporary until the medication is tapered off.*
- Importance of continuing antiepileptic medications and obtaining prescribed blood levels  
*Some antiepileptic medications may require serum medication levels to ensure that they are maintained at therapeutic levels.*
- Prevention of falls in the hospital and at home  
*Because of previous or new motor weakness or visual deficits, patients may have an increased risk of experiencing a fall either in the hospital or at home. Discussions and planning with the patient regarding potential fall or tripping hazards in the hospital and at home are necessary.*
- Wear hat or head covering as needed  
*Parts of the head may be shaved for the surgical procedure, and with administration of chemotherapy the patient is also at risk for alopecia. Wearing head coverings can decrease heat loss from the head.*
- Mouth care secondary to effects of chemotherapy and/or radiation therapy for brain tumor  
*Chemotherapeutic agents affect cells that divide quickly, which makes the patient at risk for sores in the mouth. Using a soft toothbrush and non-alcohol-containing mouthwash decreases mouth discomfort.*

### Evaluating Care Outcomes

The diagnosis of a brain tumor is very stressful to patients and families. Definitive management of brain tumors is based on the location and type of tumor. Vigilant serial monitoring of the neurological assessment compared with the patient's baseline is essential for these patients. Identifying signs of neurological deterioration early is necessary to prompt medical or surgical intervention and to preserve neurological function. Complications such as VTE, seizures, falls, infection, and aspiration should be considered and incorporated into the patient's plan of care and customized to the patient's particular brain tumor type, location, and functional status.

### CASE STUDY: EPISODE 2

Mr. Johnson is transported to the emergency department by ambulance. According to his wife, he had a headache the night before, took two aspirin, and went to bed. He awoke during the night and went to the bathroom. She heard a noise and checked on him and found him on the floor, mumbling incoherently and unable to move his left side.

A head CT is done and a CT of his neck to rule out a traumatic injury because of the fall in his bathroom. A right frontotemporal mass is found. Mr. Johnson is admitted to the neurosurgical care unit. The CT identifies a brain tumor, and he is scheduled for a craniotomy. The mass is removed and sent to pathology for identification. He is extubated without difficulty in the operating room following the procedure and admitted to the neurosurgical intensive care unit. Although his speech is slightly slowed, he is able to move his right upper extremity with +5 strength, and his right lower extremity is +4 strength. He is prescribed dexamethasone (Decadron), 4 mg IV or PO every 6 hours for 48 hours...

### Connection Check 36.3

Which assessment data does the nurse recognize as the most sensitive indicator of increased ICP?

- Pupillary
- Respiratory
- Level of consciousness
- Cranial nerves

## SEIZURES

### Epidemiology

A seizure is an uncontrolled, sudden, excessive discharge of electrical activity resulting in a range of manifestations from changes in behavior to loss of consciousness. Cryptogenic seizures are those of unknown etiology with no association

with previous insults to the CNS that are known to increase the risk of seizure activity. **Epilepsy, a chronic disorder, is characterized by two seizures unprovoked by any immediately identifiable cause occurring more than 24 hours apart.**

The type of seizure is determined by the originating source (whether it is partial/focal to a specific location) or if the seizure is generalized (encompassing both sides of the brain) and by loss of consciousness. The International League Against Epilepsy (ILAE) distinguishes three major categories for seizure type based on the presenting feature of the seizure (Fig. 36.4). This new categorization was published by the ILAE in 2017 and seeks to simplify description and categorization of seizures for clinicians and the lay public. A companion glossary of terms in Table 36.4 provides additional detail and description to explain the new classifications.

## Pathophysiology

Although no conclusive pathophysiological explanation of cryptogenic seizures has been identified, there are several hypotheses under investigation. It is speculated that the cause of unprovoked seizures involves the genetic or developmental mutation of synapses and of genes coding for sodium channel proteins, causing sodium channels in the brain to remain partly ajar or improperly closed and thereby increasing neuronal hyperexcitability of glutamate. Another possibility involves mutations causing ineffective activity of gamma-aminobutyric acid (GABA), the most common neurotransmitter.

Nonepileptic seizures (Table 36.5) are those provoked by other disorders and conditions and are sometimes

described as secondary seizures. Lesions to the brain caused by trauma, surgery, tumors, and strokes can culminate in a seizure disorder. Metabolic syndromes, as well as manifestations of other disease processes, can also cause seizures. Approximately 20% of patients under investigation for epilepsy are in fact diagnosed with psychogenic nonepileptic seizure disorder. While to all appearances the patient appears to be having an epileptic seizure, there are, in fact, no abnormal electrical discharges. Psychogenic nonepileptic seizure disorder is classified as a conversion disorder by the American Psychiatric Association. Young children and babies may experience one seizure during a febrile illness without identification of cause for the seizure or repeated seizure activity.

## Clinical Manifestations

The clinical presentation of seizure activity is related to the classification (see Fig. 36.4) and can range from rhythmic jerking of all extremities and loss of consciousness as observed in generalized tonic-clonic seizures to episodes of apparent daydreaming and no loss of consciousness as observed in absence seizures. Partial seizures are typically more localized and may have a loss of consciousness, but this does not occur in all partial seizures. Other clinical manifestations include unilateral, rhythmic muscle movements, **automatisms** (repetitive unconscious movements such as lip smacking, chewing, or swallowing), sudden loss of motor tone, and incontinence.

Seizures can be preceded by a **preictal phase** (just before the initiation of the seizure). During this phase, approximately

Glossary of Terms**

<b>Word</b>	<b>Definition</b>
<b>Absence, typical</b>	A sudden onset, interruption of ongoing activities, a blank stare, possibly a brief upward deviation of the eyes. Usually the patient will be unresponsive when spoken to. Duration is a few seconds to half a minute with very rapid recovery. Although not always available, an EEG would show generalized epileptiform discharges during the event. An absence seizure is by definition a seizure of generalized onset. The word is not synonymous with a blank stare, which also can be encountered with focal onset seizures
<b>Absence, atypical</b>	An absence seizure with changes in tone that are more pronounced than in typical absence or the onset and/or cessation is not abrupt, often associated with slow, irregular, generalized spike-wave activity
<b>Arrest</b>	See behavior arrest
<b>Atonic</b>	Sudden loss or diminution of muscle tone without apparent preceding myoclonic or tonic event lasting ~1–2 s, involving head, trunk, jaw, or limb musculature
<b>Automatism</b>	A more or less coordinated motor activity usually occurring when cognition is impaired and for which the subject is usually (but not always) amnesic afterward. This often resembles a voluntary movement and may consist of an inappropriate continuation of preictal motor activity
<b>Autonomic seizure</b>	A distinct alteration of autonomic nervous system function involving cardiovascular, pupillary, gastrointestinal, sudomotor, vasomotor, and thermoregulatory functions
<b>Aura</b>	A subjective ictal phenomenon that, in a given patient, may precede an observable seizure (popular usage)
<b>Awareness</b>	Knowledge of self or environment
<b>Bilateral</b>	Both left and right sides, although manifestations of bilateral seizures may be symmetric or asymmetric
<b>Clonic</b>	Jerking, either symmetric or asymmetric, that is regularly repetitive and involves the same muscle groups
<b>Cognitive</b>	Pertaining to thinking and higher cortical functions, such as language, spatial perception, memory, and praxis. The previous term for similar usage as a seizure type was psychic
<b>Consciousness</b>	A state of mind with both subjective and objective aspects, comprising a sense of self as a unique entity, awareness, responsiveness, and memory
<b>Dacrystic</b>	Bursts of crying, which may or may not be associated with sadness
<b>Dystonic</b>	Sustained contractions of both agonist and antagonist muscles producing athetoid or twisting movements, which may produce abnormal postures
<b>Emotional seizures</b>	Seizures presenting with an emotion or the appearance of having an emotion as an early prominent feature, such as fear, spontaneous joy or euphoria, laughing (gelastic), or crying (dacrystic)
<b>Epileptic spasms</b>	A sudden flexion, extension, or mixed extension–flexion of predominantly proximal and truncal muscles that is usually more sustained than a myoclonic movement but not as sustained as a tonic seizure. Limited forms may occur: Grimacing, head nodding, or subtle eye movements. Epileptic spasms frequently occur in clusters. Infantile spasms are the best-known form, but spasms can occur at all ages
<b>Epilepsy</b>	A disease of the brain defined by any of the following conditions: (1) At least two unprovoked (or reflex) seizures occurring >24 h apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; (3) diagnosis of an epilepsy syndrome. Epilepsy is considered to be resolved for individuals who had an age-dependent epilepsy syndrome but are now past the applicable age or those who have remained seizure free for the last 10 years, with no antiseizure medicines for the last 5 years
<b>Eyelid myoclonia</b>	Jerking of the eyelids at frequencies of at least 3 per second, commonly with upward eye deviation, usually lasting <10 s, often precipitated by eye closure. There may or may not be associated brief loss of awareness
<b>Fencer's posture seizure</b>	A focal motor seizure type with extension of one arm and flexion at the contralateral elbow and wrist, giving an imitation of swordplay with a foil. This has also been called a supplementary motor area seizure
<b>Figure-of-4 seizure</b>	Upper limbs with extension of the arm (usually contralateral to the epileptogenic zone) with elbow flexion of the other arm, forming a figure-of-4
<b>Focal</b>	Originating within networks limited to one hemisphere. They may be discretely localized or more widely distributed. Focal seizures may originate in subcortical structures

**Table 36.4 International League Against Epilepsy (ILAE) 2017 Operational Classification of Seizure Types  
Glossary of Terms—cont'd**

Word	Definition
<b>Focal onset bilateral tonic-clonic seizure</b>	A seizure type with focal onset, with awareness or impaired awareness, either motor or non-motor, progressing to bilateral tonic-clonic activity. The prior term was seizure with partial onset with secondary generalization
<b>Gelastic</b>	Bursts of laughter or giggling, usually without an appropriate affective tone
<b>Generalized</b>	Originating at some point within, and rapidly engaging, bilaterally distributed networks
<b>Generalized tonic-clonic</b>	Bilateral symmetric or sometimes asymmetric tonic contraction and then bilateral clonic contraction of somatic muscles, usually associated with autonomic phenomena and loss of awareness. These seizures engage networks in both hemispheres at the start of the seizure
<b>Hallucination</b>	A creation of composite perceptions without corresponding external stimuli involving visual, auditory, somatosensory, olfactory, and/or gustatory phenomena. Example: "Hearing" and "seeing" people talking
<b>Behavior arrest</b>	Arrest (pause) of activities, freezing, immobilization, as in behavior arrest seizure
<b>Immobility</b>	See activity arrest
<b>Impaired awareness</b>	See awareness. Impaired or lost awareness is a feature of focal impaired awareness seizures, previously called complex partial seizures
<b>Impairment of consciousness</b>	See impaired awareness
<b>Jacksonian seizure</b>	Traditional term indicating spread of clonic movements through contiguous body parts unilaterally
<b>Motor</b>	Involves musculature in any form. The motor event could consist of an increase (positive) or decrease (negative) in muscle contraction to produce a movement
<b>Myoclonic</b>	Sudden, brief (more than 100 msec) involuntary single or multiple contraction(s) of muscles(s) or muscle groups of variable topography (axial, proximal limb, distal). Myoclonus is less regularly repetitive and less sustained than is clonus
<b>Myoclonic-atonic</b>	A generalized seizure type with a myoclonic jerk leading to an atonic motor component. This type was previously called myoclonic-astatic
<b>Myoclonic-tonic-clonic</b>	One or a few jerks of limbs bilaterally, followed by a tonic-clonic seizure. The initial jerks can be considered to be either a brief period of clonus or myoclonus. Seizures with this characteristic are common in juvenile myoclonic epilepsy
<b>Nonmotor</b>	Focal or generalized seizure types in which motor activity is not prominent
<b>Propagation</b>	Spread of seizure activity from one place in the brain to another, or engaging of additional brain networks
<b>Responsiveness</b>	Ability to appropriately react by movement or speech when presented with a stimulus
<b>Seizure</b>	A transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain
<b>Sensory seizure</b>	A perceptual experience not caused by appropriate stimuli in the external world
<b>Spasm</b>	See epileptic spasm
<b>Tonic</b>	A sustained increase in muscle contraction lasting a few seconds to minutes
<b>Tonic-clonic</b>	A sequence consisting of a tonic followed by a clonic phase
<b>Unaware</b>	The term unaware can be used as shorthand for impaired awareness
<b>Unclassified</b>	Referring to a seizure type that cannot be described by the ILAE 2017 classification either because of inadequate information or unusual clinical features. If the seizure is unclassified because the type of onset is unknown, a limited classification may still derive from observed features
<b>Unresponsive</b>	Not able to react appropriately by movement or speech when presented with stimulation
<b>Versive</b>	A sustained, forced conjugate ocular, cephalic, and/or truncal rotation or lateral deviation from the midline

From Fisher, R., Cross, J. H., French, J. A., Higurashi, N., Hirsch, E., Jansen, F. E., Lagae, L. (2017). Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia*, 58(4), 522-530.

**Table 36.5 Causes of Provoked, Nonepileptic Seizures**

<b>Structural</b> (lesions to the brain)	Traumatic injury Stroke Infarct
<b>Vascular</b>	TIA
<b>Infection</b>	Migraine headache Sleep disorders Vasculitis Hydrocephalus Increased intracranial pressure HTN encephalopathy Eclampsia Fever Encephalitis/Meningitis Renal failure Lupus Malaria
<b>Inadequate oxygen to the brain</b> (decreased cerebral perfusion, decreased cardiac output)	Arrhythmias Carbon monoxide poisoning Near drowning
<b>Metabolic</b>	Hypertremia/Hyponatremia Hyperglycemia/Hypoglycemia Hypocalcemia Hypomagnesemia Underactive parathyroid
<b>Substance abuse</b>	ETOH ETOH withdrawal Cocaine Amphetamines
<b>Prescription medications</b>	Antibiotics: ciprofloxacin (Cipro), ceftazidime (Fortaz), cyclosporines (Gengraf) Buspirone (Buspar) Chlorpromazine (Thorazine) Meperidine (Demerol) Phenytoin (Dilantin) Theophylline (Theo-Dur) Overdose of tricyclic antidepressants (amitriptyline)
<b>Toxins</b>	Lead Strychnine

ETOH = Ethyl alcohol; HTN = hypertension; TIA = transient ischemic attack.

20% of those with a seizure disorder may experience what is called an aura. Auras include pleasant or unpleasant odors, visualizations/hallucinations, the sense of “butterflies” in the stomach, a sense of déjà vu, or the intense feeling that a seizure is about to happen.

Following the seizure, there is the **postictal phase**. This is a period after the seizure that lasts 5 to 30 minutes and is an altered state of consciousness. During this phase, the patient can experience drowsiness, confusion, disorientation,

nausea, hypoxia, headache, and migraine. This is the recovery phase of the seizure. Several theories exist to explain this phenomenon including increased ICP secondary to mild **hydrocephalus** (excessive accumulation of CSF in the brain), changes in cerebral blood flow, depletion of neurotransmitters, and alterations in receptor concentrations. Many patients experience exhaustion and depression following the seizure, taking 1 to 2 days for full recovery. During this phase, there may also be diminished short-term memory and poor attention span.

### Connection Check 36.4

A patient with a history of seizures experiences lip smacking and daydreams during a seizure with no loss of consciousness. The nurse recognizes these clinical manifestations as associated with which type of seizure?

- Absence seizure
- Complex partial seizure
- Atonic seizure
- Myoclonic seizure

## Management

### Medical Management

#### Diagnosis

Diagnosis of seizures is made via imaging (CT, MRI) and laboratory work-up to rule out causes (lesions, tumors, metabolic and other disorders) and through diagnostics via EEG monitoring for abnormal electrical activity. In some instances, a sleep-deprived EEG may be performed. Stress, such as that found when the individual is deprived of sleep, causes an increase in cortical activity and is a key trigger for seizures. Interviews with the patient also establish any commonalities of the activity (auras, postictal symptoms).

### Connection Check 36.5

What is used to diagnose a seizure disorder? (Select all that apply.)

- Electroencephalogram
- Lumbar puncture
- Metabolic panel
- Coagulation studies
- Electromyogram

### Age-Related Considerations

Seizures can be difficult to diagnose in older adults because of their resemblance to other conditions of advanced age such as dementia and Alzheimer’s disease. New onset of seizures can generally be attributed to other disorders of cardiovascular and metabolic dysfunction. Because many

anticonvulsant medications are cleared by the liver and liver function can decline with age, dosage adjustments must be considered in terms of half-life and toxicity.

### Medications

Pharmacological therapy is the major approach to the medical management of seizure disorders (Table 36.6). Antiepileptic drugs (AEDs) or anticonvulsants almost always provide complete control of the seizures. Generally, one medication is prescribed to achieve optimal control. Combinations of medications may be required and are introduced one at a time, with the patient observed for breakthrough seizure activity until the new medication has time to reach therapeutic effectiveness.

In some individuals, maintenance of a state of ketosis can metabolically improve seizure control. The ketogenic diet, high in fat (80%–90%) and low in carbohydrates

and protein, can be calculated with daily monitoring and formulation of meal planning.

### Complications

#### Status Epilepticus

A seizure lasting longer than 5 minutes is a medical emergency, and seizures lasting longer than 30 minutes can cause respiratory failure, brain damage, and death. **Status epilepticus**, seizure activity lasting longer than 5 minutes or two or more seizures without full recovery of consciousness can be caused by head trauma, hydrocephalus, acute drug or alcohol withdrawal, metabolic disturbances, or abrupt withdrawal of anticonvulsive medications. Airway, breathing, circulation (ABC) interventions must be initiated immediately. Patients are intubated, and arterial blood gases are monitored. Peripheral IV access must also be established. Medications such as lorazepam (Ativan) or midazolam

**Table 36.6 Medications in the Treatment of Seizures**

Medication	Seizure Type	Side Effects	Nursing Intervention
<b>Carbamazepine (Tegretol)</b>	<ul style="list-style-type: none"> <li>● Secondary tonic-clonic</li> <li>● Complex partial</li> <li>● Simple partial</li> </ul>	<ul style="list-style-type: none"> <li>● Allergy</li> <li>● Dizziness</li> <li>● Ataxia</li> <li>● Blurred/Double vision</li> <li>● Nausea</li> <li>● Behavioral changes</li> <li>● Hepatitis</li> <li>● Aplastic anemia</li> </ul>	<ul style="list-style-type: none"> <li>● Monitor for visual changes</li> <li>● Monitor liver function</li> <li>● Monitor CBC</li> <li>● Do not crush or chew sustained-release capsules</li> </ul>

(Versed), both benzodiazepines, are generally first line in the immediate treatment of seizures, including status epilepticus. To stabilize the patient, a loading dose of phenytoin (Dilantin) or levetiracetam (Keppra) (anticonvulsants) is generally administered along with around-the-clock dosing. When the

seizure is refractory to all interventions, patients are placed on high doses of propofol (Diprivan) or placed in a pentobarbital coma. Not only is close monitoring of cardiovascular status required, but continuous EEG monitoring for burst suppression is also initiated.

## Surgical Management

Several procedures have been used to treat seizure disorders not managed effectively with pharmacological therapy. Similar to a cardiac pacemaker, the vagal nerve stimulator (VNS) can provide relief for those suffering from refractory simple or complex seizures. It is proposed that stimulation of the vagus nerve (CN X) can effectively control seizure activity via alterations in the release of norepinephrine, increasing the levels of GABA (inhibitory neurotransmitter) and/or by the inhibition of aberrant cortical activity in the reticular activating system.

Implantation of the VNS is generally performed on an outpatient basis. The generator is implanted into a small “pouch” in the left chest below the clavicle. Access to the vagal nerve is then established via an incision in the neck. Either postoperatively or within a 2-week period, the generator is activated and programmed specifically to the patient. The generator is either continuously stimulating the vagus nerve, or the patient carries a small handheld magnet with which he can activate the program with the presence of an aura; thus a seizure can be minimized and extinguished.

**Deep brain stimulation** is used to treat uncontrolled seizure activity. Electrodes are placed in deep brain structures, including the thalamus, hippocampus, and internal capsule, and are programmed to activate when the seizure activity is sensed. Deep brain stimulation involves implanting electrodes into the brain that release electrical impulses. The therapeutic effect is the reduction of the frequency of seizure activity.

Other surgical approaches to the control of epilepsy in patients unresponsive to medication therapy include **partial corpus callosotomy** (pediatrics), removal of brain tissue that has been identified as containing a seizure focus through surgical excision or laser ablation. These procedures are used for patients with intractable seizures that have been localized to a specific area of the brain. During the partial corpus callosotomy a craniotomy is performed and the connection between the right and left hemispheres of the brain is either disrupted partially or totally severed. This procedure reduces the frequency and severity of the seizures because electrical activity can no longer spread from one hemisphere to the other. Postoperative management is similar to that of the patient undergoing craniotomy for a brain tumor.

Before these surgical procedures, patients are typically evaluated in a dedicated epilepsy monitoring unit, often with surgically placed EEG electrodes on the surface of the brain to specifically identify areas of brain tissue involved in seizure activity. These electrodes are placed during a craniotomy in which the surface of the brain is accessed after a section of the skull is removed, and the electrodes are placed on the surface of the brain. The skull section is replaced similarly to other types of craniotomies, with the connecting wires exposed outside of the surgical wound. The EEG electrodes are connected to an EEG machine for extended monitoring with the goal of identifying a definitive focus of the seizure activity that can be removed. An interprofessional

team consisting of neurologists, neurosurgeons, specially trained nurses and EEG technicians care for patients in the epilepsy monitoring unit (EMU).

## Nursing Management

### Assessment and Analysis

The clinical manifestations of seizure vary widely depending on the etiology of the disorder and the area of the brain involved. Management of seizure activity requires careful observation. Clinical manifestations include:

- Tonic movements
- Clonic movement
- Loss of consciousness
- Aura
- Automatism
- Loss of motor tone

### Nursing Diagnoses

- **Risk for ineffective breathing pattern** related to decreased level of consciousness secondary to the postictal state
- **Risk for injury** related to tonic-clonic motor activity
- **Ineffective coping** related to uncertainty and inability to control the seizures

### Nursing Interventions

#### ■ Assessments

- Airway  
*During the seizure and postictal state, the patient may have a compromised airway secondary to decreased level of consciousness.*
- Vital signs  
*Blood pressure, heart rate, and oxygen saturation should be carefully monitored during and after the seizure. Elevations in heart rate and blood pressure may develop during the seizure, and respiratory changes, including airway compromise, may develop after the seizure.*
- Seizure activity  
*Accurate diagnosis and treatment of seizure activity are facilitated by a detailed description of patient observations immediately before, during, and after the seizure.*
- Presence of an aura  
*Some patients may experience an aura in advance of a seizure, allowing the patient to assume a safe position.*

#### ■ Actions

- Set up suction equipment at the patient's bedside  
*The patient may be unable to protect the airway after the seizure activity and may require suctioning of the oral airway.*
- Have oxygen available at the patient's bedside  
*During the postictal phase, the patient may require supplemental oxygenation to maintain the oxygenation saturation within normal limits for the patient.*
- Safety measures (bed in lowest position, suction at the bedside, oral airway at the bedside)  
*For the patient experiencing a witnessed seizure, protection includes not forcing any object into the mouth (for fear of biting*

tongue, breaking teeth, causing injury, etc.), loosening of restrictive clothing, and turning the patient to the side (preferably to the left side to reduce the risk of aspiration). No attempt should be made to restrain the patient's movement; however, guiding the movement may be necessary to prevent injury.

- Place an IV catheter per orders  
*In the event of seizure activity, IV access may be needed to administer medications to stop the seizure activity.*
- Document specifics of seizure, observed seizure activity  
*Following the seizure, documentation should provide the date, time, and duration of the seizure; a clear description of the seizure; the sequence of the seizure progression; and preictal and postictal observations.*

### ■ Teaching

- Medication regimen  
*Control of seizure activity is largely determined by therapeutic levels of prescribed antiseizure medications.*
- Medic Alert bracelet  
*It is important for patients with seizures to wear a Medic Alert bracelet in the event of seizure activity. This facilitates prompt interventions in the event of a seizure.*
- Driving restrictions  
*It is important for the patient to research driving restrictions in the state of residence/licensed to drive, as some states restrict driving in patients with seizure disorders. People with a newly diagnosed seizure disorder are required to notify their department of motor vehicles/driving administration.*

### Evaluating Care Outcomes

Quality of life is closely related to effective control of seizure activity. Compliance with medication, dietary, and activity prescriptions are important to facilitate seizure control. People diagnosed with seizure disorders may also benefit from support and social support to prevent stress and for coping issues related to diagnosis of seizures. Most adult patients diagnosed with seizure disorders are required to take anticonvulsant medications for life.

### CASE STUDY: EPISODE 3

Mr. Johnson is postoperative day 2 following his surgery for a right frontotemporal mass. He is alert and oriented, his speech is markedly improved, and his spirits are good. He is seen by speech therapy and passes a swallowing evaluation for a regular diet. Physical therapy is working with him daily. While visiting her husband, Mrs. Johnson begins to scream for help. The nurse finds Mr. Johnson in bed, gurgling, with tonic-clonic movements, and he does not respond to her. He is placed on his left side and given 2 mg of lorazepam intravenously. After 3 minutes, the seizure subsides. The provider comes to the bedside quickly. The nurse tells the provider the details prior to the event, how long it lasted, what the patient was doing during the event, and what was given to control it.

Mr. Johnson is ordered a 1-g bolus of levetiracetam IV and 500 mg IV every 12 hours. An EEG is ordered. The nurse explains to both Mr. and Mrs. Johnson that the potential for seizures postoperatively is high, and the bed should remain in the lowest position with the side rails up...

### Connection Check 36.6

A patient with a history of complex partial seizures has a phenytoin (Dilantin) level (free) of 3.1 mcg/mL. The nurse calls the patient and instructs the patient to take which action?

- Stop the medication and make an appointment for the following week with the provider.
- Continue the medication and make an appointment right away with the healthcare provider.
- Take an extra dose now and continue with the current regimen.
- Skip the next dose and make an appointment right away with the healthcare provider.

## MENINGITIS

Meningitis is an inflammation of the **meninges**, the thin covering around the brain and spinal cord. Causes of meningitis include bacterial infection, viral infection, fungal infection, and what is called **aseptic meningitis**. Aseptic causes of meningitis include the use of antibiotics, nonsteroidal anti-inflammatory medications, and **carcinomatosis** (widespread dissemination of cancer throughout the body). Viral meningitis is also considered aseptic meningitis.

### Epidemiology

The incidence of meningitis is increased in settings where people live in close proximity, including college dormitories, military barracks, and prisons. In the United States, rates of bacterial meningitis have markedly declined, to a current rate of 0.6 to 4 cases per 100,000 yearly because of the institution of vaccines such as Hib (*Haemophilus influenzae* type b) and conjugate vaccines for *Streptococcus pneumoniae*. The prevalence of meningitis is 10-fold in developing countries. In populations not immunized against mumps, the prevalence of meningitis is 10.9 cases per 100,000, with 30% of those who contract mumps culminating in meningitis. The very young (infants) and those older than 60 years are more predisposed to contracting meningitis.

### Pathophysiology

Meningitis is classified as acute or chronic. Acute meningitis indicates a bacterial cause, with the presence of clinical manifestations occurring in hours to days and CSF **pleocytosis** (markedly increased white blood cells). The

inflammatory process within the meninges leads to increased turbidity of CSF, leading to sluggish flow of CSF. Acute bacterial meningitis is a medical emergency. Chronic meningitis has an onset of symptoms during weeks to months, with duration of symptoms longer than 4 weeks.

Several routes of entry are responsible for the development of meningitis. Direct inoculation of the organisms responsible for meningitis occurs secondary to traumatic injury and transmission during surgery, procedures such as lumbar punctures, and with monitoring devices such as intraventricular catheters. Transmission also occurs following the colonization or localized infections of bacteria, viruses, fungi, and parasites. This occurs via the skin, the nasopharynx, the respiratory tract (most common), the gastrointestinal and the genitourinary tracts. The organism invades the submucosa, gaining access to the bloodstream and CNS, where the organism begins to seed the CNS. Another means by which transmission occurs is via retrograde neuronal pathways (olfactory and peripheral nerves).

Viral meningitis, an aseptic form of meningitis, is most commonly caused by enterovirus, herpes simplex virus (HSV), herpes zoster, mumps, and measles. A self-limiting form, viral meningitis causes cell necrosis or results in enzymatic or neurotransmitter alterations, depending on the pathogen and cells involved.

Meningitis is a medical emergency because the increased turbidity and sluggish flow of CSF can lead to an increased ICP. While the ICP increases, herniation of the brain can occur because of displacement of brain tissue, CSF, and compression of blood vessels, culminating in severe brain damage, coma, and death. Increased ICP can also be caused by interstitial edema via obstruction of CSF flow and hydrocephalus, cytotoxic edema caused by bacterial release of cytotoxins and neutrophils, which cause cellular swelling, and via vasogenic edema and the increased permeability of the blood-brain barrier.

## Clinical Manifestations

The characteristic presentation of meningitis in the adult includes fever, headache, and divergent degrees of altered mental status. The patient may also report **photophobia**

(sensitivity to light), chills, nausea, and vomiting. The clinical presentation of meningeal irritation includes nuchal rigidity (neck stiffness) and **opisthotonos** (severe hyperextension of the head with arching of the back). In cases of meningococcal meningitis, a faint petechial rash can develop, which can develop into disseminated intravascular coagulation (DIC).

## Connection Check 36.7

Before the start of the semester, what type of meningitis can college-aged students be vaccinated against?

- A. Bacterial meningitis
- B. Viral meningitis
- C. Aseptic meningitis
- D. Fungal meningitis

## Management

### Medical Management

#### Diagnosis

Examination of CSF via lumbar puncture is the hallmark for the diagnosis of meningitis. Patients with suspicion for space-occupying lesions and new-onset seizures and those with a moderate to severe altered level of consciousness require a CT of the head before the procedure because they are at higher risk for herniation. The opening pressure at the time of the lumbar puncture is recorded, and specimens are tested for glucose, protein, white blood cell count, Gram stain, and culture. Patients with diabetes mellitus may have a higher than normal serum glucose. Therefore, serum glucose is drawn during the time of the lumbar puncture. The rule of thumb is that the CSF glucose level is two-thirds that of the serum glucose (Table 36.7).

Meningitis is also caused by other factors such as pericarditis and myocarditis; therefore, assessment of additional data such as heart murmurs and results of an echocardiogram are analyzed to rule out these causes. Other causes of meningitis include infection from a cochlear implant, conjunctivitis, and exposure to animals and animal bites, requiring investigation.

**Table 36.7 Cerebrospinal Fluid Examination in Meningitis**

	Glucose	Protein	White Blood Cell Count	Microbiology
<b>Normal values</b>	50–75 mg/dL	14–40 mg/dL	0–5; Lymphocytes	Negative
<b>Aseptic</b>	Normal	Normal to slight ↑	10–30; Lymphocytes	Negative
<b>Bacterial</b>	Less than 40 mg/dL	Higher than 100 mg/dL	100–500 With more than 80% polymorphonuclear (PMN) lymphocytes	Gram stain and culture + for specific pathogens
<b>Viral</b>	Normal	Normal to slight ↑	10–300	Viral isolation, polymerase chain reaction (PCR)

## Medications

On the basis of the initial assessment and presumptive diagnosis and before confirmation from microbiological data, broad-spectrum antibiotics are initiated. Treatment for meningitis is dependent on the penetration of the blood–brain barrier by the chosen antibiotic as well as by the type of pathogen itself. Treatment for meningitis generally requires 14 to 21 days of antibiotic treatment. Long-term IV access such as a peripherally inserted central line or other central venous access is typically initiated because of the need for long-term antibiotic therapy.

## Complications

Increased ICP is a life-threatening complication of meningitis, and identification and treatment of increased ICP are vital. Early signs of increased ICP are identified during the neurological examination, requiring frequent assessment. The use of dexamethasone to reduce inflammation in the treatment of meningitis remains controversial (see Evidence-Based Practice). Several studies have shown a reduction in hearing loss in those patients with meningitis caused by *H. influenzae*. Irritation of the cerebral cortex can cause seizure activity in the patient with meningitis. Patients with meningitis are also at risk for syndrome of inappropriate antidiuretic hormone (SIADH) and diabetes insipidus (DI).

## Evidence-Based Practice

### Corticosteroids in the Treatment of Bacterial Meningitis

A Cochrane Review was conducted to examine the outcomes of the use of corticosteroids in the treatment of the inflammatory response in meningitis. The search included studies between 1996 and 2015, and selection criteria included randomized controlled studies (RCTs) of corticosteroids for acute bacterial meningitis. The RCTs were scored for methodological quality, and outcome data were collected, including adverse effects. Separate analyses were completed regarding causative organisms, differences between high-income and low-income countries, and time of steroid administration. Twenty-five studies were located that included 4,121 participants, with 2,511 children, 1,517 adults, and 93 with mixed populations. Findings demonstrated a non-significant reduction in mortality in adults receiving corticosteroids. Analyses of causative organisms demonstrated that corticosteroids reduced mortality in patients with *Streptococcus pneumoniae* meningitis but not in *Haemophilus influenzae*. Corticosteroids were associated with lower rates of significant hearing loss in high-income countries but not in low-income countries. Because corticosteroids significantly reduced hearing loss and neurological sequelae, recommendations from this review support the use of corticosteroids

in patients with bacterial meningitis in high-income countries but not in low-income countries. The use of corticosteroids was not found to reduce overall mortality in the treatment of patients with meningitis.

Brouwer, M. C., McIntyre, P., Prasad, K., & van de Beek, D. (2015). Corticosteroids for acute bacterial meningitis. *Cochrane Database of Systematic Reviews*, 6 CD004405. doi: 10.1002/14651858.CD004405.pub4.

## Nursing Management

### Assessment and Analysis

Many of the clinical manifestations observed in the patient with meningitis are directly related to irritation and inflammation of the meninges that surround the brain and spinal cord. Common clinical findings include:

- Change in level of consciousness
- Headache
- Fever
- Photophobia
- Nausea and vomiting
- Rhinorrhea
- Nuchal rigidity
- **Brudzinski's sign** (involuntary flexion of the hips in response to passive flexion of the neck with the patient in a supine position) (Fig. 36.5)
- **Kernig's sign** (pain in the back of the leg [hamstring] and resistance to movement when the leg is flexed at the hip and then straightened at the knee) (Fig. 36.6)

The neurological examination is the most significant nursing intervention in the care of the patient with meningitis.

### Nursing Diagnoses

- **Disturbed sensory perception** related to meningeal irritation
- **Activity intolerance** related to pain and fatigue
- **Ineffective coping** related to the complexity of the treatment regimen to manage meningitis

### Nursing Interventions

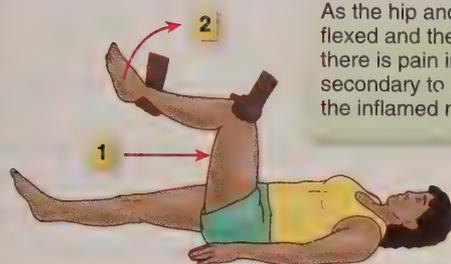

#### ■ Assessments

- Neurological status  
*Because of the risk of increased ICP secondary to increased turbidity of CSF, frequent neurological assessments are essential to recognize subtle signs. Changes in level of consciousness are the earliest sign of increased ICP and should be reported immediately to the healthcare provider.*
- Sign of meningeal irritation (nuchal rigidity, Brudzinski's sign, Kernig's sign)  
*The inflammatory process in the meninges causes pain upon movement of the neck, and the patient guards the neck. In the patient with a positive Brudzinski's sign, there is involuntary flexion of the hips in response to passive flexion of the neck with the patient in a supine position (ensure no cervical spine injury prior to attempting). To assess the Kernig's sign,*

As the neck is flexed, there is stretch on the inflamed meninges, and the knees flex involuntarily to decrease the pain caused by the stretching of the meninges

FIGURE 36.5 Brudzinski's sign.

As the hip and knee are flexed and then straightened, there is pain in the hamstring secondary to stretching of the inflamed meninges

FIGURE 36.6 Kernig's sign.

the nurse starts with the patient's hip and knee flexed at a 90-degree angle and then slowly extends (do not force) the knee. Pain behind the knee and repeated pain bilaterally are indicative of a positive sign.

- Vital signs  
Elevated temperature develops secondary to the infectious process. If increased ICP develops, the blood pressure increases with widening pulse pressure and decrease in heart rate.
- Fluid balance  
Monitor blood pressure for signs of hypo/hypertension and heart rate. If the patient develops SLADH, fluid is retained and there may be an increase in blood pressure. With DI the patient has an increased output of dilute urine and is at risk for hypovolemia, hypotension, and tachycardia.
- Headache  
The inflammation of the meninges may lead to headache.
- Cranial nerve assessment: with particular attention to CNs III, IV, and VI  
The eye on the affected side can deviate down and out because of a dilated, light-fixed pupil.
- CSF results  
Treatment of meningitis, particularly bacterial infections, is directed to the specific organism that is isolated in the CSF sample.
- Daily weight  
Changes in fluid volume status correspond to changes in body weight.
- Renal function  
Many antibiotics are cleared by the kidneys, so increases in blood urea nitrogen and creatinine may demonstrate damage to the renal system.
- Vascular assessments  
In the patient who develops DIC, there may be increased bleeding as well as decreased peripheral perfusion.

#### ■ Actions

- Administer IV fluids  
*The patient may have changes in fluid volume status related to increased fluid loss with elevated temperature or development of diabetes insipidus.*
  - Administer antibiotics as ordered  
*Antibiotics should be initiated without delay, and antibiotics that require therapeutic dosing should be monitored judiciously to facilitate their therapeutic goals.*
  - Decrease environmental stimuli  
*Dim the lights, exposure to bright lights from windows (patients may be photo sensitive); and provide quiet environment as these may exacerbate associated with meningitis.*
  - Maintain head of bed elevated to 30 degrees  
*This position increases venous outflow and may decrease intracranial pressure that may be elevated due to turbidity of the CSF.*
  - Pain management  
*Because of associated headache, it is important to implement pharmacological and nonpharmacological interventions to promote patient comfort.*
  - Implement transmission precautions  
*Standard precautions are maintained for all patients. Include droplet precautions (bacterial meningitis per hospital policy).*
  - Maintain normothermia via antipyretic, cooling baths, and cooling blankets  
*Decreases metabolic activity and decreases CNS oxygen demand*
- #### ■ Teaching
- Importance of follow-up appointments  
*Recovery from meningitis may take weeks to months and requires frequent assessment and evaluation by the health-care provider.*
  - Importance of taking full course of antibiotics  
*Extended antibiotic therapy may be indicated to lessen the chances of reoccurrence of the infectious process.*

#### Evaluating Care Outcomes

Management of meningitis requires eradication of the infectious organism. During the acute phase, the patient's chief complaints are pain, neck stiffness, and photophobia. Definitive interventions focus on antibiotic therapies and comfort measures. Antipyretics may be indicated with fever. Monitoring for increased ICP is a priority during the acute phase of meningitis. Upon discharge, the patient will be

neurologically and hemodynamically stable, and the patient also needs to be knowledgeable of signs of recurrent infection and increased ICP to seek emergent treatment. Compliance with antibiotic therapy after discharge is also a priority because the patient may be discharged while still receiving antibiotic therapy.

## ENCEPHALITIS

### Epidemiology

Several thousand cases of encephalitis are reported yearly and are primarily caused by enteroviruses such as herpes simplex I and II and arboviruses (transmitted via anthropoid vectors) such as rabies, Lyme disease, and West Nile virus. Herpes simplex virus I causes approximately 10% or 2 million cases in the United States in those from age 20 to 40 years. Herpes simplex virus is the single most rapidly progressing form in the United States. Herpes simplex virus I is contracted via bodily fluids such as oral and nasal secretions, whereas HSV II is sexually transmitted. Primary encephalitis can be sporadic or epidemic. Sporadic forms of encephalitis include HSV, whereas arboviruses such as West Nile virus, St. Louis virus, La Crosse virus, and rabies can be sporadic or epidemic. Encephalitis can also be a complication of an initial virus or reactivation of latent viruses as a result of a compromised immune system, such as varicella-zoster (chickenpox), rubeola (measles), mumps, and rubella (German measles). Most often caused by viral infections, encephalitis can also be caused by bacteria, fungi, and parasitic inoculation. Eastern equine virus is transmitted via horses, humans, and birds and is found primarily in the Eastern United States and Gulf Coast. Western equine virus, predominately found in the Central Plains, involves farming communities. St. Louis virus is seen throughout most temperate regions and throughout the country. West Nile virus, first diagnosed in 1991, is transmitted via the bites of mosquitoes through the bites of infected animals, and Lyme disease is transmitted through the bite of infected ticks.

### Pathophysiology

Encephalitis is an acute inflammation of the brain, including the cerebrum, brainstem, and cerebellum, whereas meningitis involves the layers (meninges) covering the brain and spinal cord (myelitis). While the pathogen travels to the CNS, it invades the brain tissues and reproduces, leading to inflammation of the cerebral cortex and white matter. When the inflammation involves both the brain and spinal cord, it is called **encephalomyelitis**.

Acute viral encephalitis can be a life-threatening emergency, quickly leading to increased ICP, coma, and death. Although encephalitis is dangerous in all age groups, those who are very young (infants and children), older adults, and the immunocompromised are most at risk. All forms of encephalitis can take weeks to months to resolve and can leave the patient with debilitating neurological injury and deficits.

In some cases, encephalitis can be caused by an autoimmune response. An immune response causing encephalitis has been known to occur in the presence of cancer, termed paraneoplastic disease, in presence of co-occurring autoimmune disease such as lupus erythematosus, and in response to a recent viral infection. The clinical workup for this type of encephalitis is similar to encephalitis for infectious disease except for additional blood and CSF biomarkers of cancer and specific autoimmune disorders.

### Clinical Manifestations

The clinical presentation of the patient with encephalitis includes manifestations associated with an infectious process, including fever, as well as neurological deficits associated with damage to the brain and spinal cord. Common complaints include headache, photophobia, phonophobia (fear of loud noises), and nuchal rigidity. While the infectious process develops, clinical manifestation of increased ICP may be present, including a change in level of consciousness (lethargy, disorientation), as well as focal signs, including muscle spasms and paresthesias.

### Management

#### Medical Management

#### Diagnosis

Diagnosis of encephalitis follows the procedures and protocol of meningitis, involving examination of the blood and CSF as well as the EEG, CT, and MRI scans. Antivirals are used to treat encephalitis. Acyclovir is used to treat most forms of encephalitis and is considered a prodrug because of its initial administration in a less active form, then metabolized into a more active species after administration. Bioavailability of this medication is low; it also has low solubility in water and is therefore best administered in IV form when high concentrations are required. Ganciclovir (Cytovene) is used in the treatment of encephalitis caused by organisms such as cytomegalovirus (CMV).

**Safety Alert** Considered a potential carcinogen, teratogen, and mutagen, ganciclovir, used in the treatment of encephalitis caused by CMV, requires judicious handling.

### Connection Check 36.8

The nurse monitors which diagnostic results in the patient with bacterial encephalitis? (Select all that apply.)

- A. Isolation of CSF via polymerase chain reaction
- B. Gram stain and culture of CSF
- C. CT
- D. MRI
- E. EMG

## Nursing Management

### Assessment and Analysis

The clinical presentation and management of encephalitis is similar to that of meningitis. Typical clinical manifestations include:

- Changes in level of consciousness
- Fever
- Headache
- Photophobia
- Weakness
- Nuchal rigidity

### Nursing Diagnoses

- **Ineffective cerebral tissue perfusion** related to hydrocephalus
- **Self-care deficit** related to decreased level of consciousness and weakness
- **Risk for injury** related to decreased level of consciousness

### Nursing Interventions

#### ■ Assessments

- Neurological function  
*The infectious process in the CNS may act as a space-occupying lesion and increase ICP, leading to changes in the level of consciousness.*
- Vital signs  
*Because this is an infectious process, the patient may have an elevated temperature and tachycardia. If ICP is elevated, an increase in blood pressure and widening of pulse pressure may develop.*
- Nuchal rigidity, Brudzinski's and Kernig's signs  
*Signs of meningeal irritation and involvement of the brain itself can lead to extension into the meningeal layers.*
- Cranial nerve assessment with particular attention to CNS III, IV, and VI  
*The eye on the affected side can deviate down and out, with a dilated, light-fixed pupil.*
- Intake and output  
*Fever may increase insensible water loss and some of the antibiotics, and antiviral medications may cause nausea, vomiting, and diarrhea.*
- Complete blood counts  
*Antiviral medications may cause hematological dyscrasias: granulocytopenia, neutropenia, anemia, and thrombocytopenia.*
- Monitor liver function tests (LFTs)  
*Antivirals and antibiotics may lead to elevation of liver enzymes due to potential hepatotoxicity.*

#### ■ Actions

- Position patient with head of bed elevated to 30 to 45 degrees with head in good alignment  
*This position facilitates venous drainage and minimizes the risk of increased ICP.*

- Implement seizure precautions  
*Because of the potential for increased ICP as well as the presence of an infectious process in the CNS, the patient's seizure threshold is decreased.*
- Encourage oral intake as tolerated  
*Because of nausea and vomiting that may occur as side effects of medications, it is important to optimize dietary intake.*
- Dim lights and maintain a quiet environment  
*These interventions decrease environmental stimuli. Bright lights and loud noises may exacerbate headache. Patients may have photophobia and phonophobia.*
- Turn and reposition the patient at least every 2 hours  
*Because of limited activity, the patient is at risk of complications of immobility, in particular, skin breakdown.*
- Administer stool softeners as needed to prevent constipation  
*Limited activity, potential nausea and vomiting, and decreased oral intake increase the chances of constipation; need to minimize Valsalva because of potential to increase ICP*

#### ■ Teaching

- Complications of immobility  
*Because the course of encephalitis may lead to an extended hospitalization and bedrest, the patient is at risk for skin breakdown, deep vein thromboembolism, and deconditioning. The recovery process may be extended, and the patient's compliance with interventions to recondition are imperative.*
- Importance of follow-up appointments  
*Recovery from encephalitis may take weeks to months and requires frequent assessment and evaluation by the healthcare provider.*
- Importance of taking full course of antibiotics  
*Extended antibiotic therapy may be indicated to lessen the chances of reoccurrence of the infectious process.*

### Evaluating Care Outcomes

Management of encephalitis requires eradication of the infectious organism. Patients with encephalitis are often critically ill, requiring admission to an intensive care setting. Because of complications associated with increased ICP, the patient's recovery is dependent on secondary injury associated with compression of vital structures. The nurse works with the patient and family to ensure compliance with all prescribed interventions and, before discharge, ensures that they are knowledgeable of reasons to seek medical attention.

## PARKINSON'S DISEASE

### Epidemiology

Parkinson's disease (PD) is a progressive, neurodegenerative disease of the CNS manifesting primarily in motor dysfunction. Primarily of idiopathic origin, environmental toxins (pesticides and herbicides), brain injury, brain tumors, the use of antipsychotic medication, and a genetic component have all been implicated as possible causes of PD.

Parkinson's disease is found 1.5 to 2 times more often in males than in females and generally begins between the ages

of 40 and 70 years. Progression of the disease is escalated in those who are diagnosed at later stages in life. In the United States, the highest prevalence of PD is found within Amish communities. With annual reports of 50,000 new cases per year, it is estimated that more than 500,000 people are afflicted with PD in the United States alone.

## Pathophysiology

A motor system disorder, Parkinson's involves the loss of dopamine-producing brain cells in the substantia nigra of the basal ganglia, culminating in a decreased amount of dopamine in the brain. The basal ganglia of the brain consist of several brain structures or collections of neurons (Fig. 36.7): the striatum (caudate, putamen, and globus pallidus), the substantia nigra, and the subthalamic nucleus, all innervated by the dopaminergic system. Motor activity is the result of the release of dopamine and acetylcholine (ACh) and the integration of the basal ganglia, the cerebral cortex, and the cerebellum. With stimulation of the basal ganglia, muscle tone is inhibited and voluntary movement is coordinated and smoothly executed. The coordination of the excitatory messages from the production of ACh in the basal ganglia and the inhibitory messages from dopamine via transport from the substantia nigra to the basal ganglia allow for the control of steady, well-coordinated, fine movement. Deterioration of the substantia nigra decreases the amount of dopamine in the brain. The excitatory ACh neurons continue to proliferate, remaining active while there is a continued loss of dopamine and its inhibitory mechanisms, culminating in the loss of initiation and control of voluntary movement.

## Clinical Manifestations

Four discernible symptoms of PD are resting tremors, muscle rigidity, slowness of movement (**bradykinesia**) or loss of movement (akinesia), and postural instability (impaired balance and frequent falls). Other clinical manifestations include mood, cognitive, and behavioral alterations.

Parkinson's disease is characterized by five progressive stages. In the first initial stage, the patient usually presents with unexplained unilateral weakness and upper-extremity tremors. While the patient progresses into later stages, more-pronounced physical disabilities are noted, including a slow, shuffling gait, widening on gait, and postural instability. In the final stages, movements become much slower and rigidity is more pronounced (Fig. 36.8).

## Connection Check 36.9

The nurse recognizes that the patient with Parkinson's disease is at risk for which complication?

- Excessive dry mouth due to autonomic dysfunction
- Facial twitching secondary to seizure activity
- Orthostatic hypotension due to involvement of the sympathetic nervous system
- Flaccid extremities related to the increased levels of dopamine

## Management

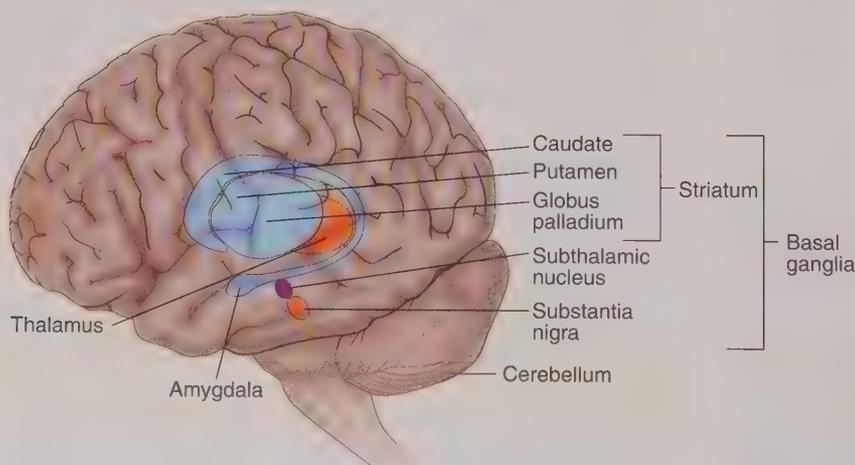

### Medical Management

#### Diagnosis

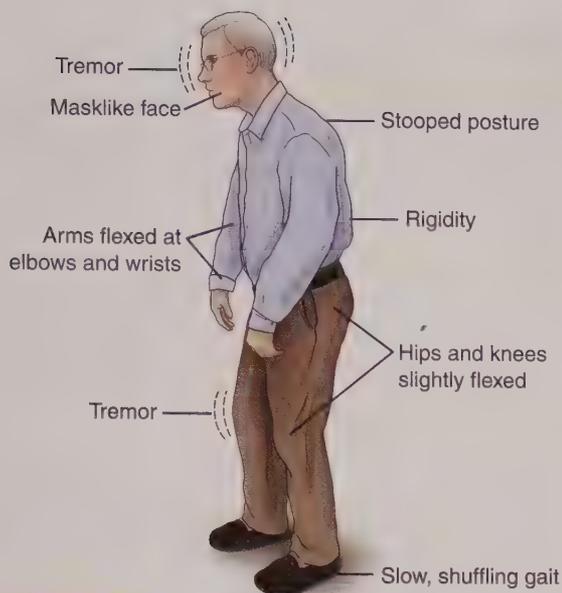

Diagnosis of PD is made when two or more cardinal symptoms with asymmetrical presentation, bradykinesia (slow movement), resting tremor, rigidity, and postural instability, are observed in the absence of other causes. There are no specific diagnostic studies to confirm PD, so the presence of progressive decline in motor function accompanied by the tremors and rigidity is typically how the diagnosis is made.

#### Medications

Pharmacological therapy is initiated when symptoms become difficult or disabling for the patient. Anticholinergics, which can reduce tremors and drooling, may be used in younger patients and include trihexyphenidyl (Artane) and

**FIGURE 36.7** Sites of damage in Parkinson's disease.

**FIGURE 36.8** Clinical presentation of Parkinson's disease.

benztropine (Cogentin). These medications are generally not used in older adults because of side effects including confusion, memory impairment, blurred vision, dry mouth, constipation, and urinary retention.

Dopamine-receptor agonists such as pramipexole (Mirapex) and ropinirole (Requip) are often first-line treatments. Side effects of these medications include nausea and vomiting, urinary frequency, drowsiness, orthostatic hypotension, lower-extremity edema, sleep attacks, and disorders of impulse control (gambling and hypersexuality).

With the progression of PD, levodopa seems to become less effective in the elimination of related motor symptoms. Eventually, the “on” state diminishes, and the “wearing off” state occurs earlier. In this “off” state, the patient with PD becomes stiff and slow and may be unable to move for several minutes. For some, this “on-off” phenomenon is predictable, and it is believed that these fluctuations respond to controlled-release forms of levodopa. For this reason, dopamine precursors such as carbidopa/levodopa (Sinemet) are later used and are most effective in the treatment of bradykinesia, tremors, and rigidity. Recently, an intestinal gel containing levodopa/carbidopa has been introduced as an option for the treatment of motor fluctuations in advanced Parkinson's disease when oral medication is no longer effective. This intestinal gel is administered by an external pump through a percutaneous endoscopic gastric-jejunal tube. These medications can cause side effects consisting of nausea and vomiting, orthostatic hypotension, constipation, arrhythmias, dyskinesias, and dry mouth.

### Surgical Management

Stereotactic pallidotomy for control of the clinical manifestations associated with PD involves the opening of the pallidum within the corpus striatum. Locating the specific site is performed via the use of multiple CTs of the head and the stereotactic head ring. Once the location is identified, a

burr hole is performed for access and a cylindrical rod or electrode is implanted, allowing the targeted area to receive mild electrical stimulation to reduce tremors and the rigidity associated with PD. Once the probe is confirmed to be in the proper location, a permanent lesion is established in order to destroy the tissue and reduce the tremors and rigidity.

### Connection Check 36.10

Which clinical manifestations are included in a diagnosis of Parkinson's disease? (Select all that apply.)

- A. Flaccidity
- B. Total resistance to movement
- C. Bradykinesia
- D. Tremors
- E. Photophobia

### Nursing Management

#### Assessment and Analysis

The clinical presentation of PD is important to the accurate diagnosis of this neurological disorder. The four cardinal signs include bradykinesia, tremor, rigidity, and postural stability. Other clinical manifestations seen in this disorder include:

- Weakness
- Fatigue
- Masklike face
- Shuffling gait
- Uncoordinated movements
- Widening gait

#### Nursing Diagnoses

- **Risk for falls** related to ataxia, muscular rigidity, and orthostatic hypotension
- **Risk for constipation** related to decreased mobility and side effects of medications used to treat PD
- **Powerlessness** related to diagnosis of a chronic, progressive disorder

#### Nursing Interventions

##### ■ Assessments

- Tremors, rigidity, and bradykinesia  
*The coordination of the excitatory messages from the production of ACh in the basal ganglia and the inhibitory messages from dopamine via transport from the substantia nigra to the basal ganglia allow for the control of steady, well-coordinated, fine movement. The lack of balance between ACh and dopamine leads to tremors, rigidity, and bradykinesia.*
- Gag and swallow  
*Patients with PD may experience difficulty swallowing, manifested by excessive drooling that places the patient at risk of aspiration because of ineffective swallowing.*

- **Mobility**  
*Ataxia, bradykinesia, and postural instability are prime symptoms of PD and decrease the patient's physical mobility and ability to complete activities of daily living (ADLs).*
- **Bowel and bladder function**  
*Parkinson's disease may impact bowel and bladder functions, making the patient at risk for incontinence and constipation.*

#### ■ **Actions**

- **Administer PD medications as prescribed**  
*Treatment of PD is primarily aimed at treating the clinical manifestations, so it is important to administer as prescribed to maximize therapeutic effectiveness.*
- **Implement safety precautions**  
*Tremors, rigidity, and orthostatic hypotension place PD patients at great risk for falls. The etiology of the disease process and side effects of medications can also cause sleep deprivation. High-risk tasks such as driving can become impaired, requiring ongoing discussion, evaluation, and consensus regarding abilities.*
- **Facilitate nutritional intake**  
*Muscles of the face become more involved while PD progresses; the patient may have difficulties with eating, swallowing, and talking. The swallowing difficulties place the patient at risk for aspiration and decreased oral intake.*
- **Elevate head of bed when eating and drinking**  
*Impaired swallowing associated with PD increases the risk of aspiration. Elevating the head facilitates the swallow reflex.*
- **Suction equipment at the bedside**  
*Because of increased drooling and impaired swallowing, the patient is at risk of aspiration.*
- **Administer stool softeners and increase fluid intake**  
*Because of impaired mobility associated with PD, the patient is at risk of constipation and these interventions are aimed to maintain normal bowel function.*
- **Encourage the patient to participate in self-care activities**  
*Patients are encouraged to participate in all areas of self-care to their best ability to maintain independence and safety.*
- **Facilitate interprofessional collaboration with physical therapy, occupational therapy, and speech therapy**  
*Physical therapists provide exercises and activities that maximize strength, flexibility, and movement. The occupational therapist provides strategies to promote independence and offers accommodations that may need to be made in the home to promote safety and maximize independence in ADLs. The speech therapist completes a swallowing evaluation and makes suggestions to promote safe oral intake. He or she may also have strategies to promote verbal communication.*
- **Communication**  
*Difficulties with speech are common in late stages of PD. Continued monitoring and interventions by speech therapy include exercises to improve breathing, swallowing, and speech and identification of assistive devices to assist in communication.*
- **Consult with social worker**  
*The social worker can provide information regarding support groups, advocacy groups, and agencies and information about palliative care/hospice care consultation.*

#### ■ **Teaching**

- **Medication compliance**  
*The effectiveness of medications prescribed for PD are dependent on compliance with dosing intervals. The patient should contact the provider if the effectiveness of the medications seems to be declining, and a dosage adjustment may be required.*
- **Safety precautions**  
*Because of the tremors, rigidity, and bradykinesia, the patient is at risk of falls. Teaching the patient to take short, deliberative steps, with the feet somewhat spread, decreases the chance of falls.*
- **Psychosocial support**  
*Cognitive dysfunction and uncontrollable muscle movement can all affect the ability of the patient to be comfortable and independent. Depression is not uncommon in this population. Increased responsibilities placed on significant others and family members can be overwhelming.*

### Connection Check 36.11

What interprofessional team members are involved in the management of the patient with Parkinson's disease? (Select all that apply.)

- Oncologist
- Speech therapist
- Occupational therapist
- Interventional radiologist
- Physical therapist

### Evaluating Care Outcomes

Care coordination and quality of life are important determinants in the evaluation of care for the patient living with PD. Because PD is a progressive, neuromuscular disorder that often ultimately results in loss of motor control and dependence upon others for ADLs, patient and family involvement in decision making about the priorities of care is essential. Patient safety is also a priority; falls are more likely because of postural instability and weakness, and while muscles of the face become more involved, the patient may also have difficulties with eating, swallowing, and talking. Modifications to the living environment are required to ensure patient safety and to maximize independence for as long as possible.

## ALZHEIMER'S DISEASE

### Epidemiology

A form of dementia involving the gradual progression of the loss of brain function, Alzheimer's disease affects memory, thinking, and behavior. Gradually, there is increasing cognitive decline, leading to severe deterioration. Life expectancy is 2 to 20 years, resulting in death secondary to causes manifested by immobility and organ failure, not from

the disease itself. It is estimated that 5.7 million Americans have Alzheimer's disease, 5.5 million older than 65, and approximately 200,000 younger than 65. It is also estimated that 500,000 Americans younger than 65 have some form of dementia, 40% of them with Alzheimer's. Approximately two-thirds of Americans with Alzheimer's disease are women, and there is an increased incidence in older African American adults. Older African-Americans are approximately twice as likely to have Alzheimer's or other dementias in comparison with older whites. Hispanics are approximately one and one-half times as likely to have Alzheimer's or other dementias as older whites. Although Alzheimer's is considered a disease of aging, many older adults do not exhibit clinical manifestations of dementia other than forgetfulness. Early-onset dementia can occur before the age of 65 and progresses rapidly. Those with blood relatives (parents, siblings) who have been diagnosed with dementia appear to be at greater risk. Although discussed as possible risk factors for the development of dementia, neither long-standing hypertension (HTN) or injury to the brain have been proven to cause Alzheimer's disease.

## Pathophysiology

Conclusive evidence as to the causes of Alzheimer's does not yet exist. The actual diagnosis of Alzheimer's is made only at autopsy, although several criteria have been formulated for presumptive identification. It is theorized that fragments of protein within nerve cells develop into neurofibrillary tangles obstructing cells, as well as the formation of beta-amyloid neuritic plaques (dying and dead nerve cells), which accumulate within the brain. This results in a decrease in the neurotransmitters that provide the connections between nerve cells within the brain, blocking communication. Mechanisms that elicit the development of these tangles and plaques are unknown; however, several theories have undergone investigation. Restriction of blood flow, destruction of cells by free radicals, and apoptosis (genetically programmed cell death)-inducing factor are several of the theories related to Alzheimer's disease.

## Clinical Manifestations

Although many people may develop periods of forgetfulness, there is initially little to no decline in the ability to care for themselves. Forgetfulness is the first symptom of Alzheimer's, which slowly progresses to difficulty with language (vocabulary and fluency), problems with short-term memory such as recent events and conversations, **agnosia** (inability to process sensory information), emotional lability, personality changes, and loss of cognitive skills (abstract thinking, judgment, and calculations). While the disease progresses, there is a loss in ability to perform multiple or complex tasks and difficulty with problem solving. In later stages, the disease progresses to word-finding difficulty and naming of familiar objects, items are misplaced, and the person is easily lost. The person's affect can become flat,

with a loss in social skills and changes in personality, and can lead to aggressive, uncontrollable acting out and behavior. The ability to care for oneself can be so limited that the person is bedridden. Death can ensue as a result of infection, pneumonia, falls, malnutrition and dehydration, and multisystem organ failure.

## Connection Check 36.12

The nurse recognizes which as the probable cause of Alzheimer's disease?

- A. Exposure to environmental toxins
- B. CNS trauma
- C. Unknown
- D. Chronic hypertension

## Management

### Medical Management

#### Diagnosis

A confirmed diagnosis of Alzheimer's can be made only on examination of the brain following death. Neurofibrillary tangles and beta-amyloid plaques can be observed microscopically. Presumptive diagnosis is made on the basis of a thorough history and physical examination that includes careful recording of clinical manifestations as well as monitoring the onset, progression, and duration.

Although cognitive impairment can be identified, the cause of the impairment requires careful investigation, especially in older adults, where many other processes can be the cause. Neurological disorders can cause a variety of changes in cognitive ability and include trauma, tumors, stroke, normal-pressure hydrocephalus, vascular abnormalities, and infection. Myocardial infarction, congestive heart failure, arrhythmias, and anemia can also cause cognitive dysfunction in older adults. Metabolic and endocrine disorders such as hyper/hypoglycemia, thyroid dysfunction, renal insufficiency and failure, and hepatic failure, as well as nutritional imbalance, infection, sensory deprivation, and depression can also impinge on cognitive functioning in this population. Additionally, medications and the multiplicity of medications taken as one ages can also affect cognitive function. Utmost care must be taken to diagnose and rule out all possible causes before the speculation of a diagnosis of Alzheimer's disease.

Following the detailed medical history, laboratory data are explored and diagnostic imaging is performed to rule out other causes. Written and oral testing for cognitive function includes mental status, language ability, functional ability, memory, and concentration. Patients also undergo a series of neuropsychiatric testing to rule out depression and delirium.

#### Medications

Presently, there is no cure for Alzheimer's disease. Although there are several medications approved for Alzheimer's, the foundation of management is physical and emotional

support of the patient with Alzheimer's disease and their caregivers. Medications used in the treatment of Alzheimer's disease (Table 36.8) are those that increase the levels of ACh (a neurotransmitter) in the brain by the inhibition of the enzymes acetylcholinesterase and butyrylcholinesterase, which normally break down ACh and butylcholine respectively. This increases communication between remaining neurons. It is also believed that vitamin E, an antioxidant, helps by decreasing the damage caused by free radicals and is often used in combination with other medications.

### Nursing Management

#### Assessment and Analysis

As described earlier, the definitive diagnosis of Alzheimer's disease is made only through autopsy. However, the clinical presentation and deterioration in the patient's cognitive and physical function are routinely used to make an assumption that Alzheimer's disease is present. Clinical manifestations that are associated with this disorder include:

- Forgetfulness that progresses with time
- Short-term memory decline
- Cognitive impairment
- Inability to handle personal finances

- Inability to self-manage medications
- Motor and verbal skill decline

#### Nursing Diagnoses

- **Acute confusion** related to manifestations of Alzheimer's disease
- **Caregiver role strain** related to the care of the patient with Alzheimer's disease
- **Ineffective coping** related to the diagnosis of Alzheimer's disease

#### Nursing Interventions

##### ■ Assessments

- **Weight and intake and output**  
*Patients with Alzheimer's disease may forget to eat and drink while the disease progresses secondary to cognitive decline.*
- **Bowel and bladder function**  
*As with other ADLs, as cognition declines the patient may experience incontinence.*
- **Skin**  
*Due to cognitive decline and associated decreased mobility, along with incontinence, the patient is at risk for skin breakdown or pressure*

**Table 36.8 Medications Used to Treat Alzheimer's Disease**

Medication	Function	Side Effects
<b>Donepezil (Aricept)</b>	<ul style="list-style-type: none"> <li>● Inhibits acetylcholinesterase, improving acetylcholinergic function</li> <li>● Treatment of mild-moderate AD</li> <li>● Modest increase in attention, concentration, and mental acuity</li> <li>● Does not slow progression of disease</li> </ul>	<ul style="list-style-type: none"> <li>● May cause bradycardia; monitor HR before administering</li> <li>● Can cause diarrhea, nausea and vomiting, and anorexia; monitor for weight loss and dehydration</li> <li>● Dosing is titrated over several weeks</li> </ul>
<b>Rivastigmine (Exelon)</b>	<ul style="list-style-type: none"> <li>● Inhibits both acetylcholinesterase and butyrylcholinesterase</li> <li>● Treatment of mild-moderate AD</li> <li>● Modest increase in attention, concentration, and mental acuity</li> <li>● Does not slow progression of disease</li> </ul>	<ul style="list-style-type: none"> <li>● May cause bradycardia; monitor HR before administering</li> <li>● Can cause diarrhea, nausea and vomiting, and anorexia; monitor for weight loss and dehydration</li> <li>● Can be administered orally or via transdermal patch</li> </ul>
<b>Galantamine (Razadyne)</b>	<ul style="list-style-type: none"> <li>● Inhibits acetylcholinesterase, improving acetylcholinergic function</li> <li>● Treatment of mild to moderate AD</li> <li>● Modest increase in attention, concentration, and mental acuity</li> <li>● Does not slow progression of disease</li> </ul>	<ul style="list-style-type: none"> <li>● May cause bradycardia; monitor HR before administering</li> <li>● Can cause diarrhea, nausea and vomiting, and anorexia; monitor for weight loss and dehydration</li> <li>● Dosing is titrated over several weeks</li> </ul>
<b>Memantine (Namenda)</b>	<ul style="list-style-type: none"> <li>● Blocks NMDA glutamate receptors, reducing neuronal excitotoxicity</li> <li>● Noncompetitive antagonist of serotonin (5-HT) receptors</li> <li>● Antagonist of different acetylcholine receptors</li> </ul>	<ul style="list-style-type: none"> <li>● Generally well tolerated</li> <li>● Rare instances can cause dizziness, confusion, headache, insomnia, and agitation</li> </ul>

AD = Alzheimer's Disease; HR = heart rate; NMDA = N-methyl-D-aspartate.

- **Activities of daily living**

*Patients with Alzheimer's disease can gradually lose the ability to feed, bathe, dress, and/or use the toilet themselves.*

- **Environment and safety**

*With cognitive decline, patients may wander and are unable to assess the safety of their surroundings. Additionally, as memory declines, they may forget to take medications as prescribed.*

- **Coping**

*The ability to cope with stress may decline, and the patient may exhibit changes in affect and mood.*

- **Actions**

- **Encourage/assist with feeding; provide finger foods**

*The patient may forget to eat without reminders and assistance secondary to cognitive changes. Finger foods may be easier for the patient to manage and may increase caloric intake.*

- **Implement safety measures (including maintaining the bed in lowest position, grab bars in the bathroom, clutter-free environment, and eliminating throw rugs)**

*Because of the patient's decreased awareness of the surroundings and decreased decision making, the environment must be safe to prevent falls.*

- **Implement routine toileting practices**

*Because of cognitive decline, the patient is at increased risk of incontinence. Establishing a regular schedule of toileting decreases complications associated with incontinence.*

- **Place a clock and calendar in the patient's room**

*Provide orientation to time and date for the patient as cognition declines.*

- **Provide a routine including walks and other activities**

*May require reminders to perform normal ADLs secondary to cognitive decline; maximizes physical mobility and minimizes complications associated with decreased mobility.*

- **Speak calmly using positive statements and reassurance when the patient is agitated**

*The patient may require frequent reminders. A calm approach and tone decrease escalation of the patient's agitation.*

- **Provide diversionary activities for the Alzheimer's disease patient**

*These activities provide stimulation for the patient and facilitate engagement with others.*

- **Provide the caregiver/family with emotional support**

*The cognitive decline of the patient is often difficult for the family to understand, especially if the patient has few other physical clinical manifestations.*

- **Facilitate activities during the day (no napping) to assist with sleep during the night**

*Sleep disturbances may develop in the patient with Alzheimer's disease. Minimizing napping during the day promotes better sleep at night.*

- **Teaching**

- **Teach families how to care for the patient with Alzheimer's disease**

*While the patient's dependence on others increases, the family must be capable of managing the patient's medication, treatments, ADLs, etc.*

- **Teach family to label all dangerous substances and items and to secure them carefully**  
*With deterioration in cognitive function, the patient may no longer be capable of recognizing unsafe environmental issues. The patient may not recognize dangerous items.*
- **Educate family on the potential for monitoring systems that will alert family members should the patient attempt to leave the home**  
*Provides support to the family if the patient has a tendency to wander; also promotes patient safety*
- **Provide referral assistance for support groups and for alternative care settings should the need arise**  
*Depression is common, and assistance and medication might be required.*
- **Provide location and contact information for support groups, the patient's provider, pharmacist, and social services**  
*Costs of caring for the AD patient can be very expensive. Social Security and Medicare/Medicaid assistance might be helpful to alleviate the financial stress related to the care of the patient with Alzheimer's disease.*

### Evaluating Care Outcomes

The diagnosis of Alzheimer's disease is frightening and stressful to both the patient and family. Patient safety and quality of life, as with other progressive neurological disorders, are priorities in the coordination and management of these patients. In addition to physical issues, there are many legal issues related to the care of these patients while their cognitive function declines. Family involvement is essential, particularly in making end-of-life decisions that are consistent with the patient's wishes.

### Connection Check 36.13

The nurse recognizes that supplementation with which vitamin has been found to help with symptoms of Alzheimer's disease?

- Vitamin A
- Vitamin C
- Vitamin D
- Vitamin E

## Making Connections

### CASE STUDY: WRAP-UP

Postoperative day 7, Mr. Johnson is ready for discharge to acute rehabilitation. The nurse reviews all medications prescribed for Mr. Johnson with him and his wife. These medications include levetiracetam 500 mg bid, amlodipine 10 mg daily, metformin 750 mg daily, glyburide 5 mg daily, and furosemide 20 mg daily. The nurse reiterates the necessity for taking his medication as

prescribed. The nurse also introduces Mrs. Johnson to the social worker, and a support group is identified to assist her in caring for herself and her husband once he returns home.

### Case Study Questions

- On Mr. Johnson's initial presentation to the clinic for headache, the nurse assesses him for which clinical manifestations of increased ICP? (*Select all that apply.*)
  - Confusion
  - Tachycardia
  - Clonus
  - Elevated blood pressure
  - Incontinence
- The nurse collaborates with which healthcare team member to arrange for Mr. Johnson to have a swallowing evaluation?
  - Dental hygienist
  - Physical therapist
  - Occupational therapist
  - Speech therapist
- What is the rationale for the administration of the dexamethasone (Decadron) to Mr. Johnson postoperatively?
  - Decreases cerebral edema
  - Decreases blood pressure
  - Suppresses seizure activity
  - Suppresses neuromuscular conduction
- On the basis of Mr. Johnson's seizure activity, the nurse implements seizure precautions. What equipment does the nurse ask the nursing assistant to place in the room?
  - EEG machine
  - Suction equipment
  - Restraints
  - Padded tongue blade
- Which statement by Mr. Johnson indicates the need for further teaching about the levetiracetam?
  - "I will not drink any alcoholic beverages."
  - "I will wear a medical alert bracelet."
  - "I will let my doctor know about all of my prescriptions."
  - "I can skip a couple of pills if I have a stomach flu."

(migraine, tension, cluster, etc.), or they may be the sign of a more dangerous pathology related to increased intracranial pressure (ICP). Management of pain is largely dependent upon the etiology and a definitive diagnosis. Pain management is a priority, as well as managing triggers or exacerbating factors for headaches.

Primary brain tumors are those tumors that originate in the brain. These tumors range from slow-growing, benign tumors to highly malignant, aggressive tumors. Primary brain tumors originate from brain cells, brain meninges, nerves, and glands. Because of the diversity of these tumors, classification is difficult and is generally based on the type of brain cells involved and the location in which the cancer evolves. Initial management of brain tumors is often focused on the control of ICP and preventing secondary injury due to compression of vital structures in the brain. Metastasis of cancer from various locations in the body to the central nervous system (brain, spinal cord and CSF) is not an uncommon complication of several types of cancer and is the most common type of brain tumor. Brain tumors may be treated surgically or with chemotherapeutic agents and radiation therapy.

Seizures are uncontrolled, sudden, excessive discharge of electrical activity resulting in a range of manifestations from changes in behavior to loss of consciousness. As with headaches, seizure activity may be the primary disorder or may be secondary to changes in the brain caused by brain tumors, trauma, and infectious processes. Control of seizures requires definitive diagnosis of type of seizure and management with appropriate anticonvulsant medications or surgical intervention.

Meningitis is an inflammation of the meninges caused by bacterial infection, viral infection, or fungal infection. There is also an aseptic meningitis secondary to the use of antibiotics and nonsteroidal anti-inflammatory medications and carcinomatosis. Management of meningitis requires eradication of the infectious organism. Compliance with antibiotic therapy after discharge is a high priority.

Encephalitis is an acute inflammation of the brain, including the cerebrum, brainstem, and cerebellum. Although encephalitis is dangerous in all age groups, those who are very young (infants and children), older adults, and the immunocompromised are most at risk. All forms of encephalitis can take weeks to months to resolve and can leave the patient with debilitating neurological injury and deficits. Management of encephalitis focuses on eradication of the infectious agent or the removal of sources of antibodies causing an autoimmune encephalitis, and preventing secondary injury related to potential increased ICP.

Parkinson's disease is a progressive, neurodegenerative disease of the central nervous system manifesting primarily in motor dysfunction. It is a motor system disorder that results secondary to the loss of dopamine-producing brain cells in the substantia nigra of the basal ganglia. Because it is a progressive neuromuscular disorder that often ultimately results in loss of motor control and dependence upon others for activities of daily living, patient and

## CHAPTER SUMMARY

Disorders of the brain are characterized by a myriad of clinical presentations that affect a person's physical and cognitive functions. Many of the disorders are chronic and degenerative with no known cure, and care coordination, quality of life, and safety are priorities of care.

Headaches are a common complaint and may represent a specific pathology secondary to different types of headache

family involvement in decision making about the priorities of care is essential.

Alzheimer's disease is a form of dementia involving the gradual loss of brain function, affecting memory, thinking, and behavior. It is characterized by increasing cognitive decline, leading to severe deterioration. Although conclusive evidence as to the cause of Alzheimer's does not yet exist and the definitive diagnosis of Alzheimer's is made only at autopsy, there are criteria used to establish a presumptive diagnosis. Management of this disorder is focused on slowing

the progression of the disorder (if possible), along with a focus on patient safety and quality of life.

The nurse plays an essential role in the management of the patient with a disorder of the brain. Assessment and analysis of subtle changes in the patient's clinical presentation are paramount in preventing secondary and possibly irreversible damage secondary to increased ICP. Because many disorders of the brain are chronic, progressive, and debilitating, working with the family to support the patient is an important nursing role.

# Chapter 37

## Coordinating Care for Patients With Spinal Cord Disorders

*Lourdes Carbuapoma*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of spinal cord disorders
2. Correlating clinical manifestations to the pathophysiological processes of:
  - a. Low-back pain
  - b. Herniated nucleus pulposus
  - c. Multiple sclerosis
  - d. Amyotrophic lateral sclerosis
  - e. Spinal cord injury
  - f. Spinal cord tumors
3. Describing the diagnostic results used to confirm spinal cord disorders
4. Discussing the management of:
  - a. Low-back pain
  - b. Herniated nucleus pulposus
  - c. Multiple sclerosis
  - d. Amyotrophic lateral sclerosis
  - e. Spinal cord injury
  - f. Spinal cord tumors
5. Developing a comprehensive plan of nursing care for patients with disorders of the spinal cord
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with disorders of the spine
7. Explaining the clinical presentation and management of complications associated with disorders of the spinal cord

### CONCEPTS

- Assessment
- Comfort
- Medication
- Mobility
- Neurologic Regulation
- Nursing Roles
- Oxygenation
- Perioperative
- Safety

### ESSENTIAL TERMS

Analeptics  
Anhidrosis  
Annulus fibrosus  
Apoptosis  
Autonomic dysreflexia  
Axial loading  
Contralateral  
Demyelination  
Electromyography (EMG)  
Excitotoxicity  
Facet joints  
Flare  
Free radicals  
Gardner-Wells tongs  
Halo traction device  
Herniation  
Ipsilateral  
Myelin  
Neurogenic shock  
Nucleus pulposus  
Phrenic nerve  
Radiculopathy  
Sclerosis  
Spinal degeneration  
Spinal shock  
Spinal stenosis

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Cynthia Reynolds is a 38-year-old female who presents to her primary healthcare provider with complaints of intermittent numbness in her left lower extremity and gait imbalance. She is obese with a history of poorly controlled type 1 diabetes mellitus. She is otherwise in good health and has annual check-ups with her healthcare provider. Cynthia reports that she has been trying to get into “better shape” and that she began a home exercise program approximately 3 months ago. She states that she continues to smoke but has “cut down to one-half pack a day”...

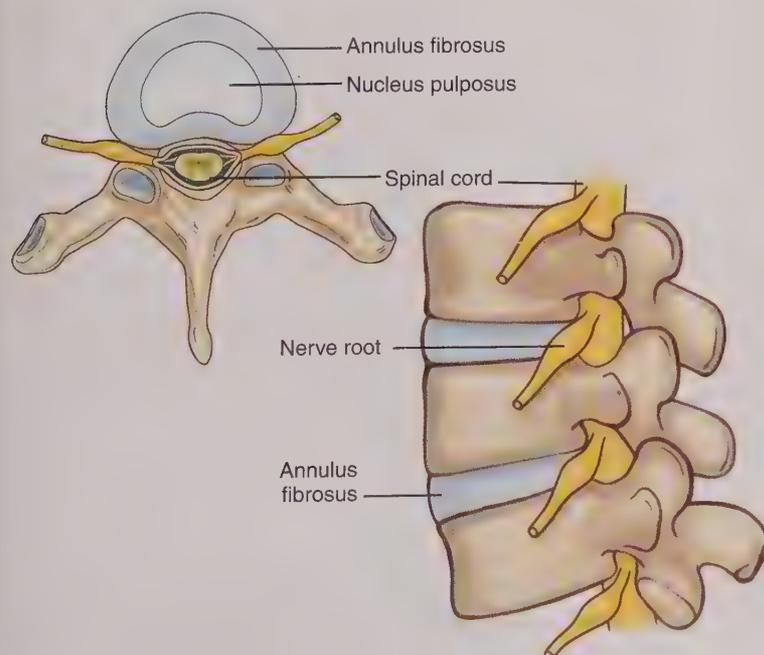

## INTRODUCTION

The spinal column is the main support for the spinal cord and the nerve pathways that carry information between the brain and the rest of the body. Composed of 33 bony vertebrae, 31 pairs of spinal nerves, 40 muscles, and multiple connecting ligaments and tendons, the spinal cord runs from the base of the skull to the coccyx. The vertebral column is divided into five sections: the cervical spine, thoracic spine, lumbar spine, sacral spine, and coccyx. Between the vertebrae are intervertebral disks that are elastic, fibrous cartilage that keep the spine flexible and protect the vertebrae from injury. The intervertebral disks are the largest avascular structures in the body. The outer layer

contains concentric rings of tough fibrous tissue called the **annulus fibrosus**. The central, or inner, portion consists of softer, spongier material and is called the **nucleus pulposus** (Fig. 37.1).

The spinal cord has multiple functions, including somatic (voluntary) and autonomic (involuntary) reflexes, motor control centers, and sensory and motor modulation. The spinal cord is protected by the vertebral column, the spinal meninges, and cerebrospinal fluid (CSF). The spinal meninges are composed of three membranous layers of connective tissue (Fig. 37.2). The outermost layer is the dura mater, the arachnoid is the middle layer, and the innermost layer is the pia mater. The dura mater forms a loose, protective, and nonelastic membrane. The arachnoid is composed of collagen and elastic fibers that form a weblike filmy covering of the spinal cord. The innermost layer, the pia mater, adheres to the brain and spinal cord, and provides support for blood vessels that supply nutrients and oxygen to the brain and spinal cord.

The gray matter of the spinal cord is butterfly-shaped and surrounded by white matter. This serves as the processing center by receiving and integrating information. The gray matter also contains motor neurons that control movement. The white matter surrounds the gray matter and contains the conduction tracts for nerve impulses (Fig. 37.3). These tracts of nerve fibers consist of axons. Axons are the long, thin nerve cell extensions that carry impulses away from the cell body. Most axons are covered with an insulating substance called **myelin** that allows signals to flow freely and quickly. The myelin is whitish in appearance, giving the name “white matter” to this outer section of the spinal cord. Axons carry signals in two directions, up toward the brain (ascending pathways) and down from the brain (descending pathways) within the specific nerve tracts.

**FIGURE 37.1** A. Intervertebral disk. B. Section of spinal column.

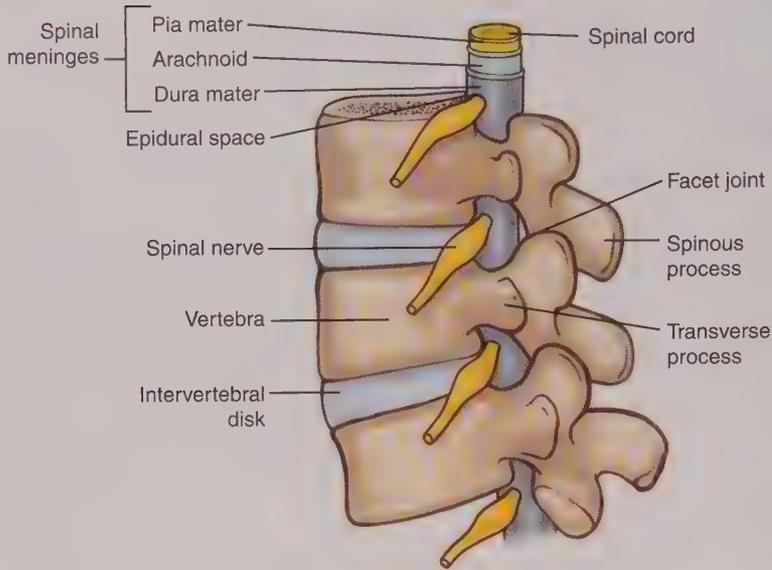

FIGURE 37.2 Spinal cord anatomy.

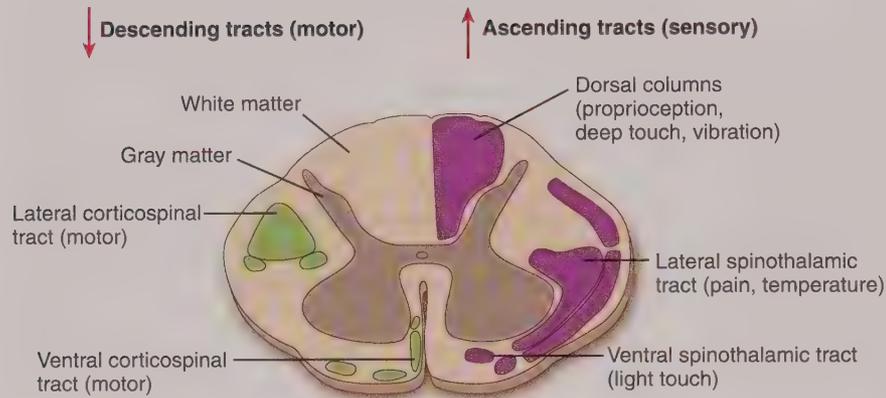

FIGURE 37.3 Spinal cord nerve tracts.

The motor nervous system is divided into the somatic and autonomic nervous systems. The somatic, or voluntary, nervous system controls skeletal muscle and external sensory organs (e.g., skin). It is called *voluntary* because most of the responses can be consciously controlled.

The autonomic nervous system (ANS) has two subdivisions. First, the *sympathetic nervous system* physiologically prepares the body to meet a crisis situation by mobilizing energy stores. The sympathetic nervous system increases the heart rate and blood pressure, dilates the pupil of the eye, shunts blood to muscles, and decreases food digestion. Second, the *parasympathetic nervous system* promotes activities to rebuild the body's energy stores. It slows the heart rate, lowers blood pressure, increases gastrointestinal (GI) tract activity, and shunts blood from the periphery to internal organs.

Both divisions of the ANS have a two-neuron chain that carries information from the central nervous system (CNS) to the periphery. The preganglionic neuron is the first neuron in the chain and has cell bodies located in the CNS. In the sympathetic division, the cell bodies are located in

spinal segments T (thoracic) 1 through L (lumbar) 2 (the thoracolumbar division). In the parasympathetic division, the cells are located in cranial nerves III, VII, IX, and X, and in spinal cord segments S (sacral) 2 through S4 (the sacrosacral division). The preganglionic axons of both ANS divisions branch out to the periphery in the cranial and spinal nerves mentioned above and terminate on postganglionic cell bodies distributed throughout the body. They innervate specific organs such as smooth muscle, cardiac muscle, and glands. The second neuron in the chain is the postganglionic neuron. In the sympathetic or adrenergic division, postganglionic neurons use norepinephrine for their neurotransmitter. The parasympathetic or cholinergic division postganglionic neurotransmitter uses acetylcholine as its receptor.

The spine is complex in both structure and function. It provides support and structure to the body, allows movement, and protects the spinal cord. The spinal cord is the primary information pathway connecting the brain and the rest of the body and helps interpret sensory input to control muscles and organs throughout the body.

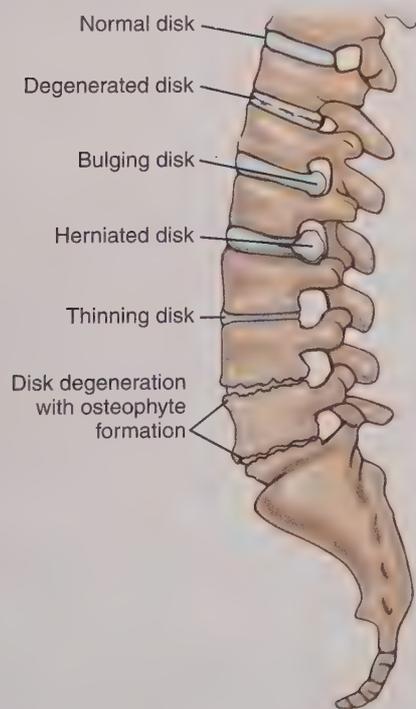

## LOW-BACK PAIN

### Epidemiology

According to the National Institute of Neurological Disorders and Stroke, back pain is the second-most common neurological ailment in the United States, equally affecting both men and women. At least 60% to 80% of the population will have an episode at least once in their lifetime. Low-back pain (LBP) often occurs between the ages of 30 and 50, with an annual cost of \$50 billion per year spent on treatment alone.

Low-back pain is a common neuromuscular condition, with unpredictable patterns of exacerbation, remission, and recurrence that affect the way the condition is classified, diagnosed, and treated. In 85% of persons with LBP, no cause can be identified, making treatment plans for patients difficult. It may be time limited and harmless, or it can become a chronic condition affecting every aspect of the patient's life. For the majority of persons, LBP does not develop into a chronic, disabling condition; however, approximately 1 in 5 patients report persistent, activity-limiting back pain by 1 year after an acute episode.

Low-back pain often follows injury or trauma but may also be caused by degenerative diseases (Fig. 37.4). These conditions include but are not limited to the following: arthritis, osteoporosis, viral infections, bone diseases, or congenital abnormalities in the spine. Risk factors for LBP include obesity, cigarette smoking, poor posture, stress, poor physical condition, poor sleeping position, and occupations that require heavy lifting. Nicotine in cigarettes is thought to interfere with vital nutrient absorption by the intervertebral disks, leading to disk degeneration.

**FIGURE 37.4** Types of disk problems.

### Connection Check 37.1

The nurse recognizes which factor as placing a patient at the greatest risk for new onset of low-back problems?

- Sedentary lifestyle
- Recent long-distance car trip
- Prolonged standing
- Cigarette smoking

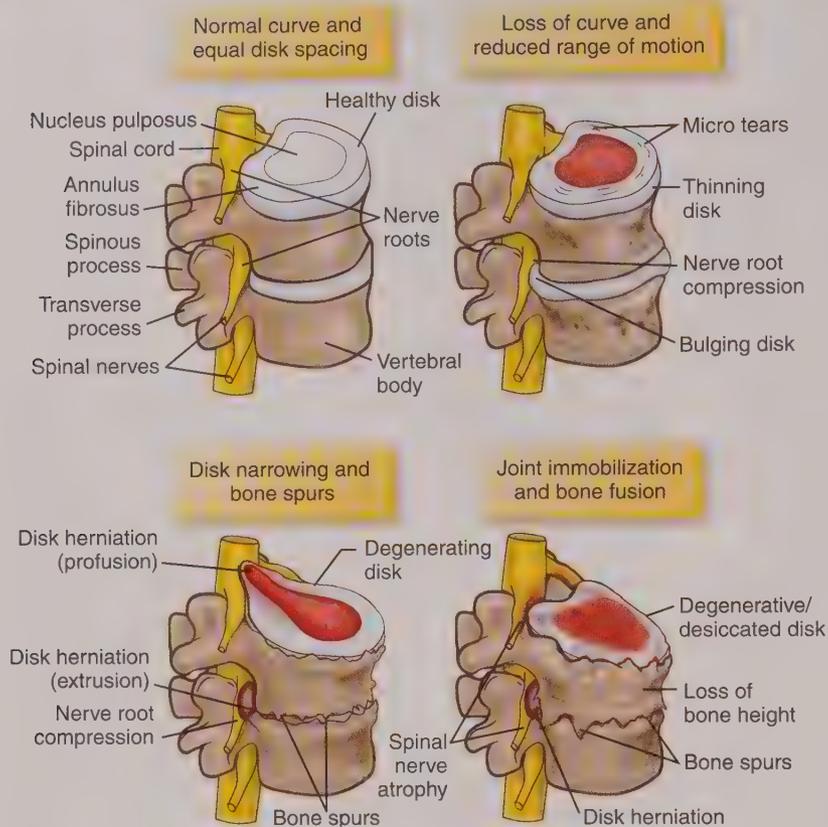

### Pathophysiology

The pathophysiology of LBP remains complex. **Spinal degeneration** (Fig. 37.5) is often associated with aging and involves the loss of normal structure and function of the spine. While water content of the nucleus pulposus decreases, the fibers of the annulus begin to wear out. The body's ability to lubricate facet joints decreases, and they begin to suffer from wear and tear. **Facet joints**, small joints located between and behind each adjacent vertebra, help support and restrict vertebral movement to prevent one vertebra from slipping over the one below. The upper half of the paired facet joints are attached on both sides and on the backside of each vertebra; then they extend downward and project forward or toward the side. The other halves of the joints arise on the vertebra below then project upward, facing backward to engage the downward portion of the upper facet halves. A small capsule surrounds the facet joints, providing a lubricant to the joint, allowing them to slide on each other without a lot of friction. The decrease in the body's ability to lubricate the facet joints results in damage from friction. The decreasing support of facet joints because of weak spinal ligaments also contributes to spinal degeneration. Spinal ligaments are tough bands of fibrous tissue that connect bones and joints. With age, these bands lose strength and elasticity and become more vulnerable to stretching and tearing.

**Spinal stenosis** refers to constriction of the spinal foramina and canals that can result in pressure on the spinal cord and nerve roots, causing pain. Spinal stenosis often develops as a result of spinal degeneration. While the disks become drier, the bones and ligaments of the spine may grow larger because of arthritis or some other form of chronic inflammation. Other causes of spinal stenosis include a previous herniated disk, spinal cord injury, congenital spinal defect, spinal tumor, or bone disease.

Another factor contributing to LBP is muscle spasm, characterized as the sudden, involuntary contraction of a single muscle or muscle group. Most back muscle spasms are caused by inflammation and soreness because of sudden movement or bending, but they can also result from age-related loss of spinal muscle strength as muscles spasm to protect the worn areas of the spine.

The acute or sudden onset of LBP acts as a warning of ongoing tissue damage. Acute pain is nociceptive and occurs

**FIGURE 37.5** Spinal degeneration.

secondary to chemical, mechanical, or thermal stimulation of A-delta and C-polymodal pain receptors. Nociceptive pain is the body's normal pain response.

Multiple elements of the lumbar spine are thought to be contributing factors to LBP. Many components of the lumbar spine have sensory innervation that can generate nociceptive signals as responses to tissue-damaging stimuli. Following a nerve injury, sensitization occurs that results in a lowered threshold for activation and an increased response to stimuli. In other words, the nociceptor has an increase in discharge that leads to an increase in pain. Ectopic neuronal pacemakers have been shown to form at various sites along the nerve. They can cause abnormal firing of the nociceptor and result in increased pain. Current theory contends that abnormal or dysfunctional sodium channels are the cause of this ectopic activity. Most chronic LBP cases are thought to involve a combination of nociceptive and neuropathic etiologies. While people age, a decrease is noted in bone strength, in muscle elasticity and tone, and in the disks' ability to cushion the vertebrae.

### Clinical Manifestations

The clinical presentation of LBP typically includes dull or acute pain in the lumbar region of the spine that may be exacerbated by movement. Muscle spasms may also be observed and may limit mobility. Decreases in flexibility and

stamina are also possible if pain decreases activity and the patient becomes more sedentary. If there are nerve-related problems, there may also be numbness and tingling or weakness in the leg or foot. As with many spinal disorders that decrease mobility, the patient may also complain of constipation.

### Management

#### Medical Management

#### Diagnosis

Low-back pain is typically classified and treated according to the clinical manifestations, duration, underlying cause, presence or absence of radicular (nerve root) clinical manifestations, and corresponding anatomical or radiographic abnormalities. Acute back pain is defined as lasting less than 4 weeks, subacute back pain lasts 4 to 12 weeks, and chronic back pain lasts more than 12 weeks. Radicular LBP results in lower-extremity pain, paresthesias, and/or weakness and is a result of nerve root impingement or compression.

A thorough history and examination is completed to identify any dangerous conditions that may be associated with the pain. The patient is asked to describe the pain in detail giving the onset, exact location, severity, and duration with movement limitations. The patient also provides any medical history that might be related to the development of the pain. A physical examination, neurological testing

such as **electromyography (EMG)** that measures the electrical impulse within muscle tissue, nerve conduction testing and evoked potentials, and various imaging studies including x-rays, computed tomography (CT), magnetic resonance imaging (MRI), bone scans, or myelograms may be ordered to determine a definitive diagnosis (Table 37.1).

### Nonpharmacological and Pharmacological Treatment

Low-back pain treatment options include nonpharmacological and pharmacological interventions. Nonpharmacological treatments include, but are not limited to exercise therapy, superficial heat, acupuncture, massage therapy, meditation/yoga and other complementary and alternative medicine interventions. Pharmacological treatments include acetaminophen, NSAIDs, skeletal muscle relaxants, opioids, systemic corticosteroids, tricyclic antidepressants, and benzodiazepines.

For acute pain or subacute LBP, nonpharmacological treatment options, such as superficial heat and massage therapy, are considered first-line treatment options because acute or subacute LBP is often self-limiting (Box 37.1). For those with acute or subacute LBP unresponsive to nonpharmacological treatment options, nonopioid over-the-counter medications, such as NSAIDs, help reduce swelling and inflammation and may also decrease mild to moderate pain. Nonpharmacological treatment options, such as

exercise, interprofessional rehabilitation, acupuncture, or mindfulness-based strategies, are first-line treatment options for patients with chronic LBP pain. In patients with chronic LBP unresponsive to nonpharmacological treatments, NSAIDs are first-line treatment. Muscle relaxants may be prescribed by a healthcare provider to help reduce pain. Medications that block sodium channels may also help reduce pain and include lidocaine, anticonvulsants, and tricyclic antidepressants (Table 37.2). Opioids such as codeine, oxycodone, hydrocodone, and morphine are reserved for the relief of severe pain.

### Surgical Management

Other treatments include:

- Interventional therapy – nerve blocks with local anesthetics, steroids, and narcotics injected into affected areas
- Transcutaneous electrical nerve stimulation – mild electrical impulses are sent along nerve fibers to block pain signals to the brain
- Back surgery – if pain is caused by serious spinal pathology related to radicular or spinal cord compression (surgical procedures discussed later in chapter with management of herniated nucleus pulposus.)

Often a combination of medications and adjunctive therapy is used to successfully treat LBP.

**Table 37.1 Tests Used to Determine Causes of Spinal Cord Disorders**

Test	Definition
<b>Computed tomography (CT scan)</b>	X-rays are passed through the back at different angles, detected by a scanner, and analyzed by a computer. This produces a series of cross-dimensional images that show the shape and size of the spinal canal, its contents, and surrounding structures. This is optimal in visualizing bony structures.
<b>Diskogram</b>	An opaque dye is injected into suspected disks, pictures are taken, and the patient's reaction and image help determine the disk's status.
<b>Magnetic resonance imaging (MRI)</b>	Energy from a powerful magnet produces signals that are detected by a scanner and analyzed by a computer. The resulting cross-sectional images of the spine show the spinal cord, nerve roots, and surrounding spaces. An MRI is optimal in detecting soft tissue damage or disease (e.g., disks between vertebrae or ligaments)
<b>Electromyography</b>	Tests to measure the electrical impulse within muscle tissue. This test indicates if there is old nerve damage that is healing or ongoing nerve injury and findings correlate to the site of damage.
<b>Nerve conduction study</b>	Test to measure the electrical nerve impulse that indicates damage to the nerve. Electrodes are placed on the skin over a nerve that supplies a specific muscle or group. A mild, brief stimulus is delivered through the electrode, and the signal strength and muscle response are measured.
<b>Myelogram</b>	A dye is injected into the spinal column, and an x-ray is taken. This can show pressure on the spinal cord or nerves from herniated disks, tumors, or bone spurs. This procedure requires a lumbar puncture to inject the contrast dye.
<b>X-rays</b>	Radiation beam is passed through the back to produce a two-dimensional picture. X-rays show the structure of the vertebrae and joint outlines.

## Box 37.1 Complementary and Alternative Medicine Practices to Treat Low-Back Pain

- **Acupuncture** – Insertion of small needles or exerting pressure on “energy” points in the body; the patient is supposed to experience a feeling of fullness, numbness, tingling, and warmth.
- **Biofeedback** – People are trained to control certain bodily processes (heart rate, muscle tension, blood pressure) to improve their health.
- **Meditation/Yoga** – These can be used as part of a general health regimen, to cope with illness, to improve physiological balance, or to increase relaxation. Techniques include physical postures and breathing techniques, with either a focused attention or an open attitude toward distractions.
- **Massage therapy** – Consists of alternating levels of concentrated pressure on the areas of spasm; once pressure is applied, it should not vary for 10 to 30 seconds. Massage also leads to increased endorphin levels (chemicals associated with decreased pain and increased euphoria) that are effective in chronic pain management.
- **Energy healing therapies** – Magnet and light therapy – based on the manipulation of veritable (measurable) energy fields to affect health
- **Qi gong** – An ancient Chinese discipline involving physical and mental exercises that focus on specific parts of the body
- Whole medical systems that are part of complementary and alternative medicine have evolved over time in different cultures; these include traditional Chinese medicine and Ayurvedic medicine

## Nursing Management

### Assessment and Analysis

The type, severity, and location of clinical findings associated with LBP are directly related to the underlying cause. This includes pain developing from muscle sprain or strain, nerve root pressure, or arthritis. Clinical findings include:

- Pain in the lower back that may radiate to the extremities
- Numbness and tingling in the extremity (with nerve root injury)
- Muscle spasms
- Decreased mobility/range of motion (ROM)

A thorough evaluation including history and physical examination is completed to identify the cause of LBP.

### Nursing Diagnoses

- **Acute pain** related to inflammation, swelling, and strained muscles
- **Impaired mobility** related to pain or discomfort
- **Risk for impaired bowel elimination** related to decreased mobility

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Evaluate for hemodynamic signs of pain including tachycardia, hypertension, and tachypnea.*
- **Pain**  
*Pain is secondary to inflammation, swelling, and strained muscles.*

**Table 37.2 Medications Used to Treat Low-Back Pain**

Class of Medication	Examples	Mechanism of Action
<b>Anticonvulsants</b>	Gabapentin (Neurontin), pregabalin (Lyrica), topiramate (Topamax), carbamazepine (Tegretol)	Not proven but are thought to block the sodium channels and decrease formation of ectopic neuronal pacemakers
<b>Tricyclic antidepressants</b>	Amitriptyline (Elavil), nortriptyline (Pamelor), imipramine (Tofranil)	Thought to block the sodium channels and to decrease formation of ectopic neuronal pacemakers
<b>Local anesthetics</b>	Lidocaine	Same as tricyclics
<b>NSAIDs</b>	Aspirin, ibuprofen, ketorolac tromethamine (Toradol), naproxen	Block COX enzymes and prostaglandins throughout the body, thereby decreasing pain and inflammation
<b>Corticosteroids</b>	Prednisone, cortisone, hydrocortisone	They mimic the effects of hormones produced in the adrenal glands; they decrease inflammation by blocking the production of substances that trigger allergic and inflammatory reactions (e.g., prostaglandins)
<b>Opioids</b>	Morphine, codeine, oxycodone	Block the perception of pain by attaching to proteins (opioid receptors) found in the brain, spinal cord and GI tract
<b>Muscle relaxants</b>	Cardisoprodol (Soma), cyclobenzaprine (Flexeril), methocarbamol (Robaxin), metaxalone (Skelexin), diazepam (Valium)	Depress the CNS

CNS = Central nervous system; COX = cyclooxygenase; GI = gastrointestinal.

- **Mobility**  
*Determining how mobility/activities of daily living (ADLs) are affected by pain is important baseline information to follow as different interventions are initiated.*
- **Numbness and tingling in extremities**  
*Low back pain secondary to nerve root compression (radiculopathy) causes numbness and tingling in the affected extremities.*
- **Bowel function**  
*Immobility and side effects of some pain medications increase the chance of constipation that can exacerbate pain if the patient strains with defecation.*

### ■ Actions

- **Administer pain medications (see Table 37.2)**  
*Blocks the perception of pain*
- **Administer anti-inflammatory medications (see Table 37.2)**  
*Reduces inflammation and pain to help increase mobility*
- **ROM**  
*Increases muscle strength and reduces pain by stretching and strengthening the muscles*
- **Administer stool softeners as needed**  
*Decreased mobility, as well as the side effects of some pain medications, increases the risk of constipation. Straining with bowel movements can exacerbate the LBP.*
- **Increase fluid intake**  
*Facilitates normal bowel elimination that may be impacted by immobility and side effects of pain medications*

### ■ Teaching

- **Low-back exercises**  
*Stretching and strengthening muscles facilitates reduction of pain and minimizes future injury. Abdominal strengthening also decreases stress and strain on the low back.*
- **Take medications as prescribed**  
*To decrease pain peaks and help promote activity levels*
- **Nonpharmacological pain relief measures (see Box 37.1)**  
*To help resume normal functioning without use of medications that can affect thinking and behavior*
- **Weight control**  
*Being overweight adds additional stress to back muscles, so being at ideal body weight may decrease pain and complications associated with LBP.*

### Evaluating Care Outcomes

Patients with LBP can often resume normal functioning with proper treatment, including medications and lifestyle changes such as exercise. Medications are used short term to relieve pain and inflammation, and lifestyle changes are initiated to help decrease the risk of future episodes of LBP. Proper posture, exercise, and use of body mechanics during exercise and work help reduce the patient's risk of re-injury. If the patient experiences clinical manifestations of back pain, these should be reported to the primary care provider.

## HERNIATED NUCLEUS PULPOSUS

### Epidemiology

While people age, the disks between the vertebrae degenerate and weaken, and the disk becomes more inflexible and more prone to tearing or rupturing with movement. **Herniation**, or leaking out of the interior disk contents into the vertebral areas, is a major cause of severe chronic and recurrent back pain. Ninety percent of herniations occur at the lumbar segments of the spine, especially L4 through L5 and L5 through S1. Herniated disks are most common between age 30 and 45, with males more commonly affected in lumbar disk herniation by a 3:2 ratio. Rarely, a traumatic event such as a fall or a blow to the back can cause a herniated disk. Factors that increase the risk of a herniated disk include age, gender, obesity, smoking, and occupation. Genetics are also suspected of playing a role in disk herniation. Other risk factors include repetitive lifting, pulling, pushing, bending sideways, and twisting. Pain is usually greatest when sitting and decreases when standing.

### Pathophysiology

A herniated disk occurs when a weakening of or a tear in the outer fibrous ring (annulus fibrosus) of the intervertebral disk allows the central soft component (nucleus pulposus) to bulge or to be extruded (herniate) outside the disk (Fig. 37.6). Intervertebral disk deterioration occurs over a lifetime as the water-retaining ability of the nucleus pulposus declines. This leads to stiffening of the disk and to the annulus weakening. Herniation of nuclear material into the spinal canal is associated with a significant inflammatory response. Acute nerve root compression, radiculopathy, is responsible for dysfunction, and the type of nerve compressed (motor or sensory) determines the clinical manifestations the patient experiences such as pain, weakness, or numbness.

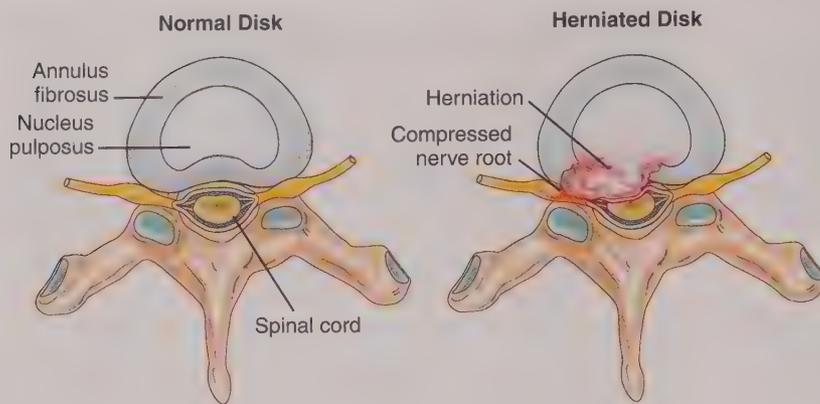

### Clinical Manifestations

Patients with herniated nucleus pulposus typically present with pain caused by the inflammatory process as well as compression to nerve roots. Radiculopathy is nerve root compression and can result in numbness in the affected extremity as well as pain, weakness, and inability to control motor movement in the affected area. The location of the radicular signs can be correlated to the respective dermatome distribution of the spinal nerves.

### Connection Check 37.2

In completing the history and physical assessment of a patient with back pain, which finding is most suggestive of a herniated nucleus pulposus?

- Constipation
- Numbness in left lower extremity
- Hyperactive reflexes
- Hematuria

**FIGURE 37.6** Comparison of normal and herniated disks.

## Management

### Medical Management

#### Diagnosis

The healthcare provider performs a complete history and physical, with a focused neurological examination to test reflexes, muscle strength, gait, and the patient's ability to feel touch and vibration. Tests used in diagnosing the herniated disk include imaging studies such as x-rays, CT scans, MRIs, and myelograms. Additional neurological tests used to pinpoint the location of the nerve damage are EMG and nerve conduction studies. See Table 37.1 for full explanations of diagnostic tests.

#### Treatment

Most patients with a herniated disk show improvement with 1 to 2 months of conservative treatment. This consists of avoiding painful positions and following a regimen of planned exercise and pain medications. Specific exercises include spinal stretching and strengthening, abdominal strengthening, pelvic tilts, and hip stretching. If obesity is a contributing factor, weight loss measures are also indicated.

Medications, including over-the-counter NSAIDs, muscle relaxants, sedatives-tranquilizers, and nerve pain medications such as gabapentin (Neurontin), pregabalin (Lyrica), duloxetine (Cymbalta), and tramadol (Ultram, Ryzolt) and amitriptyline (Elavil) often help relieve pain related to nerve damage. Because of their milder side effects, nerve pain medications are increasingly used as first-line prescription medications for people with herniated disks. Muscle relaxants such as diazepam or cyclobenzaprine also may be prescribed for muscle spasms. Finally, corticosteroids may be given orally or injected directly into the area around the spinal nerves to reduce inflammation and decrease pain.

Physical therapy is used to improve pain and to strengthen muscles. The patient is shown positions and exercises designed to minimize the pain of a herniated disk. While the pain improves, physical therapy advances to a rehabilitation phase of core strength and stability to maximize back health and help protect against future injury. Therapy recommendations include heat or ice, traction, ultrasound, neck or low-back bracing, or electrical stimulation.

Interventions for a herniated disk may be conservative or surgical. Medical management focuses on pain relief, improving function, and preventing future injury. Only approximately 10% of people with herniated disks eventually need surgery to relieve pressure on nerve roots and to stabilize the spine. Surgery is often recommended if the following occurs:

- Conservative treatment fails to improve clinical manifestations.
- Progressive neurological deficits such as weakness develop.
- Problems standing or walking
- Loss of bowel or bladder function

### Surgical Management

Several surgical options are used in the treatment of a herniated disk. One procedure is a *laminotomy*, which opens the lamina to decrease pressure on the compressed nerve root or spinal cord. During a *microdiscectomy*, the disk is removed to relieve pressure on the spine or nerve root, and this is often performed as a minimally invasive procedure or in conjunction with a *laminectomy* or partial laminectomy. The partial laminectomy is the surgical removal of part of the lamina and posterior arch of the vertebra. A laminectomy is the surgical removal of the lamina and part of the posterior arch of the vertebra. These procedures are done to remove pressure on the spinal cord or nerve roots and, when done along with the *discectomy*, to allow the surgeon a better view of the herniated disk. Laminectomies are most commonly used to treat spinal stenosis but can be used to treat other processes such as a herniated disk, traumatic injury, and tumors.

A developing alternative to the discectomy is artificial disk replacement that involves the surgeon using a manufactured disk to replace a diseased disk. This provides pain relief and restores motion without compromising the spine's anatomical structure.

Spinal fusion is surgery that joins two bones (vertebrae) together. Because fusing permanently joins the two bones together, there is no longer movement between them. Spinal fusion is usually performed along with other surgical procedures such as laminectomy and discectomy to provide spinal stability. In a spinal fusion, a bone graft (often from

the pelvis) or metal hardware is used to join the vertebrae together (Fig. 37.7).

Bone grafts may be obtained from several different places. First, a bone graft from the patient's own body is called an *autograft*. A bone graft may also be obtained from a bone bank. The bone bank is a facility for collecting and storing donated human bone for use in patients requiring a bone *allograft* (bone transplantation between two unrelated people). The third and least common type of graft is the use of a synthetic bone substitute.

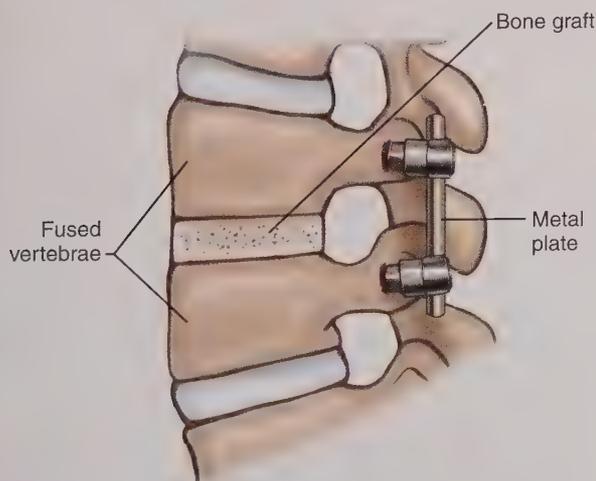

Currently, there are several different ways to fuse vertebrae together; bone graft material may be placed over the back part of the spine or placed between the vertebrae, or tiny, hollow metal cages may be placed into the disk space. The cage is filled with the bone graft or a spongelike material that promotes bone growth. Over time, the bone grows through the holes in and around the cage, fusing the vertebrae together. Finally, the vertebrae are often stabilized with instrumentation such as rods, plates, and screws. This decreases movement of the vertebrae and allows the bone grafts to fully heal. Lumbar fusion remains the “gold standard” for treating patients with LBP who have not been helped by conservative measures.

### Complications

Because a herniated disk often results in pain or loss of function from mechanical nerve root compression, complications vary depending on the location of the herniated disk. Common complications include:

- Numbness (paresthesias) and weakness
- Loss of bowel and bladder control
- Increased pain - back, arm, leg, neck
- Saddle anesthesia - progressive loss of sensation around areas that would touch a saddle (inner thighs, back of legs, and around the rectum)
- Chronic pain

The development of any of the above complications may require surgical intervention to prevent permanent loss of function.

**FIGURE 37.7** Lumbar spinal fusion.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of herniated nucleus pulposus vary depending on the location of the herniated disk. Clinical findings include:

- No symptoms at all
- Arm or leg pain
- Numbness or tingling
- Muscle weakness
- Neck pain
- Extreme constant back pain that shoots down an arm or leg (radicular pain)

Often the pain occurs on one side of the body and may vary widely from a dull ache to a burning or pulsating sensation or a sharp, shooting feeling.

### Nursing Diagnoses

- **Pain** related to nerve compression by the protruding disk
- **Impaired physical mobility** related to pain or neuromuscular impairment secondary to the nerve compression and inflammation
- **Self-care deficit** related to pain and physical restrictions secondary to surgical management of herniation of the nucleus pulposus (HNP)
- **Impaired home maintenance** related to pain or physical limitations due to nerve compression, inflammation, or postoperative restrictions

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Assess for hemodynamic signs of pain including tachycardia, hypertension, and tachypnea. In patients after back surgery (laminectomy and/or discectomy), temperature is assessed because elevation may develop related to infection or decreased fluid deficit.*
- Pain  
*Pain is secondary to compression of the nerve roots by the protruding disk.*
- Level of function/mobility  
*Baseline of how ADLs/mobility is affected because of pain, or numbness and weakness associated with impaired innervation to muscles*
- Muscle tone and strength  
*Because of pain, the patient may decrease use of the affected extremity, leading to loss of muscle tone and strength.*
- Bowel elimination  
*Decreased mobility, as well as side effects of opioid medications, increase the risk of constipation.*
- Surgical incision  
*The surgical incision needs to be evaluated for approximation, inflammation, and redness that may indicate a postoperative complication*
- Urine output  
*POUR (postoperative urinary retention) may develop in patients after back surgery due to impaired innervation or*

side effects of anesthesia. This complication increases the patient's risk of urinary tract infection and urosepsis.

### ■ Actions

- Give pain medications as prescribed (see Table 37.2)  
*Pain medications are indicated to promote comfort.*
- Administer corticosteroids as prescribed  
*Corticosteroids decrease the inflammatory process and decrease swelling in the affected area.*
- Position of comfort  
*Positioning the patient with head of bed elevated 30 – 45 degrees with knees bent helps to decrease strain on back muscles.*
- Encourage ROM exercises  
*To increase function, prevent contractures, and strengthen core muscle groups*
- Increase fluid intake and fiber  
*Increasing fluids and high-fiber food decreases the risk of developing constipation.*

### ■ Teaching

- Importance of exercise and mobility  
*Core muscle strengthening helps stabilize and support the spine.*
- Good posture  
*Helps decrease pressure on the spine and disks that will reduce the possibility of reinjury*
- Avoid bending at the waist and bend knees with a straight back when lifting

*Bending at the waist when lifting can place additional stress on the area of herniation and increase pain. Bending at the knees with the back straight uses the leg muscles to lift and decreases strain on the back muscles.*

- Avoid lifting, pulling or pushing objects greater than 5 pounds  
*Decreases strain on surgical site and allows bone healing in patients after spinal fusion.*
  - Review disease process and prognosis  
*Helps increase understanding and enhances ability to make informed choices*
- Table 37.3 provides an overview of postoperative nursing management for patients after laminectomy, discectomy, or spinal fusion.

### Evaluating Care Outcomes

Most patients have improvement with conservative therapy within 2 months. These patients may need to adopt lifestyle changes to prevent re-injury of the spine. The lifestyle changes include a healthy diet, exercise to improve core strength and stability, smoking cessation, and the use of good body mechanics at both work and home. Patients who do require surgical intervention still must make lifestyle changes but must also face the added risks that come from having surgery. Some postsurgical patients may experience a prolonged recovery period before resuming activity levels that were present prior to the herniation and surgery. Most patients recover and go on to lead active lives.

**Table 37.3 Nursing Interventions for Surgery for Herniated Nucleus Pulposus**

Intervention	Rationales
<b>Assess respiratory status</b>	Changes in respiratory rate and effort may indicate ventilatory impairment.
<b>Monitor vital signs</b>	Hemodynamic signs of pain and hemorrhage include tachycardia, hypotension, tachypnea.
<b>Monitor neurological status</b>	To detect early and subtle changes in motor and sensory examination
<b>Assess pain</b>	Pain occurs secondary to compression of nerve roots and postoperative swelling at site.
<b>Inspect surgical site</b>	To detect signs of infection, hemorrhage, or CSF leak
<b>Maintain the body in good alignment</b>	Promotes stabilization of the surgical site to optimize function
<b>Assist with turning, coughing, and deep breathing</b>	Because of muscle weakness or lack of diaphragmatic innervation, assistance is needed to remove secretions.
<b>Encourage range-of-motion exercises</b>	Increase function, promote strengthening of core muscle groups, and decrease risk of contracture development
<b>Teach importance of following activity level</b>	Dependent on level of injury and stabilization of injured site to prevent further damage
<b>Teach clinical manifestations of infection</b>	Redness, drainage, swelling at the site, and fever are signs of infection and need to be reported to the provider for evaluation and treatment.
<b>Implement bladder and bowel training</b>	Damage to nerves that coordinate the muscles of the bladder and urethra and urination impairs function (urinary retention); assess patient for possible catheterization to empty bladder. Bowel movements may occur on a reflexive basis when the bowel is full. The patient may also experience a permanently relaxed bowel that results in inability to initiate own bowel movement.

## MULTIPLE SCLEROSIS

### Epidemiology

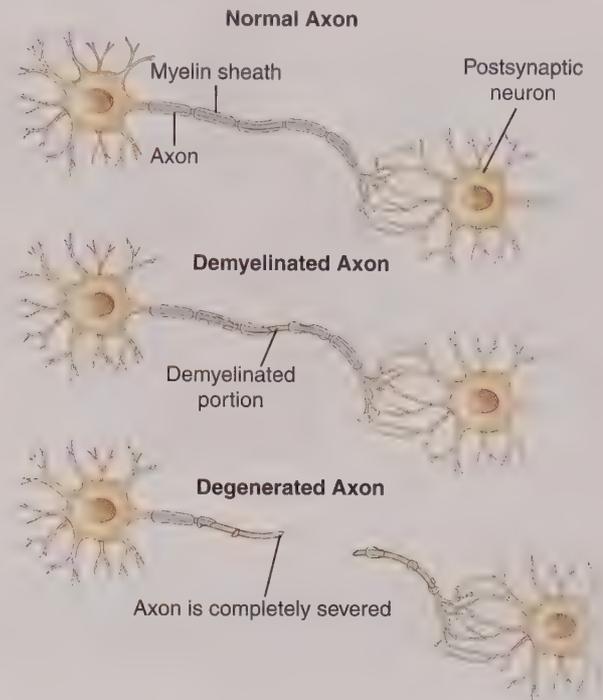

Multiple sclerosis (MS) is a chronic neurological disorder in which the nerves of the CNS (brain and spinal cord) degenerate. The disorder derives its name from the build-up of scar tissue (**sclerosis**) or plaques that form during **demyelination** (destruction of myelin sheath). Multiple sclerosis is classified as an autoimmune disease, in which the immune system mistakenly identifies normal body substances and tissues as foreign and attacks them. Approximately 400,000 people in the United States have MS, with typical onset between 20 and 50 years. It affects more women than men and twice as many Caucasians as any other group. Other risk factors include a positive family history, immunological factors, and certain viral infections. There is a higher prevalence of MS in colder, more northern latitudes.

There are four main types of MS:

1. **Relapsing-remitting:** The most common form of MS, it affects twice as many women as men (typically in their 20s and 30s). Characterized by relapses (exacerbations) during which new clinical manifestations appear and old ones worsen or reappear, these relapses can last days or months. Relapses are followed by periods of remission during which the patient has either a partial or total recovery; this can be slow or almost instantaneous.
2. **Secondary progressive:** The patient who initially had relapsing-remitting develops gradual worsening of the disease. In the early phase, the patient still may experience relapses, but these will progress into a general deterioration. Although some improvement may be seen after a relapse, no real recovery occurs.
3. **Progressive relapsing:** Progressive course with a gradual worsening of clinical manifestations from onset, and the relapses may or may not have recovery.
4. **Primary progressive:** Gradual progression with no remissions; however, there may be temporary plateaus. This form affects men and women equally and typically occurs in the late 30s and early 40s. Initial disease activity is in the spinal cord, not the brain, so these patients are less likely to develop cognitive problems.

### Pathophysiology

Myelin is the protective sheath that covers the spinal cord and nerves. It not only protects the nerve, but it also helps the impulses travel along the nerves at a faster rate. These impulses control muscle movements, as well as transmitting sensory data. The CNS contains the blood-brain barrier that separates circulating blood from the brain's extracellular fluid. The barrier is composed of tight junctions between endothelial cells in the CNS vessels that restrict the passage of solutes from the bloodstream. Demyelination is the loss of the myelin sheath (Fig. 37.8). It begins with a breakdown of the blood-brain barrier that allows immune cells (T lymphocytes) to infiltrate and attack the myelin. In MS, the immune system attacks the brain and spinal cord (CNS).

**FIGURE 37.8** Comparison of normal and demyelinated axons.

### Clinical Manifestations

The resulting inflammation in MS destroys the myelin, resulting in impaired sensation, movement, and thinking. Although nerves can regain myelin, this process occurs more slowly than deterioration in MS. The clinical manifestations and severity are due to the extent of demyelination and the location of scar tissue. Nerve conduction is slowed or irregular due to loss of myelin that facilitates impulse transmission. Depending on the location of the affected nerve fibers, a wide variety of clinical manifestations (Fig. 37.9) may be exhibited, including:

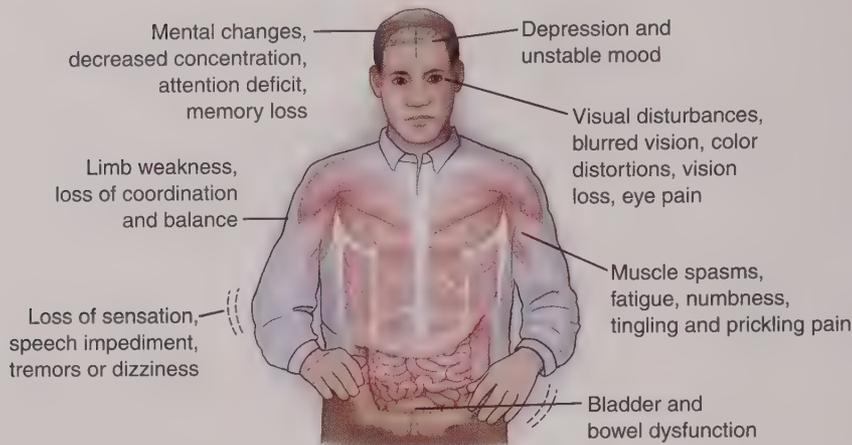

- Numbness or weakness in one or more limbs
- Partial or complete vision loss, often with pain during eye movement (optic neuritis)
- Double or blurred vision
- Tingling or pain
- Electric-shock sensations that occur with head movements
- Tremor, lack of coordination, or unsteady gait
- Fatigue
- Dizziness

### Management

#### Medical Management

#### Diagnosis

Because clinical manifestations can be intermittent or mimic other diseases and there is no specific test for MS, it can be difficult to diagnose. Therefore, a patient may not be diagnosed for months to years after onset of clinical manifestations. The diagnosis is ultimately made by ruling out conditions with similar clinical presentations. A detailed history, physical, and neurological examination are performed. Blood samples are sent to the laboratory to rule out

**FIGURE 37.9** Clinical manifestations of multiple sclerosis.

other inflammatory or infectious diseases that may have the same clinical manifestations, including tests for vitamin B<sub>12</sub> and E deficiencies, Lyme titer, antineutrophilic antibodies (ANAs) for autoimmune diseases, angiotensin-converting enzyme for sarcoidosis, HIV/HTLV (human T-lymphotropic virus), erythrocyte sedimentation rate (ESR) for inflammation, rapid plasma reagin (RPR) for neurosyphilis, anticardiolipin antibodies, and lupus anticoagulant for coagulopathy/vascular conditions. A lumbar puncture is often performed to send a CSF sample to be tested for abnormal levels of white blood cells (WBCs) or proteins and to help rule out other causes of these clinical manifestations such as viral infections. Other diagnostic tests include MRI scans to identify brain lesions (plaques), electrophysiological tests, and evoked potentials to examine how quickly impulses are traveling through the nerves. For a definitive diagnosis, the patient must have at least two separate symptomatic events or MRI changes in at least two separate locations.

### Treatment

There is no cure for MS. Treatment often focuses on improving the speed of recovery from attacks, reducing the number of attacks, and slowing the progression of the disease. Lifestyle management includes adequate rest, exercise, staying cool, eating a healthy, balanced diet, and relieving stress, because these can all trigger an exacerbation or **flare** of MS.

Medical management focuses on several areas. First, medications used to modify the disease course include beta interferons (interferon beta-1a [Avonex, Betaseron, and Rebif] and interferon beta-1b [Extavia]), glatiramer (Copaxone), fingolimod (Gilenya), and immunosuppressive agents such as natalizumab (Tysabri) and mitoxantrone (Novantrone). These medications are used to slow the progression of the disease. Second, strategies used to treat attacks include corticosteroids and plasma exchange (plasmapheresis) to decrease the inflammatory and immunologic factors involved in the exacerbation. The final focus is on medications used to treat clinical manifestations. Muscle relaxants such as baclofen (Lioresal and Kemstro) and tizanidine (Zanaflex) decrease spasticity. Physical therapy is used to help strengthen muscles and improve daily function. Medications may also

be prescribed to help reduce fatigue and to treat depression, pain, and bladder or bowel problems. Medications used in the treatment of MS are listed in Table 37.4.

### Connection Check 37.3

The nurse correlates which diagnostic result as most conclusive of a diagnosis of MS?

- MRI changes in at least two separate locations
- Elevated ESR
- Elevated WBC
- Decreased CSF protein levels

### CASE STUDY: EPISODE 2

During the assessment, the healthcare provider notes that Cynthia has left lower extremity numbness and previously unnoticed weakness. This is affecting her balance, causing gait ataxia. The healthcare provider also notices increased reflexes in Cynthia's left arm and leg and visual changes in her right eye. An MRI of the brain and spinal cord is ordered to reveal any CNS process that may be present. Because Cynthia has poorly controlled diabetes and because of her upper motor neuron signs (increased reflexes) and leg weakness, the healthcare provider also wants to rule out amyotrophic lateral sclerosis (ALS) as a potential cause of Cynthia's current deficits.

The MRI of the brain and spinal cord reveals lesions or plaques associated with MS. The healthcare provider then orders blood tests and a lumbar puncture to send CSF for testing to rule out other inflammatory or infectious processes. All of these results are normal. Cynthia's CSF results demonstrate increased immunoglobulin G (IgG) synthesis rate and IgG index, which indicate increased rate of IgG production and higher levels when compared to serum levels. These increased IgG levels signify an inflammatory process (MS, infection, cancer, etc.) is occurring within the CNS. Cynthia's

CSF results also show a slight increase in protein and a normal WBC count. The results indicate possible MS.

At her follow-up appointment, the healthcare provider discusses the test results with Cynthia. She is informed that she may have MS, but for a definitive diagnosis, the patient must have at least two separate symptomatic events or MRI changes in at least two separate locations. She has started physical therapy twice a week and reports that her symptoms have improved, and her balance is better. Cynthia has been trying to reduce stress and has continued to lose weight by following a healthy diabetic diet and a supervised exercise program with a trainer at a local gym. She has had several months without any further deficits developing...

## Complications

Because MS affects nerves throughout the body, complications can vary. These clinical manifestations may have periods of worsening and have a recovery period with some improvement. Common complications include:

- Muscle stiffness or spasms
- Paralysis, often in the legs
- Problems with bladder, bowel, or sexual function
- Mental status changes – memory loss, problems concentrating
- Depression
- Seizures

Other complications include pressure injuries resulting from immobility, skin breakdown caused by bowel and bladder incontinence, ataxic gait caused by weakness and

**Table 37.4 Medications Used to Treat Multiple Sclerosis**

Class	Examples	Mechanism of Action
<b>Immunomodulator</b>	Interferon beta-1a (Avonex, Rebif)	Alters the immune response by reducing the body's ability to make antibodies; these antibodies are what attack the myelin; therefore, this slows the attack on myelin and slows disease progression.
<b>Immunomodulator</b>	Interferon beta-1b (Betaseron, Extavia)	See above
<b>Immunomodulator – synthetic protein</b>	Glatiramer (Copaxone), fingolimod (Gilenya)	See above Gilenya is the first oral immunomodulator approved for MS.
<b>Immunosuppressants</b>	Natalizumab (Tysabri), mitoxantrone (Novantrone)	Suppresses body's immune response to prevent leukocytes from attacking each other
<b>Muscle relaxant and antispasmodic</b>	Baclofen (Lioresal, Kemstro), tizanidine (Zanaflex)	Depress CNS to reduce pain and inhibit reflexes at the spinal level to decrease muscle spasm
<b>Corticosteroids</b>	Prednisone, cortisone, hydrocortisone, methylprednisolone sodium succinate (Solu-Medrol)	Mimic the effects of hormones produced in the adrenal glands; decrease inflammation by blocking the production of substances that trigger allergic and inflammatory reactions (e.g., prostaglandins)
<b>Anticholinergic; antispasmodics</b>	Oxybutynin chloride (Ditropan)	Inhibits transmission of impulses through parasympathetic nerve fibers
<b>Analeptics</b>	Modafinil (Provigil), Armodafinil (Nuvigil)	Alter neurotransmitters to improve wakefulness
<b>Anticonvulsants</b>	Phenytoin (Dilantin), gabapentin (Neurontin), pregabalin (Lyrica), topiramate (Topamax), carbamazepine (Tegretol)	Not proven but are thought to block the sodium channels and decrease formation of ectopic neuronal pacemakers
<b>Stool softeners</b>	Docusate (Colace)	Absorb water in the large intestine, increasing the bulk of the stool
<b>Antimuscarinics</b>	Tolterodine (Detrol)	Reduces bladder spasms by inhibiting acetylcholine
<b>Laxatives – osmotic</b>	Milk of magnesia, Miralax, lactulose	Pull fluids into the intestine from other tissue and blood vessels; the extra fluid makes the stool softer and easier to pass.
<b>Laxatives – stimulant</b>	Correctol, Dulcolax, Senokot	Irritates the intestinal lining and speeds up how quickly stool moves through the intestines

loss of position sense in the legs. Speech defects caused by muscle weakness; mood changes such as depression, euphoria, denial, and forgetfulness may be caused by both medications and the demyelination process.

### Nursing Management

#### Assessment and Analysis

Because MS affects varying nerves throughout the body, the clinical presentation may change with each attack. These clinical manifestations are the direct result of the demyelination process. Often, patients have an “attack” with a partial recovery of the symptoms.

Clinical manifestations include:

- Numbness/weakness
- Complete or partial loss of vision
- Double or blurred vision
- Fatigue
- Dizziness
- Tremor
- Lack of coordination/balance
- Speech problems – especially articulation
- Memory loss

Other clinical manifestations include depression, paranoia, and reduced bowel or bladder control.

#### Nursing Diagnoses

- **Impaired physical mobility** related to neuromuscular impairment secondary to demyelination
- **Self-care deficit** related to reduced neurotransmission and impaired physical mobility secondary to demyelination
- **Impaired coping, depression** related to the chronic, progressive nature of the disease

#### Nursing Interventions

##### ■ Assessments

- Neuromuscular function  
*Evaluate for changes in clinical presentation or for new symptoms to be addressed as the disease progresses and new areas of demyelination occur.*
- Vision/eye movement  
*Demyelination of cranial nerves can result in optic neuritis, causing visual changes.*
- Skin integrity  
*Immobility promotes breakdown as a result of compression of soft tissue between a bony prominence and an external surface. This compromises blood flow and decreases delivery of oxygen and nutrients to cells, resulting in cellular death and injury to the surrounding tissue.*
- Ability to perform ADLs  
*Evaluate need for assistive devices to decrease the danger of falls.*
- Bowel and bladder function  
*Impaired innervation to the bladder and bowel may result in incontinence and constipation.*

##### ■ Actions

- Encourage ROM exercises  
*Increase venous return, prevent stiffness, and maintain muscle strength and endurance.*
- Administer interferon beta-1b (Betaseron)  
*Interferon beta-1b is used to decrease exacerbations and slow disease progression.*
- Administer corticosteroids during exacerbations  
*During an exacerbation of MS, typically a result of some type of stress, administration of corticosteroids decreases the inflammatory processes associated with the flare.*
- Implement safety measures  
*Because of changes in mobility, sensation, and vision, the patient is at increased risk of falls and injury.*
- Patch each eye daily as needed in patients with visual deficits and/or diplopia  
*Alternating the patching of each eye several times per day improves balance and vision.*

##### ■ Teaching

- Take medications as prescribed  
*To decrease exacerbations/slow progression; to treat clinical manifestations as needed*
- Importance of rest periods and preventing fatigue and overheating  
*Fatigue, overexertion, and overheating stimulate MS exacerbations*
- Clinical manifestations of MS exacerbation  
*To detect early signs of exacerbation to receive early treatment*
- Visual scanning  
*Because peripheral vision may be decreased in patients with MS, visual environment scanning decreases the risk of injury.*
- Check water temperature prior to entering the bathtub or shower  
*Decreased sensation secondary to demyelination makes the patient at risk of burn injuries if the water is too hot.*
- Maintain ideal body weight  
*Impaired immobility may increase weight gain and increased weight is associated with complications with mobility and fatigue in patients with MS.*
- Review disease process and prognosis  
*To help increase understanding and enhance the patient's ability to make informed choices*

#### Evaluating Care Outcomes

Patients with multiple sclerosis live their lives never knowing when the next exacerbation or attack will occur. Compliance with the medication regimen, specifically Betaseron, helps reduce these exacerbations. Patient and family education are important regarding the medication regimen, the clinical manifestations of exacerbation, and the importance of getting adequate rest and exercise. The goals of care are to keep the patient as active and functional as possible, to provide symptomatic relief, and to provide continued support to the patient and family. Because the problems of

MS are relatively permanent, there is an increased need for personal responsibility and the involvement of supportive family and friends in the patient's care. Most of the patient's time may be spent homebound; therefore, the role in symptom management is central to the most optimal outcomes of needed therapies throughout the course of this illness.

## AMYOTROPHIC LATERAL SCLEROSIS

### Epidemiology

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a rapidly progressing, fatal CNS (brain and spinal cord) disease that affects voluntary muscle control. It is the most common adult-onset motor neuron disease. Amyotrophic lateral sclerosis results in gradual degeneration and death of motor neurons, causing muscle weakness and atrophy, but does not impair the senses or ability to think. Clinical Manifestations usually develop after age 50, and the prevalence of ALS in the United States is 3.9 per 100,000 people. Most people die from respiratory failure within 3 to 5 years of onset of clinical manifestations. Although in most cases the cause is unknown, 10% of cases are caused by a genetic defect (see Genetic Connections).

### Genetic Connections

#### Heritability of Amyotrophic Lateral Sclerosis

On the basis of twin studies in Ireland, it is estimated that heritability of amyotrophic lateral sclerosis (ALS) ranges from 61% to 76%. These findings suggest that both genetic and environmental factors have a role in the development of this disease. Findings suggest that genetic variants are important in explaining the role of genetics in ALS. Regional differences noted in this study also suggest that there are both new environmental and genetic risk factors and that larger studies are needed to examine these factors.

### Pathophysiology

Motor neurons are located throughout the CNS and serve as controlling and communication links between the nervous system and voluntary muscles. Messages are passed from upper motor neurons (located in the brain) to lower motor neurons (located in the spinal cord) and on to particular muscles. In ALS, both upper and lower neurons degenerate and die. Unable to function, muscles gradually weaken, atrophy, and twitch (**fasciculation**). The progressive degeneration leads to death of the cells, resulting in the brain losing the ability to initiate and

control muscle movement (Fig. 37.10). Eventually, all voluntary muscles are affected, and patients are paralyzed, but sensation is intact. Bulbar ALS, also known as progressive bulbar palsy, is a form of ALS that prominently affects the muscles involved in speech, swallowing, and tongue movements. Amyotrophic lateral sclerosis affects the diaphragm and chest wall, resulting in respiratory failure and the need for placement of an artificial airway (endotracheal tube or tracheostomy) and ventilator support.

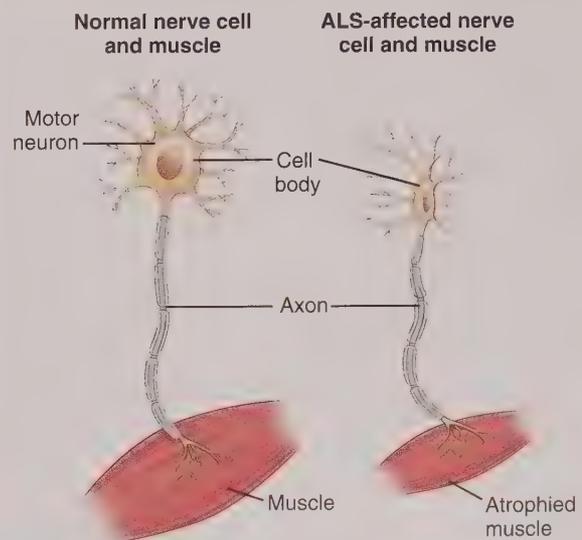

### Clinical Manifestations

Patient clinical manifestations are often described first as general complaints of muscle cramps or stiffness, muscle weakness on one part of the body first, slurred speech, and difficulty swallowing (dysphagia). The early clinical presentation depends on which part of the body is damaged first. While the disease progresses, the patient experiences weakness and atrophy in other parts of the body. To be diagnosed with ALS, patients must have clinical manifestations of both upper and lower motor neuron damage that cannot be attributed to other causes. Upper motor neuron damage is associated with spasticity, while lower motor neuron damage is characterized by flaccidity.

### Connection Check 37.4

The nurse monitors for which complication in the patient with bulbar ALS?

- Lower back pain
- Dementia
- Paresthesias
- Dysphagia

**FIGURE 37.10** Comparison of normal and amyotrophic lateral sclerosis (ALS)-affected cell and muscle.

## Management

### Medical Management

#### Diagnosis

No single test can be used to diagnose ALS; therefore, a complete history and physical examination must be performed by the healthcare provider. This includes muscle strength and endurance testing to see if weakness, spasticity, atrophy, and hyperreflexia (increased reflexes) are increasing. Other diagnostic tests that may be performed in patients with suspected ALS include:

- B<sub>12</sub> for deficiency
- RPR for neurosyphilis
- ANAs as a general autoimmune screen
- Thyroid-stimulating hormone for hypothyroidism
- Serum protein electrophoresis/immunofluorescent electrophoresis for protein disorders
- Rheumatoid factor
- ESR as a general inflammatory screen
- Creatine phosphokinase for muscle injury
- Electrolyte panel for imbalances
- Complete blood count and peripheral smear for leukemias/plasma cell dyscrasias
- Anti-MAG and anti-GM1 antibodies for other neuromuscular diseases
- Parathormone for deficiency
- Urinalysis and 24-hour urine for heavy metals
- Serum lead, acid maltase, and hexosaminidase levels for other metabolic-neuromuscular diseases
- Free erythrocyte protoporphyrin for porphyrias

A lumbar puncture is also needed to evaluate CSF protein and cytology.

A CT scan and/or MRI of the neck and head may be performed to rule out other conditions that can mimic ALS (spinal cord tumor, herniated disk, spondylosis, brain tumor, MS, etc.). If there is a known family history of ALS, genetic testing is performed. Electromyography and nerve conduction studies are used to determine which nerves are damaged and to rule out other conditions such as peripheral neuropathy. Swallow studies are ordered to see if the muscles controlling the patient's ability to swallow have been affected because the patient is at risk for aspiration with dysphagia.

Because of the prognosis of ALS and the fact that several diseases can mimic the early clinical manifestations, it is not uncommon for a patient to obtain a second opinion. Because no cure exists, management focuses on slowing disease progression and managing clinical manifestations. Riluzole (Rilutek) is the first medication approved to slow disease progression. While this medication does not repair damaged neurons, it has been shown to both increase survival and to extend the period without the need for ventilatory support.

#### Treatment

Treatment includes medications for symptomatic relief, such as baclofen for muscle cramps, laxatives and stool softeners for constipation, **analeptics** (CNS stimulants) for

fatigue and weakness, and tricyclic depressants for excessive salivation, pain, and depression. See Table 37.5 for examples of medications used to treat ALS.

Often physical, occupational, and speech therapies are used to maximize function. While the disease progresses and muscles weaken, assistive and breathing devices may be used. Nutrition is a very important component of the plan of care. Patients with ALS tend to lose weight, and often a gastric feeding tube must be placed to help meet their nutritional requirements. As the chest and diaphragm muscles weaken, patients need to consider forms of mechanical ventilation requiring a tracheotomy. Patients need to be fully informed about the risks and long-term effects of ventilation.

#### Complications

Amyotrophic lateral sclerosis is a progressive disease that leads to the inability to move. Complications include aspiration of food or fluid, respiratory failure, pneumonia, pressure injuries, deep vein thrombosis (DVT), pulmonary embolism (PE), constipation, contractures, depression, weight loss, and loss of the ability to care for self. While the patient's physical condition deteriorates, it is important to make decisions about enteral feedings, intubation and mechanical ventilation, as well as end-of-life decisions.

#### Nursing Management

##### Assessment and Analysis

The first clinical manifestations of ALS are general complaints because of weakness of the involved muscles. The clinical presentation is directly related to the progressive wasting of the motor neurons and includes:

- Difficulty breathing
- Difficulty swallowing – choking, drooling
- Speech problems – slurring words, slow speech
- Voice changes – hoarseness
- Muscle cramps
- Head drop due to weak neck muscles
- Muscle twitching (fasciculation)
- Increasing muscle weakness – localized to one part of the body then spreads
- Paralysis
- Weight loss
- Tongue atrophy

Although muscle weakness occurs in 60% of patients and is the initial hallmark sign of ALS, clinical manifestations vary with each individual, and can begin in the muscles of the arms, legs, hands, or feet or in the muscles of speech and swallowing. Although everyone with ALS does not experience the same clinical manifestations or progression of the disease, progressive muscle weakness and paralysis are universally experienced.

#### Nursing Diagnoses

- **Ineffective airway clearance** related to weak cough secondary to motor neuron death and muscle weakness

**Table 37.5 Medications Used in the Treatment of Amyotrophic Lateral Sclerosis**

Classification	Examples	Mechanism of Action
<b>Benzothiazole</b>	Riluzole (Rilutek)	Decreases glutamate levels, an amino acid that affects the nerves that send messages from the brain to the muscles
<b>Muscle relaxant and antispasmodics</b>	Baclofen (Lioresal, Kemstro), tizanidine (Zanaflex)	Depresses CNS to reduce pain and inhibit reflexes at the spinal level to decrease muscle spasm
<b>Analeptics</b>	Modafinil (Provigil), armodafinil (Nuvigil)	Alter neurotransmitters to improve wakefulness
<b>Antidepressants - tricyclics</b>	Imipramine (Tofranil), amitriptyline (Elavil), nortriptyline (Pamelor)	Contain three fused benzene rings that block the reuptake of norepinephrine and serotonin in the CNS
<b>Laxatives - osmotic</b>	Milk of magnesia, Miralax, lactulose	Pulls fluid into the intestine from other tissue and blood vessels; the extra fluid makes the stool softer and easier to pass.
<b>Laxatives - stimulant</b>	Correctol, Dulcolax, Senokot	Irritates the intestinal lining and speeds up how quickly stool moves through the intestines
<b>Antimuscarinics; anticholinergics</b>	Glycopyrrolate (Robinul)	Inhibits acetylcholine activity on structures innervated by postganglionic cholinergic nerves and on smooth muscles that respond to acetylcholine by blocking cholinergic innervation; results in diminished volume and free acidity of gastric secretions and control of excessive pharyngeal, tracheal, and bronchial secretions

CNS = Central nervous system.

- **Risk for aspiration** related to weakness of muscles of swallowing
- **Ineffective breathing pattern** related to weakness of the respiratory muscles secondary to motor neuron dysfunction
- **Potential for injury** related to impaired physical mobility secondary to motor neuron death and muscle weakness
- **Impaired oral communication** related to dysarthria and tongue atrophy secondary to motor neuron death
- **Ineffective coping** related to the diagnosis of a progressive disease that results in motor paralysis

## Nursing Interventions

### ■ Assessments

- **Airway**  
*Because motor weakness involves muscles of the face, mouth, and neck, maintaining an intact airway is compromised. Airway compromise is greater as the patient demonstrates weakened cough and impaired swallowing.*
- **Oxygen saturation**  
*Motor neuron death and resultant muscle weakness may impair respiratory function and the ability to clear secretions, which leads to decreased oxygenation.*
- **Motor strength**  
*While the disease progresses, muscle weakness increases because of neuronal degeneration and cell death.*

- **Ability to swallow**  
*Increased risk of aspiration with difficulty swallowing food or fluid because of neuronal degeneration and resultant muscle weakness*
- **Skin**  
*Immobility promotes breakdown because of the compression of soft tissue between a bony prominence and an external surface. This compromises blood flow and decreases delivery of oxygen and nutrients to the cells, resulting in cellular death and injury to the surrounding tissue.*
- **Coping skills**  
*For current skills that work and to identify support system*

### ■ Actions

- **ROM**  
*Prevents contracture and strengthens unaffected muscles*
- **Administer medications** to treat clinical manifestations  
*To maintain patient's comfort by alleviating muscle cramps, pain, constipation, fatigue, depression, etc.*
- **Elevate the head of the patient's bed** when eating, drinking, or brushing teeth  
*Because of impaired swallowing secondary to motor neuron disease, elevating the head of the bed helps prevent aspiration.*
- **Turn, cough, and deep breathing**  
*While motor strength declines, the patient needs to be turned and repositioned to promote gas exchange.*

- Turn scheduled for every 2 hours  
*The patient with ALS is at increased risk for impaired skin integrity because of impaired mobility. The patient can usually let the nurse know when repositioning is needed because of discomfort (as sensation is intact).*
- Emotional support  
*Because of the progressive nature of the disease, patients require maximum support from staff and family.*

### ■ Teaching

- Report increased difficulty swallowing or breathing  
*Indicates disease progression as motor neuron death and muscle weakness affect the muscles needed to breathe and swallow*
- Disease prognosis and process: need for ventilator  
*Discuss so that patient can make informed decisions while still having mild symptoms*
- Communication strategies  
*To help patient communicate with family and healthcare providers*

### Evaluating Care Outcomes

Patients with ALS face a difficult future. As a progressive disease, ALS eventually leads to the inability to move and to ventilator dependence. The nurse must help prepare the patient and family for the disabilities that will result from the degeneration, keep the patient comfortable and independent for as long as possible, and help prepare the patient and family for death. The effectiveness of interventions is reflected in the lack of respiratory compromise, stable body weight, and intact skin. The focus of care needs to be supporting the patient and his or her family through this difficult process.

## SPINAL CORD INJURY

### Epidemiology

Acute spinal cord injury (SCI) is an unexpected catastrophic event that results in the loss of function such as mobility or sensation. Spinal cord trauma may result from either direct injury to the cord or indirectly from damage to surrounding bones, tissues, and blood vessels. The mechanism of this injury may be caused by hyperextension, hyperflexion, rotation and vertical compression (**axial loading**), or penetrating injuries. The incidence of SCI in the United States is approximately 12,000 per year. Currently, approximately 300,000 Americans are living with SCIs, and the cost of care is \$4 billion each year.

While spinal cord injuries occur in people of all ages, the majority occur between the ages of 16 and 18, and most commonly affect men. Risk factors include activities such as participating in high-risk physical activities such as speeding and drinking while under the influence of alcohol, substance use, and not using protective gear in sports or recreational activities. In the older population, there is increased risk of spinal cord trauma related to

fall-related injuries. Injuries at the C4, C5, C6 and T12 spine levels are most common, with half of the injuries resulting in paraplegia and half in quadriplegia. The leading cause of SCI is automobile accidents (56%), followed by falls (14%), acts of violence/guns (9%), and sports injuries (7%).

### Pathophysiology

Spinal cord injury is damage to the spinal cord with resulting functional loss of mobility and/or sensation. Spinal cord injuries result from concussion, contusion, compression, tearing, laceration, transection, or ischemia of the spinal cord. The spinal cord is about 18 inches long, and the nerves within the cord carry messages from the brain to the spinal nerves (*upper motor neurons*) and back. Spinal nerves called *lower motor neurons* branch out from the spinal cord to specific areas of the body. The lower motor neurons have two parts, a sensory portion that carries messages from the body to the brain and a motor portion that carries messages back to the body parts to initiate actions such as muscle movement.

The spinal cord does not have to be severed for loss of functioning to occur. In fact, most injuries leading to spinal column bony fractures result in various types of SCI. Neuron axonal injury occurs as a result of this trauma. The number of axons damaged can vary, allowing some types of injuries to recover and others to result in paralysis. At the moment of injury, affected axons are damaged beyond repair, and the neural cell membranes are ruptured. Blood vessels may sustain trauma resulting in bleeding that, within a short period of time, can spread from the central gray matter to other areas of the spinal cord. Minutes after the initial injury, the spinal cord can swell and fill the entire spinal cavity at the level of injury. This swelling results in anoxia caused by lack of blood flow and oxygen to the spinal cord tissue. While the body loses its ability to self-regulate, blood pressure drops, interfering with the electrical activity of neurons and axons.

The initial trauma of crushing or tearing of axons sets off a biochemical cascade that destroys neurons, demyelinates axons, and triggers an inflammatory response that can result in damage to spinal cord segments above or below the initial injury level. Blood flow changes in and around the injured area of the cord begin to spread, resulting in various movement and sensory changes throughout the body. The reduction in blood flow to the injured cord causes the blood vessels located in the gray matter to leak. Blood flow to the injured area is further reduced while cells lining the still intact blood vessels begin to swell. This combination of decreased blood flow with leaking and swelling vessels prevents the normal delivery of oxygen and nutrients to neurons, resulting in their death.

Additional damage can be caused by overexcitation of the nerve cells with the increased release of neurotransmitters. When spinal cells are injured, neurons flood the injured area

with an excitatory transmitter (glutamate) normally used to stimulate activity in neurons. This excessive glutamate results in **excitotoxicity**, a process in which neurons are damaged and destroyed by overstimulation.

Normally, the blood–brain barrier keeps immune system cells from entering the brain or spinal cord. After an SCI, the barrier is broken, and WBCs can invade the surrounding tissue and trigger an inflammatory response characterized by fluid build-up and the arrival of immune cells (neutrophils, T cells, macrophages, and monocytes) to the site. The immune system response may help fight infection and clean up cellular debris, but this may also contribute to the formation of scar tissue within the cord. Another consequence of inflammation is the production of **free radicals**. Free radicals are a by-product of normal cell metabolism and are thought to be involved in degeneration, cancer, and the aging process. In the injured spinal cord, free radicals attack and destroy molecules vital for cell function.

The process of **apoptosis**, or cell death, results in more damage to the spinal cord and further decreases the ability to communicate with the brain. Apoptosis normally helps the body get rid of old, unhealthy cells. The cells shrink and die, and then scavenger cells remove the debris. After an SCI, apoptosis occurs, killing oligodendrocytes (the cells that form myelin) in the damaged area and in adjacent intact areas. The mechanisms of secondary damage (decreased blood flow, inflammation, excitotoxicity, free radical release, and apoptosis) increase the area of spinal cord damage. This increases the resulting deficits the patient experiences as a result of damage to the spinal cord.

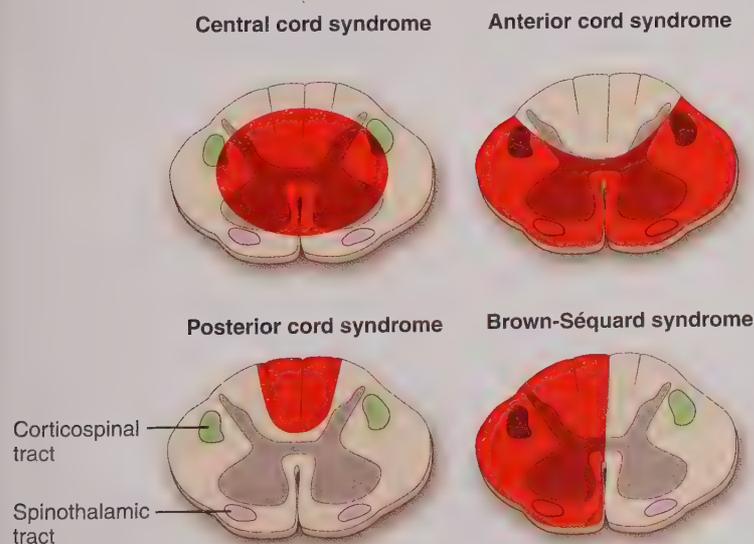

Spinal cord injuries are divided into two classifications—complete and incomplete injuries. A complete injury results in a total loss of motor and sensory function below the level of injury. In an incomplete injury, there is incomplete structural damage with some function preserved below the

primary injury level. Four types of incomplete injury have been identified (Fig. 37.11):

1. Central cord syndrome
  - Most common
  - Etiology: hyperextension injury with central cord swelling
  - Clinical manifestations: functional motor loss greater in arms than legs, bladder dysfunction, and variable loss of sensation
2. Anterior cord syndrome
  - Etiology: acute anterior compression from bony fragments or acute disk herniation
  - Clinical manifestations: Loss of motor function (paresis or paralysis), pain, temperature, crude touch and pressure below the level of injury; preserved sense of proprioception (position sense), fine touch and pressure, and vibration
3. Posterior cord syndrome
  - Etiology: acute compression
  - Clinical manifestations: loss of proprioception, fine touch and pressure, and vibration; intact pain, temperature, and crude touch and pressure
4. Brown-Séquard syndrome
  - Etiology: hemisection of the spinal cord resulting from penetrating injury (i.e., gunshot or knife injury); may also occur as result of primary ischemia, infection, or hemorrhagic event
  - Clinical manifestations: **ipsilateral** (on the same side as the injury) loss of motor function, proprioception, and vibration; **contralateral** (on the opposite side) loss of pain and temperature

### Clinical Manifestations

The level of injury helps predict what parts of the body might be affected. Cervical injuries can result in the inability to breathe (above C4) as the **phrenic nerve** that

**FIGURE 37.11** Incomplete spinal cord lesions.

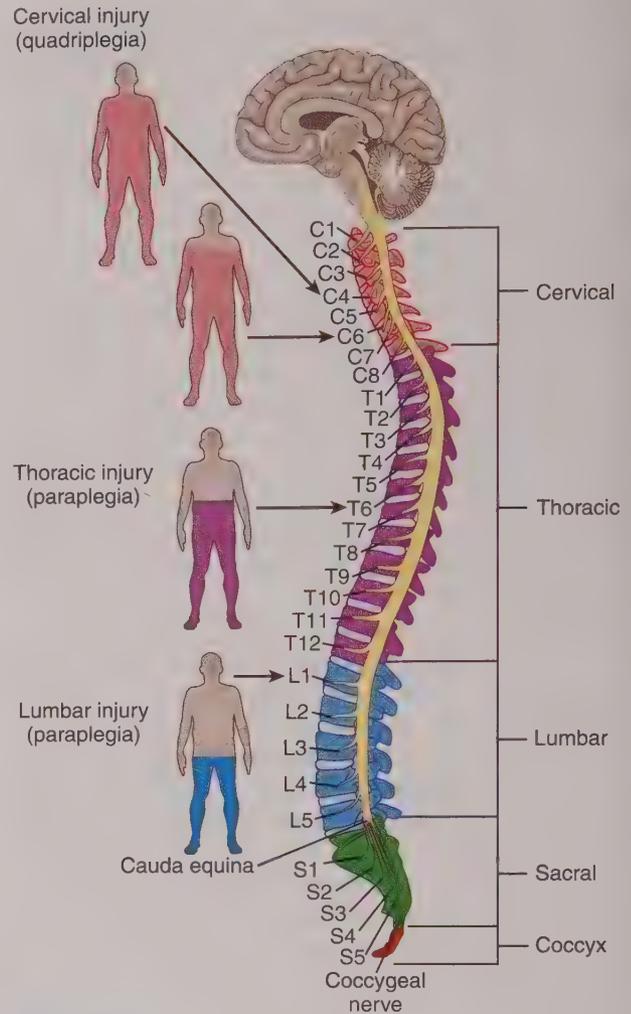

innervates the diaphragm is innervated in this area, and quadriplegia. Thoracic injuries often result in paraplegia and can include poor trunk control. Lumbar and sacral injuries result in decreasing control of legs, bowel and bladder function, and sexual function. See Table 37.6 and Fig. 37.12 for a list of injuries and functional losses. Other effects include chronic pain, low blood pressure, inability to sweat below the level of injury, and decreased temperature control.

**Management**

**Medical Management**

**Diagnosis**

The time between SCI and treatment greatly affects patient outcome. If the patient is admitted with a suspected SCI (associated with trauma to the head or neck), the spine is immobilized (cervical collar, spine backboard) until an examination is performed to identify the level of injury because any significant movement of the spine can result in further damage. A thorough physical and neurological examination, including reflexes, is performed. An x-ray may be performed to look for damage to the vertebrae. If the patient has clinical manifestations of an SCI (inability to move/feel), a CT scan or MRI may be performed to show the location and extent of damage and to reveal problems such as hematomas. The level of injury refers to the vertebra closest to the site of the injury.

**FIGURE 37.12** Spinal cord injury levels.

**Treatment**

Currently, there is no way to reverse spinal cord damage. During the acute stage of injury, treatment focuses on maintaining airway patency, adequate breathing and oxygenation, preventing spinal shock, restoring and maintaining blood pressure, preventing further cord damage, spinal immobilization, and avoiding possible complications. Patients are monitored for vital sign changes that may indicate spinal shock.

Before arrival to the hospital, rapid assessments of vital signs including the patient’s respiratory effort need to be evaluated. A high cervical cord injury (at or above C3, C4, or C5 level) affects the phrenic nerve that innervates the diaphragm, the major muscle of respiration. High cervical injuries result in cessation of breathing as a direct result of loss of diaphragmatic function. Patients with high cervical injuries require immediate ventilatory support.

**Pharmacological and Fluid Management**

The loss of autoregulation and reduced sympathetic stimulation result in cardiac dysrhythmias, hypotension, decreased blood vessel tone, and reduced cardiac output. The most

**Table 37.6 Injury Level and Resultant Functional Loss**

Injury Level	Functional Loss
<b>C1-C4</b>	Quadriplegia with loss of spontaneous respiratory function
<b>C4, C5</b>	Quadriplegia with possible phrenic nerve involvement
<b>C5, C6</b>	Quadriplegia with gross arm movements, phrenic nerve intact
<b>C6, C7</b>	Quadriplegia with biceps intact, diaphragmatic breathing
<b>C7, C8</b>	Quadriplegia with triceps, biceps, and wrist extension intact and some function of intrinsic hand muscles
<b>T1-T5</b>	Paraplegia with trunk and leg involvement, normal arm and hand movement,
<b>T6 - T12</b>	Paraplegia with fair ability to control balance and trunk, little or no voluntary bowel or bladder control
<b>Below L1</b>	Cauda equina injury, variable motor and sensory loss in lower extremities; a reflexive bowel and bladder

profound clinical manifestations are seen in upper thoracic and cervical injuries and in complete SCI. Interruptions to the cardiac accelerator nerves from a cervical SCI can cause the heart to beat dangerously slowly or pound rapidly and irregularly. Medications and even a pacemaker may be required to control the irregular heartbeat.

Loss of vasomotor tone causes blood to pool in vessels and results in low blood pressure. IV fluids, vasopressors, and inotropes are often used to provide adequate fluid resuscitation, increase tone, and increase cardiac output. Several options for volume expansion are commonly used in patients with SCIs. They include crystalloids, colloids, blood products, or a combination of these. Because of fluid shifts after injury, patients with SCIs are at risk for developing pulmonary edema and must be carefully monitored. Vasopressors and inotropes may be indicated in SCIs when the patient remains hypotensive after adequate fluid resuscitation. The vasopressor of choice depends on the patient's hemodynamic profile. Common medications include dopamine hydrochloride (dopamine), norepinephrine bitartrate (Levophed), phenylephrine hydrochloride (Neo-Synephrine), epinephrine, vasopressin (Pitressin), and dobutamine (Table 37.7).

Patients on vasoactive medications must be carefully monitored to prevent complications. High doses of vasopressors and the resultant vasoconstriction can cause decreased perfusion especially in the GI tract, kidneys, and extremities leading to decreased GI motility, impaired renal function, and ineffective peripheral perfusion, respectively.

Current guidelines for the management of acute SCIs no longer recommend the use of corticosteroids for acute SCI. Because there is no strong medical evidence supporting benefits from the administration of corticosteroids, this therapy is avoided because of stronger evidence that the administration of high-dose steroids is associated with harmful side effects, including hyperglycemia and immunosuppression.

## Immobilization and Stabilization

After the patient arrives at the hospital, the fracture/dislocation must be reduced early, and spinal immobilization must be obtained to prevent further loss of function, ischemia, pain, and necrosis. Realignment of the spine with traction, a halo device, or surgery is used to achieve optimal function.

A **halo traction** device is used to maintain cervical immobilization for specific types of cervical fractures (Fig. 37.13). The halo traction is made up of a ring around the patient's head attached to a special vest by four rods. Titanium screws are screwed into the skull bone and attached to the halo traction device; weights connect to the halo at the head of the bed over a pulley system. Weights are slowly added, with x-rays taken between each additional weight, until spinal alignment is achieved.

**Gardner-Wells tongs** are U-shaped tongs used for spinal traction (Fig. 37.14). Pressure-controlled pins are inserted into the skull at opposite ends to permit a longitudinal force to be applied to the axis of the spinal column. The tongs are attached to weights using a pulley system at the head of the bed.

Current management strategies for SCI focus on early surgical intervention if indicated, immobilization, and hemodynamic and respiratory support to prevent secondary injury and optimize recovery.

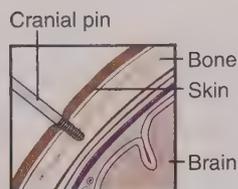

## Connection Check 37.5

Which interventions are indicated to treat the loss of vasomotor tone in the patient with an acute SCI? (Select all that apply.)

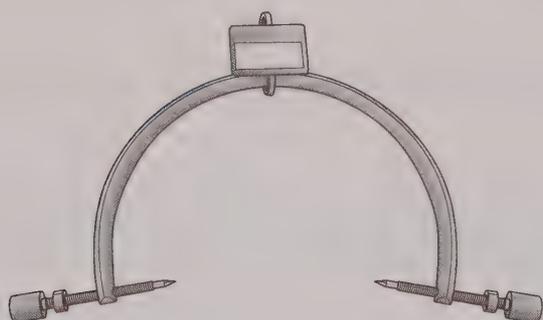

- A. Positive inotropes
- B. Corticosteroids
- C. Antispasmodics
- D. IV fluids
- E. Vasopressors

**Table 37.7 Summary of Common Vasoactive Medications**

Medication	Typical Dose	Receptors	Mechanism of Action
<b>Dopamine</b>	2–10 mcg/kg/min	$\beta_1, \beta_2, D_1$	Vasodilation of renal, mesenteric, and coronary arteries
	5–10 mcg/kg/min	$\alpha_1, \beta_1, \beta_2, D_1$	Increases cardiac contractility, heart rate, and cardiac output; mild vasodilatory effects with preserved dopaminergic activity
	10–20 mcg/kg/min	$\alpha_1, \beta_1, \beta_2, D_1$	Peripheral vasoconstriction; preserved chronotropic and inotropic effects
<b>Epinephrine</b>	2–10 mcg/min	$\alpha_1, \beta_1, \beta_2$	Peripheral vasoconstriction, increased cardiac contractility, smooth muscle relaxation
<b>Norepinephrine</b>	2–30 mcg/min	$\alpha_1, \beta_1$	Vasoconstriction and increased cardiac contractility
<b>Phenylephrine</b>	40–200 mcg/min	$\alpha_1$	Arterial vasoconstriction
<b>Dobutamine</b>	5–15 mcg/kg/min	$\beta_1$ , Mild $\beta_2$	Increased cardiac contractility, mild vasodilation
<b>Vasopressin</b>	0.04 unit/min	V1, V2, V3	Vasoconstriction of vascular smooth muscle

**FIGURE 37.13** Halo traction device.

**FIGURE 37.14** Gardner-Wells tongs.

### Complications

An SCI produces a wide variety of changes in systemic physiology that can lead to a number of complications. These complications are both common and severe and can rival the neurological deficits in their impact on both function and quality of life. Currently, the most common causes of death for patients with SCI are respiratory diseases and cardiovascular events. Depending on the level of injury and the nerves affected, a patient may have multiple potential complications of SCI. The higher the level of injury, the more extensive the disability and the greater the risk of complications.

### Spinal Shock

**Spinal shock** occurs immediately after injury and applies to all phenomena surrounding spinal cord transection. This results in a complete but temporary loss or depression of all or most spinal reflexes as well as sensory, motor, and autonomic activity below the injury level. Depending on the

level of the lesion, hypotension due to sympathetic tone loss is a possible complication. Although the main mechanism of injury that causes spinal shock is usually traumatic in origin and occurs immediately, it can be caused by other mechanisms and progress more slowly. During spinal shock, the brain is unable to transmit signals to muscles and organs, resulting in loss of sensation, movement, and other body functions. Clinical manifestations include flaccid paralysis of all skeletal muscles, absence of deep tendon reflexes, impaired proprioception, decreased visceral and somatic sensations, penile reflex, urinary and fecal retention, **anhidrosis** (absence of sweating), and paralytic ileus. This can last from 24 hours to 1 to 6 weeks, and the return of reflex activity below the level of injury indicates the end of spinal shock.

### Neurogenic Shock

**Neurogenic shock** is a distributive type of shock that occurs in patients with brain, upper thoracic, and cervical injuries and is caused by the sudden loss of the autonomic nervous system signals to the smooth muscle in the vessel walls. This results in loss of vasomotor tone and sympathetic innervation of the heart. The cardiac output decreases because the vessels lose tone, allowing blood to pool in the periphery and blood pressure to fall. In a normal situation, the heart reflexively increases to compensate for the peripheral pooling of blood. In neurogenic shock, the sympathetic pathways to the heart are blocked or damaged, resulting in bradycardia. Clinical manifestations include vasodilation, bradycardia, body temperature instability, and hypotension. Neurogenic shock can be very dangerous and can lead to serious complications such as organ dysfunction and even death if not promptly identified and treated. Treatment often includes fluid, vasopressors, and other medications such as atropine. (See Chapter 14 for a more detailed discussion of neurogenic shock.)

### Autonomic Dysreflexia

**Autonomic dysreflexia** is a syndrome of massive imbalanced reflex sympathetic discharge occurring in 80% of patients with SCI above the T5–T6 level. It most often occurs after the first year of injury but can occur any time after spinal shock subsides. A strong sensory input, such as pain, distended bladder, rapid temperature changes, infection, or a full rectum, is carried into the spinal cord via intact peripheral nerves. This input travels up the spinal cord and evokes a massive sympathetic surge from the intact thoracolumbar sympathetic nerves, resulting in widespread vasoconstriction, causing peripheral arterial hypertension. The brain detects this hypertensive crisis through intact baroreceptors (receptor cells in the bloodstream that relay information about blood pressure to the brain) in the neck and uses two methods to stop its progression. First, the brain attempts to shut down the sympathetic surge by sending descending inhibitory impulses. Unfortunately, these impulses are blocked in the injured spinal cord. Second, the brain attempts to decrease blood pressure by slowing the

heart rate via the vagus nerve (parasympathetic). This bradycardia is inadequate, and the hypertension continues. Clinical manifestations include severe headache, hypertension, bradycardia, tachycardia, diaphoresis, and flushing above and pallor below the injury level. Once the inciting stimulus has been removed, reflex hypertension resolves. The most frequent cause of autonomic dysreflexia is a full bladder, and the second most is a full bowel; other causes include tight clothing, GI disturbances, DVT, pressure injury, bladder or kidney infection, temperature extremes, shoes, lying or sitting on a hard object, or a minor injury.

Nursing care of the patient with autonomic dysreflexia includes observing for a rapid rise in blood pressure, often 20 to 40 mm Hg above the patient's baseline: bradycardia; diaphoresis, flushing of the skin above the level of the lesion, chills, and pallor below the lesion level. The patient often reports a severe headache with one or more of the following clinical manifestations: nasal congestion, anxiety, blurred vision, chest pain, or a sense of impending doom. Table 37.8 identifies nursing interventions and their rationale. If the acute episode of autonomic dysreflexia is not identified and treated, the patient may develop seizures, pulmonary edema, myocardial infarction, cerebral hemorrhage, and death.

#### Halo Brace/Traction Device Complications

Several complications have been identified with the use of halo brace/traction devices to stabilize the head and neck. These include pin infections, skin breakdown, loosening or movement of pins, swallowing problems, and possible dural tears.

Pin site infections occur in approximately 20% of patients with a halo vest. The sites must be frequently assessed for signs of infection and site care provided once a shift and as needed. Pin sites are kept clean using a clean cotton-tipped applicator or gauze soaked with normal saline. A new clean applicator or gauze is used for each pin site. If crusting is noted on assessment, wrap a gauze soaked with normal saline around the pin site for 15 minutes. After removing the gauze, use a clean cotton-tipped applicator to gently remove the crust from the pin site. Ointments and solutions such as hydrogen peroxide should not be used because they can irritate the skin and may cause breakdown at the pin site.

#### Safety Alert

Pin site loosening is one of the most common complications associated with a halo brace. This can lead to cervical instability and infection. Pin site loosening occurs in as many as 60% of patients with a halo brace. Clinical manifestations that may indicate that the pins are loose include redness, swelling, drainage, site pain, or areas where the skin has pulled away from the site. If no infection is present, the healthcare provider may tighten the pins.

If the pins remain loose, the halo ring may migrate, resulting in a loss of immobilization. The patient often complains

of neck pain and that “the vest does not fit correctly/feel the same.” Some patients may notice the ability to move their neck. If this occurs, notify the healthcare provider immediately, place the patient in a hard cervical collar (Collar) for spinal immobilization, and prepare for radiological imaging to assess for a change in spinal alignment. The nurse also needs to perform a thorough neurological examination to determine if the patient has worsening or new deficits. The halo will likely be reapplied using new pin sites.

**Table 37.8 Nursing Interventions for the Treatment of the Patient With Autonomic Dysreflexia**

Intervention	Rationale
Monitor BP closely, at least every 5 minutes	To evaluate treatments and to see if the source of the episode has been found and removed
Administer antihypertensive medications as ordered	To reduce blood pressure if severe or sustained hypertension occurs
HOB at 45 degrees or sit the patient up	Helps reduce blood pressure by allowing blood to pool in lower extremities
Loosen restrictive clothing; remove braces, antiembolism stockings, shoes – look for source of pain from these items	Allows pooling of blood in lower extremities to reduce blood pressure; may be source of episode
Check the bladder; if patient has an indwelling catheter, ensure patency and adequate drainage; if patient does not have an indwelling catheter, perform intermittent catheterization or place indwelling catheter per order; collect sample for UA	This is a possible source of the episode; a urinalysis is sent to assess for a urinary tract or kidney infection.
Check the bowel for impaction	To assess for possible source and remove to terminate episode; a digital rectal examination may be delayed until cardiovascular condition is stabilized because this can exacerbate the hypertension.
Check the patient's body for other sources of noxious stimuli—pressure injuries, wounds, bites, scratches, etc.	To assess for possible source and remove to terminate autonomic dysreflexia episode

BP = Blood pressure; HOB = head of bed.

Pressure injuries that develop under the vest portion of the halo brace often result from improper vest size, poor vest application, or insufficient padding. Meticulous skin care and assessment for early signs of skin irritation are key to reducing/preventing breakdown. Other ways to prevent skin breakdown include turning and repositioning every 2 hours and as needed and making sure the vest fits properly and has sufficient padding.

Swallowing difficulties (dysphagia) may occur when the head and neck are placed in an exaggerated extension position. Notify the healthcare provider if the patient complains of swallowing difficulty. The provider may need to adjust the halo to help resolve the problem, or a speech and language pathologist can be consulted to evaluate dysphagia. Other complications are listed by system in Table 37.9.

### Surgical Management

Patients with no evidence of external pressure on the spinal cord are transferred to the intensive care unit (ICU) in traction. If there is evidence of spinal cord compression, progressive deficits, compound vertebral fractures, penetrating spinal cord wounds, or bony fragments in the spinal canal, early surgery is performed for decompression and fusion to stabilize the spinal column. Otherwise, patients with neurological evidence of spinal

instability are admitted to the ICU for a comprehensive diagnostic work-up, and neurological monitoring. Surgery, if indicated, is performed depending on the nature of the sustained spinal injury.

Several types of surgery are utilized to stabilize SCIs. Types of surgery include decompression laminectomies, using anterior cervical and thoracic approaches, with fusion in which one or more laminae are removed to allow for cord expansion because of edema. Another approach is the posterior laminectomy and fusion with bone graft to immobilize the neck and prevent further damage to the spinal column, and a posterior approach using either a bone graft or the insertion of rods or other instruments to correct and stabilize the deformities.

### Nursing Management

#### Assessment and Analysis

Spinal cord trauma results in motor and sensory loss below the level of injury. Clinical manifestations vary depending on the location and severity of the cord damage and are caused by loss of innervation at the affected spinal cord level(s).

Cervical cord injuries that occur in the neck result in clinical manifestations that affect the arms, legs, and middle of the body, and include:

- Difficulty breathing
- Loss of bowel and bladder control (see Evidence-Based Practice)
- Numbness
- Weakness or paralysis
- Pain
- Sensory changes
- Spasticity

Thoracic cord injuries occur at chest level, and the following clinical manifestations can occur:

- Loss of normal bowel and bladder control (may include constipation, incontinence, and bladder spasms)
- Numbness
- Sensory changes
- Spasticity (increased muscle tone)
- Pain
- Weakness, paralysis

Lumbar sacral injuries occur at the lower back level; varying degrees of clinical manifestations can occur:

- Loss of normal bowel and bladder control
- Numbness
- Pain
- Sensory changes
- Spasticity (increased muscle tone)
- Weakness and paralysis

Injuries to the cervical or high thoracic spinal cord may also result in blood pressure problems, abnormal sweating, and difficulty maintaining normal body temperature.

**Table 37.9 Spinal Cord Injury Complications**

System	Complications
<b>Respiratory</b>	Poor cough, atelectasis, pneumonia, ineffective breathing pattern, ARDS
<b>Cardiovascular</b>	Hypotension, bradycardia, decreased cardiac output, venous pooling, impaired tissue perfusion
<b>Neuro/Musculoskeletal</b>	Loss of sensation/function (paralysis), contractures, spasticity, muscle atrophy
<b>Gastrointestinal</b>	Paralytic ileus, septic or necrotic bowel, gastrointestinal bleed, malnourishment, retention, neurogenic bowel, impaction
<b>Genitourinary</b>	Urinary incontinence, urinary tract infection, neurogenic bladder, chronic kidney disease
<b>Skin</b>	Pressure areas leading to skin breakdown and potential pressure injuries

ARDS = Acute respiratory distress syndrome.

## Evidence-Based Practice

### Catheter-Associated Urinary Tract Infections

Because most patients with spinal cord injuries, multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS) require either short-term or long-term indwelling urinary catheters, it is important that healthcare staff understand the importance of preventing a catheter-associated urinary tract infection (CAUTI). By knowing and adhering to the CAUTI bundle implemented in their facility, nursing staff members play a pivotal role in decreasing the incidence of CAUTI in their patient population.

Catheter-associated urinary tract infection is the most common type of nosocomial infection, accounting for approximately 40% of all healthcare-associated infections. The current estimated cost of CAUTI can range from \$1,200 to more than \$2,700 per incident. Research indicates that many CAUTIs are preventable. A multipronged, or bundled, approach to prevent these infections has reduced the risks of CAUTI. Evidence suggests that the following interventions reduce the rate of CAUTI in patients who require short-term indwelling catheterization:

- Using catheters only when medically necessary
- Daily assessments of the need for catheterization and documenting the continued need
- Use reminder systems targeting early removal of catheters
- If appropriate, use external catheters on males
- Consider intermittent catheterization instead of indwelling catheter insertion with the use of a portable ultrasound bladder scanner to check for residual amounts of urine
- Early removal of all unnecessary urinary catheters

Specific nursing interventions that have also been noted to reduce CAUTIs include daily cleaning of the urethral meatus using a perineal cleanser, maintaining a closed urinary drainage system, use of catheter securement devices to prevent movement and urethral traction, maintaining the drainage bag below the level of the bladder, and changing the indwelling catheter only when necessary, not at a routine interval.

John, S., Thomas, M., Cardona, M., Santarina, S. A., Iacono, L., Scanlon, K., ... Rice, K. L. (2015). Staff nurses eliminated catheter-associated urinary tract infections in a neurosurgical intensive care unit. *Journal of Continuing Education in Nursing*, 46(9), 384–386.

Rebmann, T., & Greene, L. (2010). Preventing catheter-associated urinary tract infections: An executive summary of the Association for Professionals in Infection Control and Epidemiology, Inc, elimination guideline. *American Journal of Infection Control*, 38, 644–646.

### Nursing Diagnoses

- **Alteration in respiratory function** related to paralyzed muscles, hypoventilation secondary to loss of diaphragm function due to denervation of phrenic nerve
- **Decreased cardiac output** related to loss of vasomotor tone secondary to spinal/neurogenic shock
- **Impaired physical mobility** related to neuromuscular impairment secondary to loss of nerve cells at injured level
- **Fear/anxiety** secondary to loss of motor function and potential for permanent impairment

### Nursing Interventions

#### ■ Assessments

- **Respiratory function**  
*Loss of intercostal muscle function results in decreased tidal volume and may lead to hypoventilation; C4 and higher injuries may result in complete loss of diaphragmatic effort.*
- **Vital signs**  
*Depending on the level of injury, because of loss of sympathetic input, the patient may experience spinal shock, neurogenic shock, respiratory or cardiac arrest, or autonomic dysreflexia. Patients are unable to regulate temperature, and hypothermia may result because of loss of control of blood vessels.*
- **Motor function/Sensory level**  
*Locate specific injury level used to choose and evaluate treatment; used to see if deficits increase or decrease over time*
- **Pain**  
*There may be increased pain above the level of injury as a result of damage to the spinal cord or nerve roots.*
- **Intake and output**  
*Fluid volume status is important in evaluating the effectiveness of therapies, particularly with spinal shock. Also, with decreased renal perfusion, there is decreased urine output.*
- **Surgical and/or pin sites**  
*The sites must be frequently assessed for signs of infection, bleeding, or CSF leak.*
- **Bowel sounds**  
*Decreased perfusion to the GI tract can lead to decreased GI motility and paralytic ileus.*

#### ■ Actions

- **Maintain suction equipment at the patient's bedside**  
*With decreased cough effectiveness, the patient may require suctioning to clear the airway.*
- **Facilitate cough effectiveness**  
*Because of muscle weakness or lack of diaphragmatic innervation, assistance is needed to remove secretions.*
- **Maintain spinal immobilization and stabilization**  
*To prevent further injury from an unstable spinal column*
- **Passive ROM**  
*Prevents contractures and loss of muscle tone; strengthens unaffected muscles; minimizes risk of developing deep vein thrombosis (DVT)*

- Reposition and maintain in good alignment  
*Prevents pressure injuries and decreases risk of DVT due to immobility*
- Perform routine pin site care  
*Pin sites are kept clean using a clean cotton-tipped applicator or gauze soaked with normal saline. A new clean applicator or gauze is used for each pin site. If crusting is noted on assessment, wrap a gauze soaked with normal saline around the pin site for 15 minutes. After removing the gauze, use a clean cotton-tipped applicator to gently remove the crust from the pin site.*

### ■ Teaching

- Clinical manifestations of respiratory distress  
*Because patients with high cervical injuries are at risk of ineffective breathing and cough, they need to recognize these manifestations in order to seek timely treatment*
- Clinical manifestations of autonomic dysreflexia  
*It is critical that patients and their families understand the clinical manifestations, as well as causes of this potentially life-threatening emergency*
- Skin care/management  
*To help identify causes of and prevent skin breakdown. In patients who require a wheelchair, they need to be taught to refrain from sitting in one position too long because it can lead to decreased perfusion.*

### Evaluating Care Outcomes

The primary focus is to get the patient through the acute phase of the spinal cord trauma and to prevent complications. This includes airway management, cardiopulmonary support, maximizing spinal cord perfusion and oxygen delivery, pain relief, and preventing further injury or complications. Nursing management also encompasses pulmonary care (suctioning or assisting with cough), turning to prevent pressure injuries, deep vein thrombus prophylaxis, bowel and bladder training, and management of nutrition, limb edema, and orthostatic hypotension. Once the patient is stable, focus shifts to the rehabilitation phase and the optimal recovery of neurological function. Physical therapy is needed to minimize muscle wasting and to prevent contractures. Spinal cord-injured patients require intense inpatient therapy and are often sent to a facility that specializes in spinal trauma. Throughout the hospitalization, providing emotional support is essential for the patient and family. Assisting with the challenging adjustment to the new onset in alterations of daily living is an important focus for the nursing team in the care of this patient population.

must be aware of the possible risk of autonomic dysreflexia occurring if the patient's bowel becomes distended because of constipation or impaction. Healthcare staff require training in the procedure of manual evacuation to prevent this medical emergency from occurring.

### Connection Check 37.6

Which action is the highest priority in the patient who presents with autonomic dysreflexia?

- Prepare for intubation
- Initiate vasopressors
- Remove the stimulus
- Place a temporary pacemaker

## SPINAL CORD TUMORS

### Epidemiology

A spinal cord tumor is an abnormal tissue growth (benign or malignant) in or around the spine. Because the spinal column is rigid, any abnormal growth can place pressure on tissues and impair function. Primary spinal tumors originate within the CNS; secondary tumors originate outside the CNS then metastasize or spread to the spine. Approximately 10% to 15% of all primary CNS tumors are found in the spinal cord. The spinal column is the most common site for bone metastases, with a minimum of 30% and as many as 70% of cancer patients having spinal metastasis.

### Pathophysiology

The spinal cord consists of nerve bundles that descend from and ascend to the brain carrying electrical impulses that facilitate movement and sensation. A spinal tumor is an abnormal growth of tissue within or surrounding the spine. As this abnormal tissue grows, it causes compression and stretching of the fiber tracts. This results in further neurological deterioration because of the loss of motor and sensory function. Although some spinal tumors can be attributed to exposure to cancer-causing agents, the cause of most tumors remains unknown. This growth can be benign or malignant, primary or secondary.

Spinal tumors are classified in several ways including the area of the spine in which they occur (cervical, thoracic, lumbar), their location in the spine: anterior (front) or posterior (back), and their relationship to the dura (outermost membranous layer surrounding the brain and spinal cord). The types of tumors are based on their relationship to the dura, with extradural located outside the dura, intradural located within the dura, extramedullary located inside the dura but outside the cord, and intramedullary located within the cord. Primary tumors include both malignant and benign tumors (Table 37.10). Secondary spinal tumors

#### Safety Alert

Some patients with an established spinal cord lesion depend on manual bowel evacuation (the digital removal of feces) as their routine method of bowel care because they have lost normal bowel function. Manual evacuation is rarely undertaken in the acute setting and may be unfamiliar to nurses. All nursing staff

**Table 37.10 Table of Primary Central Nervous System Tumors**

Type	Origin	Status
<i>Astrocytoma</i>	Cells of tissue that support nerve cells	Most are benign or low-grade malignant tumors.
<i>Ependymoma</i>	Cells lining the center of the spinal cord	Most are benign.
<i>Meningioma</i>	Tissue cells covering the spinal cord (meninges)	Most are benign but can recur and can become malignant based on location and damage to vital structures.
<i>Neurofibroma</i>	Peripheral nerve cells (arise from Schwann cells)	Usually are benign
<i>Sarcoma</i>	Connective tissue cells	Malignant tumors
<i>Schwannoma</i>	Cells that form myelin sheath around peripheral nerve fibers	Benign tumors

are metastases and therefore always malignant. These metastases most often spread from lung, breast, prostate, renal, gland, or thyroid cancer. To prevent permanent spinal cord damage, spinal cord compression must be diagnosed and treated immediately.

### Clinical Manifestations

The clinical presentation of a spinal tumor has manifestations similar to low-back pain (LBP) and herniated nucleus pulposus, as well as multiple sclerosis. On the basis of the location of the tumor, the patient may present with back pain that may radiate down the arms or legs. Additional clinical manifestations based on location include numbness and tingling, weakness in the distal extremities, urinary incontinence, and bowel pattern changes. With tumors in the cervical area, the patient may notice loss of manual dexterity and clumsiness.

### Management

#### Diagnosis

To make a correct diagnosis, the healthcare provider completes a thorough history and physical examination, focusing on back pain and any noted motor or sensory deficits. If the patient has a known primary tumor and develops back pain with deficits such as weakness or tingling, the provider will have a high suspicion of a metastatic process and order radiological testing such as CT or MRI. If the patient does not have a history of tumor, the healthcare provider must rule out other conditions that affect spinal cord function, including bone bruises, muscle spasms, fractured vertebrae, or compression by blood clot, herniated disk, or abscess. Diagnostic studies that may be ordered to diagnose a tumor may include a MRI, considered to be the gold standard for examining spinal structures, or myelography with CT if MRI is unavailable. If a primary mass is detected, the patient needs a biopsy to diagnose the type of tumor and a CT of the chest and abdomen (for staging purposes).

#### Medical and Surgical Management

Although the ideal goal of therapy is to completely remove the tumor, this is complicated by the type and location of the tumor. Removing some tumors may result in permanent nerve damage. Treatment options include:

- **Monitoring:** often used for small, benign tumors that are not growing or pressing on surrounding tissues; periodic scans are needed to monitor the tumor
- **Surgery:** usually the first step in treating tumors that can be removed with an acceptable risk of nerve damage; often an option used with benign tumors
- **Radiation therapy:** used following an operation to eliminate the tumor remnants or to treat inoperable tumors; often first-line therapy for metastatic tumors
- **Stereotactic radiosurgery:** delivers a high dose of targeted radiation; effective in brain tumors and currently being studied for spinal cord tumors
- **Chemotherapy:** has not been proven effective for most spinal cord tumors due to issues penetrating the blood brain barrier
- **Corticosteroids:** to reduce swelling following surgery or during radiation treatments

#### Complications

Both benign and malignant spinal tumors can compress spinal nerves and cause loss of movement or sensation below the tumor level, spinal instability, changes in bowel and bladder function, and sexual dysfunction. Unless the cause is quickly identified and removed, permanent nerve damage can occur. If the patient requires surgery, other complications include:

- Bleeding or hematoma
- CSF leak
- Meningitis
- Chronic pain
- Injury to CNS tissue
- Spine instability
- Sensory loss

- Sexual dysfunction
- Paralysis
- Infection
- Ventilator dependence
- Wound dehiscence

Nerve damage from spinal cord tumor compression is often permanent, with disabilities continuing after the tumor is removed.

### Nursing Management

#### Assessment and Analysis

Pain in the middle or lower back is the most common symptom of both benign and malignant spinal tumors. Other clinical manifestations are related to the area of the spine involved and may include:

- Back pain radiating to other parts of the body
- Loss of sensation or muscle weakness, often in the legs
- Difficulty walking
- Decreased sensitivity to pain, heat, or cold
- Loss of bladder or bowel function
- Paralysis
- Scoliosis or other spinal deformity

#### Nursing Diagnoses

- **Impaired physical mobility** related to neuromuscular impairment
- **Acute pain** related to nerve impingement
- **Ineffective coping** related to diagnosis

#### Nursing Interventions

##### ■ Assessments

- Neurological status  
*Locate level of function – sensory and motor to determine necessary interventions as well as to evaluate for signs of deterioration as well as for signs of improvement with treatments.*
- Pain  
*Patient's pain perception is used to determine an effective pain management plan; may have increased pain above the level of the tumor.*
- Bowel or bladder function  
*Tumors that compress the spinal cord are associated with dysfunction of bladder and bowel function. The patient may present with incontinence, urinary retention, or constipation.*
- Coping skills  
*Identify current coping skills that work and the patient's support system.*

##### ■ Actions

- Administer medications  
*Pain medications to decrease pain, corticosteroid therapy to decrease swelling and inflammation, and medications as ordered for patient comfort*
- Increase intake of fluid and fiber in diet  
*Fluids and fiber decrease complications associated with bowel constipation that may develop secondary to decreased mobility, pain, and opioid medications.*

- ROM exercises  
*Prevent contractures and loss of muscle tone; strengthen unaffected muscles*
- Reposition every 2 hours and as needed  
*To prevent skin impairment and pressure injuries and maintain comfort*

#### Teaching

- Preoperative teaching if scheduled for surgery  
*To decrease anxiety level and help promote compliance*
- Report clinical manifestations of increased weakness, loss of bowel/bladder function  
*May be due to recurrent tumor or spinal cord edema*

#### Evaluating Care Outcomes

The prognosis and outcome depend on the type and location of the tumor and the treatment required. If the tumor is not identified and quickly removed, permanent damage results from the compression on the spinal cord. Risks to the patient can include neurological deficits with clinical manifestations related to the location of the compression site. Some tumors can be safely and completely removed, resulting in full recovery. Often, postoperative radiation therapy follows the removal of tumors. If the tumor is inoperable, radiation therapy is often done as a palliative care measure to control the patient's pain.

### Connection Check 37.7

Which intervention is typically the initial treatment of a metastatic spinal cord tumor?

- Radiation therapy
- Local chemotherapy into the cord
- Surgical decompression
- Corticosteroids

## Making Connections

### CASE STUDY: WRAP-UP

Six months later, Cynthia again reports left leg numbness and weakness and a new symptom of arm weakness and numbness. A second MRI of the head and spine is completed, revealing new areas of demyelination. Cynthia is formally diagnosed with multiple sclerosis. After a long discussion with her healthcare provider, she agrees to begin Betaseron therapy in hopes of reducing exacerbations and slowing progression of the disease. Cynthia decides to start Avonex intramuscular injections once a week. She is also given a prednisone course to treat her exacerbation, and her clinical manifestations improve within 2 weeks.

Cynthia returns to physical therapy to develop an exercise plan to strengthen her muscles and improve daily function. She may also require medications to treat common complications associated with MS. These include medications to help reduce fatigue, depression, and pain and to help control bowel and bladder problems. Cynthia is given information regarding lifestyle changes to her diet and the importance of continuing her exercises and getting plenty of rest. It is vitally important that she take good care of herself to help try to reduce disease progression and exacerbation. Cynthia is also given the numbers and Web sites of both local and national associations that can provide additional support and information.

### Case Study Questions

- The nurse needs to monitor Cynthia for which complication of MS?
  - Intolerance to cold
  - Myopia
  - Muscle spasms
  - Tinnitus
- Which statement by Cynthia indicates that teaching about Avonex has been effective?
  - "I am so glad I only have to do this once a week."
  - "I hope that my husband can help since it is three times a week."
  - "I am glad this medication does not cause the flulike symptoms like Betaseron can."
  - "There is no increased risk for infections."
- What exercise modifications need to be included in Cynthia's plan of care?
  - Increasing weights and repetitions three times a week
  - Exercising in a warm environment to relax muscles
  - Low- to moderate-intensity endurance training
  - High-intensity resistance training
- The nurse monitors for which clinical manifestations of Cynthia's MS? (*Select all that apply.*)
  - Blurred vision
  - Speech problems
  - Muscle weakness
  - Bradycardia
  - Fasciculations
- Based on her current clinical presentation, the nurse incorporates which problem into Cynthia's plan of care?
  - Bowel dysfunction
  - Impaired mobility
  - Urinary retention
  - Visual deficit

## CHAPTER SUMMARY

At least 60% to 80% of the population will have an episode of low-back pain at least once in their lifetime. Low-back pain often occurs in individuals between 30 and 50 years old with an annual cost of \$50 billion per year on treatment alone. Low-back pain/problems often follow injury or trauma. Spinal degeneration is often associated with aging and involves the loss of spinal structure and function. Decreased water content of the disk nucleus results in wear and tear on the annulus and joints. Sudden movement or bending may cause muscle spasm. Patients do not always experience severe back pain with a pulled muscle or bulging disk. A new exercise program with sudden movements could have strained a muscle or caused inflammation in a small area of the spine.

Herniated disks are most common between ages 30 and 45, with males more commonly affected in lumbar disk herniation by a 3:2 ratio. While the disk becomes more inflexible, the possibility of HNP into the spinal canal increases. The resulting nerve compression is responsible for the loss of function, with the type of nerve compressed (motor or sensory) determining the symptom (pain or numbness).

Clinical manifestations of herniated nucleus pulposus vary depending on the location of the herniated disk; often, pain occurs on one side of the body and may vary from a dull ache to sharp, shooting pain. Common clinical findings are no clinical manifestations to, arm or leg pain, numbness or tingling, muscle weakness, and neck or back pain that shoots down one arm or leg. Most patients with a herniated disk have improvement with 1 to 2 months of conservative treatment. This consists of avoiding painful positions and following a regimen of planned exercise and pain medications. Other patients require surgical intervention before they have any improvement of their clinical manifestations, and there are several surgical options used in the treatment of a herniated disk. A laminotomy, surgery in which a large hole is made in the lamina, or a laminectomy, surgical removal of most of the lamina, are often used in conjunction with a discectomy to remove pressure on the spinal cord or nerve roots. Use of an artificial disk is a developing alternative to the discectomy. In this new option, the diseased disk is replaced with a manufactured disk; this provides pain relief while allowing the spine's anatomical structure to remain intact.

Currently, the microdiscectomy is the standard procedure used to treat a herniated disk. In this procedure, a small portion of the bone over or the disk material under the nerve root is removed to relieve pressure and to provide room for the nerve to heal. This is done through a small incision, allowing the spinal structure supports to remain intact. Spinal fusion is surgery that joins two bones (vertebrae) together. Because fusing permanently joins the bones together, there is no longer movement between them. Spinal fusion is usually performed along with other procedures such as a laminectomy and discectomy to provide spinal stability. In a spinal fusion, a bone graft, often from

the patient's pelvis, or metal hardware is used to join the vertebrae together.

Multiple sclerosis (MS) is a chronic, degenerative neurological disorder in which the nerves of the central nervous system (CNS) degenerate. There is no cure for MS. Approximately 400,000 people in the United States have MS, with a typical onset between 20 and 50 years of age. Multiple sclerosis is classified as an autoimmune disease. In these diseases, the immune system mistakenly attacks the nerves of the brain and spinal cord, resulting in destruction of the myelin sheath. The myelin sheath covers the spinal cord and nerves, serving as protection and helping relay nerve impulses at a faster rate.

This demyelinating process culminates in impaired movement, sensation, and thinking. Multiple sclerosis is difficult to diagnose because symptoms can be intermittent and can vary depending on the location of the affected nerves. Treatment often focuses on improving the speed of recovery from attacks, reducing the number of attacks, and slowing the progression of the disease. Lifestyle management includes getting plenty of rest and exercise; staying cool; eating a healthy, balanced diet; and relieving stress. Because MS affects varying nerves throughout the body, clinical manifestations change with each attack, and these symptoms are the direct result of the demyelination process. Often, patients have an "attack" with a partial recovery of the clinical manifestations. Common findings include numbness/weakness, complete or partial loss of vision, double or blurred vision, fatigue, dizziness, tremor, lack of coordination/balance, speech problems, and memory loss.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a rapidly progressing, fatal CNS disease that affects voluntary muscle control, and results in gradual degeneration and death of motor neurons. Resulting in muscle weakness and atrophy, ALS does not impair senses or ability to think. In ALS, both upper and lower neurons degenerate and die, leading to gradual muscle weakening, atrophy, and fasciculations. The progressive degeneration leads to death of the cells, destroying the brain's ability to initiate and control muscle movement. Eventually, all voluntary muscles are affected, and patients are paralyzed, resulting in ventilator dependence.

The incidence of spinal cord injury (SCI) in the United States is approximately 12,000 per year, most commonly affecting men aged 16 to 18. Spinal cord trauma may result from either direct injury to the cord or indirectly from damage to surrounding bones, tissues, and blood vessels. Spinal cord trauma is damage to the spinal cord with resulting functional loss such as mobility or feeling. The spinal cord does not have to be severed for loss of function to occur, and in fact, most injuries cause fractures or compressions of the spinal cord that result in damage to the axons. The number of axons damaged can be few to many, allowing some injuries to recover almost completely and others to result in paralysis.

The initial trauma of crushing or tearing of axons sets off a biochemical cascade that kills neurons, demyelinates

axons, and triggers an inflammatory response that can result in damage to segments above or below the initial injury level. Blood flow changes in and around the injured area of the cord begin to spread out and cause problems throughout the body. Spinal cord injuries are divided into two types, complete and incomplete. A complete injury results in a total loss of motor and sensory function below the level of injury. In an incomplete injury, there is incomplete structural damage with some function preserved below the primary injury level. Four types of incomplete injury have been identified: central cord syndrome, anterior cord syndrome, posterior cord syndrome, and Brown-Séquard syndrome. The level of injury helps predict what part of the body might be affected. Cervical injuries can result in inability to breathe and quadriplegia. Thoracic injuries often result in paraplegia and can include poor trunk control. Lumbar and sacral injuries result in decreasing control of legs, bowel and bladder function, and sexual function.

Autonomic dysreflexia, an overactivity of the autonomic nervous system (ANS), occurs in patients after SCI at T5 and above. Autonomic dysreflexia can develop suddenly and, if not promptly treated, can lead to seizures, stroke, and even death. It occurs when an irritating stimulus, e.g., full bladder, is introduced below the level of the SCI. The stimulus sends nerve impulses to the spinal cord, where they travel upward until they are blocked at the level of injury. Because the impulses cannot reach the brain, a reflex is activated that increases sympathetic activity, increasing blood pressure. Nerve receptors in the heart and blood vessels detect the increased blood pressure and send a message to the brain. The brain sends a message to the heart, causing the heartbeat to slow down and the blood vessels above the injury level to dilate. However, the brain cannot send messages below the level of injury and therefore fails to control the blood pressure.

Patients may develop two different shock syndromes after SCI, spinal or neurogenic. Spinal shock occurs immediately after injury and applies to all phenomena surrounding spinal cord transection. This results in a temporary loss or depression of all or most spinal reflex activity below the injury level. Depending on the level of the lesion, hypotension resulting from sympathetic tone loss is a possible complication. Neurogenic shock occurs in patients with upper thoracic and cervical injuries and is caused by the sudden loss of the ANS signals to the smooth muscle in the vessel walls. This results in loss of vasomotor tone and sympathetic innervation of the heart. Clinical manifestations include vasodilation, bradycardia, and hypotension.

A spinal cord tumor is an abnormal tissue growth (benign or malignant) in or around the spine. Because the spinal column is rigid, any abnormal growth can place pressure on tissues and impair function. Approximately 10% to 15% of all primary CNS tumors are found in the spinal cord, and the tumors can be benign or malignant, primary or secondary. Spinal tumors are classified in several ways, including the area of the spine in which they occur (cervical, thoracic, lumbar), their location in the spine: anterior (front) or

posterior (back), and their relationship to the dura (outermost layer surrounding the brain and spinal cord).

To prevent damage, spinal cord compression must be diagnosed and treated immediately. A thorough evaluation by the healthcare provider includes a history and physical examination focusing on back pain and any noted deficits. If a patient has a known primary tumor and develops back pain with deficits such as weakness or tingling, the provider should have a high suspicion of a metastatic process. However, if the patient does not have a history of tumor, the healthcare provider must rule out other conditions that affect spinal cord function. The gold standard for examining

spinal structures is MRI. Although the ideal goal of therapy is to completely remove the tumor, this is complicated by the type and location of the tumor, because removing some tumors may result in permanent nerve damage.

Because both benign and malignant spinal tumors can compress spinal nerves, and loss of movement or sensation below the tumor level, spinal instability, changes in bowel and bladder function, and sexual dysfunction may result. Unless the cause is quickly identified and removed, permanent nerve damage can occur, and nerve damage from spinal cord tumor compression is often permanent, with disabilities continuing after the tumor has been removed.

# Chapter 38

## Coordinating Care for Patients With Peripheral Nervous System Disorders

*Barbara Fitzsimmons*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of peripheral nervous system disorders
2. Explaining the pathophysiological processes of peripheral nervous system disorders
3. Correlating clinical manifestations to pathophysiological processes of
  - a. Myasthenia gravis (MG)
  - b. Guillain-Barré syndrome (GBS)
  - c. Trigeminal neuralgia
4. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the peripheral nervous system
5. Discussing the medical management of selected disorders of the peripheral nervous system
6. Developing a comprehensive plan of nursing care for patients with peripheral nervous system disorders
7. Developing a teaching plan for a patient with a peripheral nervous system disorder

### CONCEPTS

- Assessment
- Comfort
- Medication
- Neurological Regulation
- Perioperative

### ESSENTIAL TERMS

Acetylcholine (ACh)  
Acetylcholinesterase (AChE)  
Apheresis procedure  
Autoimmune  
Bulbar symptoms  
Cholinergic crisis  
Demyelination  
Diplopia  
Dysarthria  
Dysphagia  
Edrophonium  
Fasciculations  
Myasthenia gravis  
Myasthenic crisis  
Neuromuscular junction  
Nicotinic receptors  
Plasmapheresis  
Polyneuropathy  
Ptosis  
Saltatory conduction  
Schwann cell  
Single-fiber electromyography  
Tensilon

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Stephanie Jordan is a 45-year-old married female with a 15-year history of myasthenia gravis (MG). She is a math teacher at a private middle school. Over the last week, she developed an upper respiratory infection with a fever of 101.1°F (38.39°C). During this time, she also developed increasing muscular weakness of her legs. Because of her weakness, she has stayed home from work for the past 2 days. This evening during dinner, she experienced marked difficulty with chewing and swallowing. The development of these problems prompted her husband to drive her to the emergency department of the local hospital for an evaluation. Her current medications include pyridostigmine 60 mg every 4 hours while awake, pyridostigmine time-release 180 mg at bedtime, and prednisone 20 mg daily. Following an evaluation in the emergency department, Ms. Jordan is admitted to a neuroscience inpatient unit, where she begins a course of antibiotics for her upper respiratory infection. The provider's plan is also to adjust Ms. Jordan's medications. Her pyridostigmine dose is increased to 90 mg every 4 hours around the clock, and the prednisone is increased to 40 mg daily...

## INTRODUCTION

Nurses encounter patients with diseases of the peripheral nervous system (PNS) in a variety of settings. Diseases of the PNS vary in severity from mild to potentially life threatening when patients develop respiratory involvement. These patients may present to the emergency department, general medical-surgical setting, outpatient setting, obstetrics/gynecology department, or neuroscience areas with a new onset of clinical manifestations. Because of the nature of the disorders, nurses need to have an understanding of the pathophysiology of the disorder and treatment so that appropriate care can be planned. Nurses must also be cognizant of the neurological disorder even if the patient is not being admitted for management of the neurological problem because of the potential deterioration of these patients when under stress. This chapter addresses the management of patients with myasthenia gravis (MG), Guillain-Barré syndrome (GBS), and trigeminal neuralgia.

## PERIPHERAL NERVOUS SYSTEM

In order to understand the disorders of the PNS, it is important for the nurse to have an understanding of the structures comprising this system. As a review of anatomy,

the nervous system is made of two divisions: the central nervous system, or CNS, and the PNS. The CNS includes the brain and spinal cord. In the CNS, oligodendrocytes make the myelin that covers nerve fibers. The PNS is divided into both sensory and motor divisions. The sensory division includes sensory neurons that are responsible for innervating the skin, muscles, joints, and viscera. The motor division includes the motor neurons that control skeletal muscles and the autonomic nervous system (ANS) that innervates smooth and cardiac muscles and glands. The PNS is composed of nerves outside the cranium and vertebral column that include cranial and spinal nerves; **neuromuscular junctions**, which are the synapses between the somatic motor neuron's axon and the muscle; muscles; and the ANS. In the PNS, the **Schwann cells** make the myelin that wraps around the nerves.

## Autonomic Nervous System

The ANS is the part of the nervous system that regulates involuntary body functions. The sympathetic division of the ANS is often called the “fight-or-flight system” because it prepares the body to fight or flee from danger. Input is received from the thoracic and lumbar regions of the spinal cord. The sympathetic part of the ANS elevates the heart rate (HR) and blood pressure (BP), increases the respiratory rate (RR), dilates the pupils, shunts blood to the skeletal muscles and skin, and slows digestion. The activity of the sympathetic nervous system mimics the body's response of fleeing a bear in the woods during a walk after a picnic.

## Parasympathetic Nervous System

The parasympathetic division is often referred to as the “rest and digest” portion of the nervous system. It is responsible for slowing the HR, lowering the BP, decreasing respirations, shunting blood from the periphery of the body to the internal organs, constricting the pupils, and digesting food. The activity of the parasympathetic nervous system mimics the body's response while resting on the beach on a warm and sunny day after a picnic.

**Acetylcholine (ACh)** is the neurotransmitter synthesized by parasympathetic neurons. When an action potential is conducted down the axon of the preganglionic autonomic neuron, ACh is the substance released into the synapse between the axon terminal and the membrane of the postganglionic neurons. It crosses the synapse to bind to **nicotinic receptors** (a type of receptor that responds to ACh) of the membrane of the postganglionic neurons, depolarizing that membrane and possibly causing the postganglionic neurons to develop an action potential. An action potential is conducted down the axon of postganglionic parasympathetic neurons as the result of a depolarizing force received from the preganglionic neurons. This causes ACh to be released from the axon terminal into the synapse. Acetylcholine diffuses across the synapse and binds to muscarinic ACh receptors on the parasympathetic end organ. The activity of ACh is terminated by an enzyme called

**acetylcholinesterase (AChE)**, the enzyme that breaks down acetylcholine at the neuromuscular junction.

### Motor System

The motor division of the PNS involves areas of the brain; descending fiber tracts; and motor neurons involved in producing or altering the movement of skeletal, cardiac, and smooth muscles and in regulating the secretions of various exocrine and certain endocrine glands. On the basis of the motor neurons and effector organs, the motor division can be divided into the somatic and autonomic parts.

The somatic nervous system sends cholinergic motor axons from the spinal cord or brain to the skeletal muscles. Motor fibers from the brain stimulate somatic motor neurons. The axons of these motor neurons travel within the spinal nerves and terminate at the neuromuscular junction. This is the synapse between the somatic motor neuron's axon and the muscle. When a motor neuron depolarizes, ACh is released from axon terminals into the synapse at the neuromuscular junction and binds to nicotinic receptors on skeletal muscles. This causes depolarization, resulting in contraction. Similar to the autonomic fibers described previously, the activity of ACh in the neuromuscular junction is also terminated by the enzyme AChE (Fig. 38.1).

## MYASTHENIA GRAVIS

**Myasthenia gravis**, an acquired **autoimmune** neuromuscular junction disorder that results in the body's immune system attacking healthy cells, is caused by antibodies that are directed toward skeletal muscle nicotinic ACh receptors and muscle-specific kinase (MuSK). The name of the disorder is derived from the Greek term *myasthenia*, referring to muscle weakness, and the Latin term *gravis*, meaning "grave"; hence, MG refers to grave muscle weakness. This chronic neurological disorder is characterized by skeletal muscle weakness that may fluctuate across the day. Patients are typically diagnosed and managed in the outpatient setting. However, periodic inpatient admissions may be required for medication adjustments or when patients experience increased weakness from an infection.

## Epidemiology

Myasthenia gravis is a motor disorder characterized by fluctuating, localized skeletal muscle weakness and fatigue. It is an acquired autoimmune disease in which antibodies bind to the ACh receptors on the muscle membrane. It may be made worse by or induced by penicillamine (Cuprimine), used in the treatment of rheumatoid arthritis, but in most cases, MG is idiopathic. The course of the disease may vary from mild, with ocular symptoms of **ptosis** (drooping eyelids) and **diplopia** (double vision), to severe cases with generalized weakness and respiratory involvement.

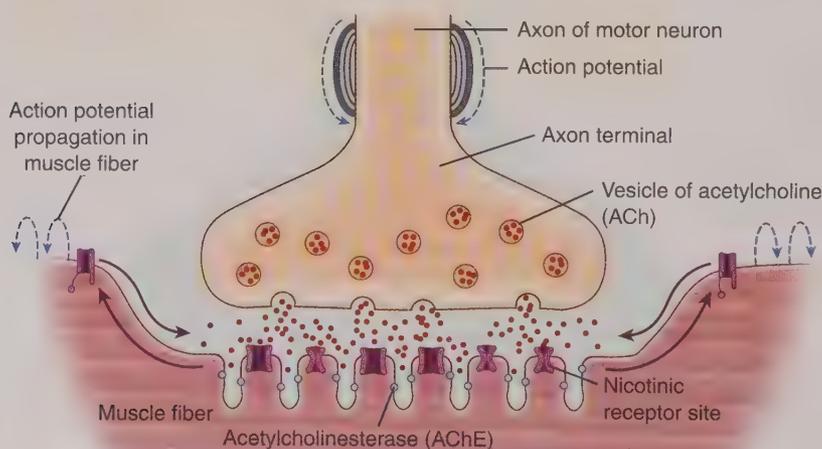

The prevalence of MG in the United States is 14 to 20 per 100,000 population, for a total of 60,000 cases. Although MG previously was more common in women, it is now more common in men. The average age of onset in women is 20 to 30 years, whereas in men, the onset is 60 to 80 years. For these reasons, it is a disorder affecting younger women and older men. Most patients with MG are over age 50. There are no known risk factors associated with developing the disease.

## Pathophysiology

In normal nerve transmission, ACh is produced and secreted in the terminal ends of the motor nerves. Acetylcholine crosses the synaptic clefts and attaches to ACh receptors (AChRs) embedded in the folds of the postsynaptic membrane. This ACh–AChR binding results in depolarization of the end plate. Muscle membrane depolarization quickly occurs, resulting in skeletal muscle contraction.

In MG, circulating anti-AChR antibodies bind with the AChR, resulting in complement-mediated destruction of receptor sites. Postsynaptic membranes lose their folds, and ACh binding is blocked. Sensitivity to normal amounts of ACh is diminished with a reduction of initiating depolarization and therefore muscle contraction. This results in skeletal muscle weakness and fatigability. It is important to realize that in MG, there is an adequate amount of ACh released, but postsynaptic receptor sites are not available.

Myasthenia gravis presents as one of three serotypes: anti-AChR, MuSK, or seronegative MG (SNMG). The

**FIGURE 38.1** Action of acetylcholine (ACh) and acetylcholinesterase (AChE) at the neuromuscular junction. When a motor neuron depolarizes, ACh is released from axon terminals into the synapse at the neuromuscular junction and binds to nicotinic receptors on skeletal muscles. This causes depolarization, resulting in contraction. The activity of ACh in the neuromuscular junction is also terminated by the enzyme AChE.

anti-AChR antibody is found in approximately 80% of patients with MG, whereas 10% are MuSK type, and the remaining 10% have no identified circulating antibodies, which is referred to as SNMG.

The thymus gland is an organ of the immune system that produces T cells or T lymphocytes. Seventy percent of patients with MG have thymic hyperplasia (enlarged thymus), whereas 10% have thymoma (tumor of the thymus gland). Although the relationship between MG and thymoma is not clear, it is believed that the thymus gland may give flawed instructions to developing immune cells, eventually resulting in the development of AChR antibodies. This tumor of the thymus gland tends to be benign and enclosed. Patients with thymoma typically have higher levels of antibodies and a more severe disease course. Thymectomy, a surgical procedure for MG patients, is discussed later in this chapter.

### Clinical Manifestations

Myasthenia gravis is categorized into ocular, bulbar, or generalized presentations, and patients with MG often seek medical care for muscular weakness and fatigue. Two-thirds of patients with MG present with ocular symptoms, namely, ptosis and diplopia. Many MG patients experience these symptoms within 2 years of disease onset. Ptosis may be unilateral or bilateral. Diplopia is a result of extraocular muscle weakness, and ocular symptoms may worsen with activities that require sustained use of the eye muscles.

**Bulbar symptoms** are the first to appear in about 16% of MG patients and refer to clinical manifestations involving cranial nerves (CNs; CN IX, CN X, CN XI, and CN XII) that emerge from the medulla of the brainstem (Fig. 38.2 and Table 38.1). The medulla is shaped like a bulb (i.e., tulip bulb), and this is the link to the term *bulbar*. These clinical manifestations include difficulty with phonation, chewing, and swallowing.

Trunk weakness and limb weakness are the initial clinical manifestations in roughly 16% to 20% of MG patients, and typically the patient experiences greater weakness of

proximal muscles than distal muscles. Although MG can affect any muscles, the muscles of the neck, deltoids, triceps, wrists, fingers, and ankles are commonly affected. Weakness varies across the day but generally worsens late in the day, and clinical manifestations worsen with sustained muscle use. Patients may complain of difficulty with completing activities of daily living, such as bathing and dressing.

### Connection Check 38.1

The nurse recognizes which explanation as the pathophysiological basis for MG?

- There is an inadequate number of muscarinic receptors.
- Antibodies to AChRs block neuromuscular junction transmission.
- Thymomas are present in 80% of patients with MG.
- There is an abundance of ACh, which binds to viable receptors.

### Management

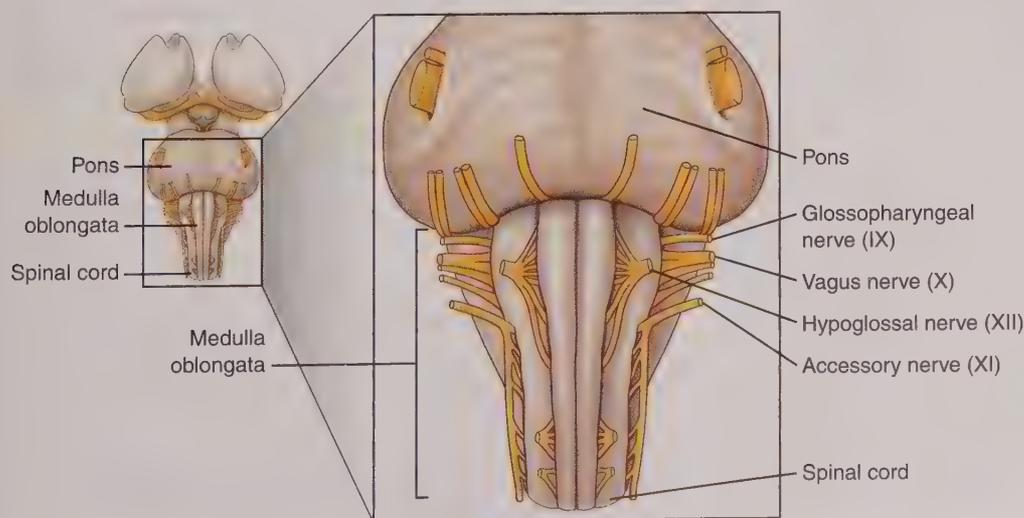

#### Medical Management

#### Diagnosis

The diagnosis of MG is based on clinical assessment as well as analysis of diagnostic tests. Serological tests, electromyography, and the edrophonium (Tensilon) test all aid in establishing a diagnosis of MG.

#### Serological Testing

An assay for AChR antibodies is essential for making a diagnosis of MG. The AChR-binding antibodies are found in roughly 80% of patients with generalized MG but only 55% of patients with ocular MG. The AChR-binding antibody assay is very specific, and positive antibody studies verify MG in the presence of a clinical picture that is consistent with MG. The AChR antibodies compete for the neurotransmitter's ACh binding sites. Additionally, antibodies to

**FIGURE 38.2** Brainstem with lower cranial nerves (CNs). Cranial nerve IX, CN X, CN XI, and CN XII emerge from the medulla of the brainstem.

**Table 38.1** Cranial Nerve Involvement in Myasthenia Gravis

Cranial Nerve	Function
<b>IX (glossopharyngeal)</b>	<ul style="list-style-type: none"> <li>● Motor fibers control tongue movement, swallowing, and gagging.</li> <li>● Sensory function controls taste, touch, and temperature from the tongue; also has a role in blood pressure control.</li> </ul>
<b>X (vagus)</b>	<ul style="list-style-type: none"> <li>● Innervates organs in the head, neck, and thoracic and abdominal cavities</li> <li>● Key role in function</li> </ul>
<b>XI (spinal accessory)</b>	<ul style="list-style-type: none"> <li>● Controls movement of the head, neck, and shoulders</li> </ul>
<b>XII (hypoglossal)</b>	<ul style="list-style-type: none"> <li>● Controls tongue movement</li> </ul>

MuSK are found in about one-third of patients with generalized MG. Patients with MuSK are generally females with prominent bulbar clinical manifestations, shoulder girdle weakness, and respiratory weakness.

#### Repetitive Nerve Stimulation and Electromyography

Repetitive nerve stimulation is a diagnostic tool used to evaluate neuromuscular transmission and measures muscle action potential after repeated nerve stimulations. With nerve stimulation, immediate stores of ACh at the neuromuscular junction are depleted. This results in a failure to generate an action potential. In MG, there is decreased muscle response with repetitive stimulation.

**Single-fiber electromyography** is the most sensitive diagnostic tool for detecting an abnormality in neuromuscular transmission. This test requires needles to be placed in the muscle to measure electrical activity. The recording from normal muscles shows two evoked responses from two muscle fibers firing, with minimal fluctuation of the interval between the two. The fluctuation is called “jitter” and is due to the variable time required for neuromuscular transmission from discharge to discharge. In MG, there is increased “jitter.”

#### Tensilon (Edrophonium) Test

Another diagnostic test that is performed by a provider is called the edrophonium or **Tensilon** test. Up to 10 mg of **edrophonium**, a short-acting anticholinesterase medication, is administered via IV push. Edrophonium temporarily improves neuromuscular transmission by inhibiting AChE, which is the enzyme that degrades ACh after binding to the AChR site. Before the medication is administered, the provider focuses on a weak group of muscles, such as the ocular muscles. An initial dose of 2 mg is given while the patient has sustained visual focus on an object. The provider assesses for improvement of the ptosis. If no effect is observed, additional doses of 3 and 5 mg are administered

at 1-minute intervals. Improvement of muscle weakness at 2 to 5 minutes followed by a return to baseline over the next 5 minutes indicates a positive test.

Edrophonium is a rapid-acting AChE inhibitor. This leads to increased levels of ACh at the neuromuscular junction, leading to improved muscle strength in patients with myasthenia. Unfortunately, the activity is not specific to the neuromuscular junction, and ACh accumulates in the parasympathetic ANS as well. This accounts for the majority of the side effects, including bronchospasm, bradycardia, and diarrhea. Increased stimulation of the muscarinic receptors leads to bradycardia in the heart and bronchospasm in the lungs.

Atropine is a muscarinic blocker, and thus the side effects of edrophonium and other AChE inhibitors can be reversed with this medication. Because it works only in the ANS, it will not interfere with the activity at the neuromuscular junction. In short, atropine should be available to reverse any severe bradycardia that may occur during the edrophonium test. This test is best performed in a controlled setting in the hospital, such as an inpatient unit or intensive care unit.

#### Chest Computed Tomography Scan

A chest computed tomography (CT) scan is routinely performed to evaluate the patient with MG for thymoma. A chest CT scan is more sensitive than plain x-ray films.

#### Medications

The treatment of MG is individualized to meet the needs of each patient (Table 38.2). The healthcare provider considers the severity of the patient's illness, age, and lifestyle, as well as the financial demands of long-term therapy. Treatments are aimed at (1) symptomatic treatment to increase the availability of ACh, (2) immunosuppression, (3) approaches to alter the immunopathogenic mechanism underlying MG, and (4) immunomodulatory effect with thymectomy.

#### Pyridostigmine (Mestinon)

Pyridostigmine is a medication that is a reversible inhibitor of AChE. It improves neuromuscular transmission by increasing ACh stimulation of the AChRs that are available. This medication is the accepted initial treatment of choice for MG. The standard dosage is 30 to 60 mg by mouth every 4 hours while the patient is awake, and it is available in tablets or liquid. A pyridostigmine sustained-release formula (180-mg) tablet may be given to the patient at night before sleep. Possible muscarinic side effects include stomach cramps, diarrhea, increased secretions, nausea, bradycardia, and muscle twitches.

**! Safety Alert** Pyridostigmine must be administered exactly as prescribed to maintain optimal muscle strength. Additionally, it is important to adhere to the patient's medication schedule followed at home. Often, patients take pyridostigmine 30 to 60 minutes before meals to minimize difficulty with chewing and swallowing.

**Table 38.2 Medications Used to Treat Myasthenia Gravis**

Medication	Typical Dosage	Nursing Considerations
<b>Pyridostigmine (Mestinon)</b> <b>(anticholinesterase inhibitor)</b> <ul style="list-style-type: none"> <li>● Oral tablets</li> <li>● Liquid</li> <li>● Sustained release</li> </ul>	60-mg tablets every 4 hours while awake 180-mg tablet	Medication should be administered exactly at the prescribed hour; administer 30–60 minutes before meal; monitor for increase in secretions, muscle cramps, and diarrhea.
<b>Prednisone (Deltason, Prednicot) (corticosteroid)</b>	Low dose: 15–20 mg daily High dose: 60–80 mg daily in controlled setting	Provide education about side effects of steroids: immunosuppression, gastrointestinal bleed, hyperglycemia, weight gain, truncal obesity, and sleep disturbance.  Monitor blood glucose levels closely. Patient may require insulin coverage.  Confer with provider to provide patient with calcium and vitamin D supplementation to decrease bone loss.

### Neostigmine (Prostigmin)

Neostigmine is a shorter-acting AChE inhibitor. This medication is administered intravenously when the patient's oral route is not available because of surgery or other conditions such as Crohn's disease, gastrointestinal bleed, or paralytic ileus. Most acute care facilities have a policy for this medication that limits administration to patients in a monitored setting because of the potential side effects of bradycardia or cardiac dysrhythmias. The IV site needs to be monitored frequently to ensure patency because of the short half-life of neostigmine. Some policies require dual IV access so that a second IV site is available if the first one infiltrates. The provider determines the proper dose conversion to oral pyridostigmine when the patient is ready to resume taking medications orally. The ratio of IV neostigmine is 1 mg equals 60 mg pyridostigmine. The nurse administers the oral pyridostigmine 1 hour before stopping the IV medication. Side effects of this medication are similar to those of pyridostigmine.

### Immunotherapy

There are several immunosuppressant medications available to treat MG. These medications are initiated when AChE inhibitors are not adequate in moderately severe MG, and prednisone is the principal medication from this category that is used in MG. The patient may be hospitalized when prednisone is initiated because deterioration may occur in the first few weeks of treatment.

Azathioprine (Imuran) is a steroid-sparing medication that may also be used. It inhibits T-cell and B-cell proliferation through interaction with purine metabolism and nucleic acid synthesis. Another medication that may be used is cyclosporine, which inhibits T helper cell–mediated synthesis of cytokines and other T helper cell–mediated immune reactions. Cyclosporine has been used successfully in

patients when steroids and thymectomy have failed. The time to treatment response is approximately 7 months.

Mycophenolate mofetil (CellCept) suppresses both T-cell and B-cell proliferation. This medication is commonly used in the United States. The usual dosage is 1 g twice a day, and adverse effects include diarrhea, anemia, leukopenia, and infections.

Cyclophosphamide (Cytoxan), a chemotherapeutic agent, is also used in the management of MG. At high doses, this medication is used to ablate (destroy) bone marrow and allow the patient's endogenous stem cells to repopulate the immune system with new lymphocytes. This approach allows the patient's immune system to “reboot.”

### Medications to Be Used With Caution in Myasthenia Gravis

The provider and nurse must be familiar with medications that are contraindicated in MG because some medications have an adverse effect on neuromuscular transmission and may lead to increased weakness. The medications that are contraindicated in MG include some antibiotics, calcium-channel blockers, D-penicillamine, and magnesium. Antibiotics such as streptomycin and polymyxin exhibit a nondepolarizing blocking action on neuromuscular transmission. Calcium-channel blockers and magnesium block calcium, which is necessary for normal neuromuscular transmission.

Aside from IV magnesium sulfate, nurses need to be aware of certain antacids and laxatives that also contain magnesium because they should be avoided in patients with MG. There may be some clinical situations where administration of these medications may be warranted by the patient's clinical condition (i.e., hypomagnesemia). If any of these medications are ordered, the nurse should consult with the provider to determine if increased clinical assessments should be performed (e.g., forced vital capacity).

Patients and families should be educated to inform healthcare providers about these medications when being treated in settings such as the emergency department or surgical setting, where providers may be unfamiliar with MG (Table 38.3).

### Additional Therapies

In addition to medication therapies, two additional therapies, IV immunoglobulin (IVIG) and plasmapheresis, are also used in the treatment of MG. These therapies have a quicker onset of action when compared with the immunosuppressant therapies. Their effects are limited to 4 to 6 weeks and are typically used when the patient is hospitalized for exacerbation of MG or prior to surgery. Randomized controlled trials have suggested that IVIG and plasmapheresis are equally effective. The choice of treatment is the provider's decision. Intravenous immunoglobulin is administered by the IV route, whereas plasmapheresis requires the insertion of a dual-lumen catheter.

### Intravenous Immunoglobulin

Intravenous immunoglobulin is a concentrated immunoglobulin (Ig) solution primarily composed of IgG that is produced from pooled blood donors. The mode of action is complex, and it inactivates abnormal autoantibodies and suppresses T-cell function. The medication is costly, and a treatment course is approximately \$10,000. The total dose administered intravenously over 3 to 5 days is 2 g/kg. This medication is administered slowly, and the rate is carefully titrated. Vital signs are checked frequently, and the patient is monitored for flu-like symptoms (e.g., fever, headache, chills, myalgia). Renal functions, including blood urea nitrogen (BUN) and creatinine, are monitored prior to the initial infusion and then periodically. This medication is carefully administered in patients with diabetes mellitus

or renal insufficiency because renal failure is a potential complication.

For decades, steroids and acetylcholinesterase inhibitors were the mainstay of therapy for patients with MG. In late 2017, a new treatment, eculizumab, was added to the armamentarium of treatments for patients with anti-acetylcholine receptor (AChR) antibody-positive MG. Many of these patients could not tolerate standard treatments. Eculizumab is a monoclonal antibody that is a complement inhibitor. Uncontrolled activation of the complement system plays a major role in the clinical manifestations experienced by patients with MG. Providers must confirm that patients have received a meningococcal vaccine at least 2 weeks before the medication is administered because the risk of meningococcal disease is 1,000-fold to 2,000-fold higher among patients taking this medication. For MG, the medication is administered as an IV infusion of 900 mg/week for the first 4 weeks, 1,200 mg for week 5, and then 1,200 mg every 2 weeks afterward. Adverse effects of the medication include hypertension, nausea, vomiting, diarrhea, and headache. Other medications that inhibit complement are currently under investigation and could potentially change how patients with MG are managed.

### CASE STUDY: EPISODE 2

On Ms. Jordan's admission, her examination reveals bilateral ptosis, **dysarthria** (difficulty speaking), and **dysphagia** (difficulty swallowing). Her speech is slurred, and she has difficulty with swallowing secretions. Her vital capacity is 1.3 L. She has diminished strength in all four extremities and requires the assistance of one nurse for ambulation. Her vital signs are as follows: BP 110/70 mm Hg, HR 114 bpm, RR 28, and temperature of 100.3°F (37.9°C). Ms. Jordan requires the insertion of a nasogastric tube for medications, and an infusion of normal saline is initiated for dehydration...

**Table 38.3 Medications Known to Exacerbate Myasthenia Gravis**

Class of Medications	Names
<b>Antibiotics</b>	Aminoglycosides, ciprofloxacin, clindamycin, telithromycin, ampicillin, erythromycin
<b>Antiarrhythmics</b>	Procainamide, propranolol, timolol, verapamil, quinidine
<b>Neuropsychiatric</b>	Phenytoin, trimethadione, lithium
<b>Other</b>	Trihexyphenidyl, neuromuscular-blocking agents, magnesium preparations, carbamazepine, oral contraceptives, transdermal nicotine

### Plasmapheresis

**Plasmapheresis** requires the insertion of a large-bore dual-lumen catheter and is usually limited to large medical centers. During plasmapheresis, the patient's blood is removed through the arterial lumen and circulated through the plasmapheresis machine, which removes antibodies that block AChR function. The goal of this treatment is to improve muscle strength. Anticoagulation is required to prevent clotting in the extracorporeal blood during an **apheresis procedure** (a procedure that involves removing whole blood and separating the blood into individual components so that one particular component can be removed). Citrate is the anticoagulant of choice during a plasmapheresis procedure. Citrate is added to the blood when it is outside the body to prevent clotting from occurring. The citrate binds with calcium

and effectively blocks the calcium-dependent clotting factor reactions.

The solid blood components, red blood cells, white blood cells, and platelets, are returned through the venous lumen with normal saline and albumin. A total of seven treatments is usually ordered for the patient. Treatments may be done at the bedside, or the patient may be transported to a pheresis center. Because plasmapheresis involves the removal of plasma, medications in the plasma may be removed. Prior to the treatment, the nurse should consult with the provider to determine if any medications should be held. Antihypertensives may increase the chance of hypotension during the treatment, and there is also the potential for plasmapheresis to affect therapeutic levels of medications. Patients are monitored for blood clotting following each session because the procedure can also remove coagulation factors in the blood.

Patients may experience paresthesias from citrate-induced hypocalcemia, and hypotension may occur at the start of the exchange. Patients are asked to report any numbness or tingling, especially around the lips, because these findings are indicative of hypocalcemia. Because the citrate binds with calcium to effectively prevent clotting, the patient has an increased risk of hypocalcemia, and this is the most common side effect of this procedure. The ionized calcium level decreases in the patient as a result of the citrate infusion, the removal of calcium in the patient's wasted plasma, and the calcium-binding properties of albumin. However, these complications may be prevented by adding calcium to the replacement fluid, 5% albumin, or by slowing down the infusion of the citrate during the procedure. If citrate reactions are not treated, they can progress from paresthesias, vibration sensation, nausea/vomiting, and diarrhea to hypotension, chest tightness, tetany, and cardiac arrhythmias.

During plasmapheresis, fluid shifts are caused by removing plasma and replacing the plasma with substitute fluids or 5% albumin, and some patients may experience nausea and vomiting because of these fluid shifts and electrolyte imbalances. The change in intravascular volume and the dilutional effects of the plasma constituent levels may cause hypovolemia. Clinical manifestations of hypovolemia may include dizziness, light-headedness, nausea, diaphoresis, tachycardia, and hypotension. These can be treated by pausing the procedure, placing the patient in a Trendelenburg position if not contraindicated, and administering a saline bolus of fluids. In subsequent procedures, replacement fluids may be adjusted with an increase in colloids and a decrease in crystalloids.

Patients may also experience a vasovagal reaction during or after the plasmapheresis procedure. These patients may experience pallor, sweating, diaphoresis, nausea/vomiting, hypotension, and bradycardia, and the treatment is the same as for hypovolemia. Electrolytes, namely, potassium and calcium, need to be monitored in the patient receiving plasmapheresis.

The pheresis nurse instills heparin in each port of the dual-lumen catheter following the plasmapheresis treatment.

The catheter also needs to be instilled with heparin on nonpheresis days to prevent clotting. The integrity of the line is preserved and clotting prevented by allowing heparin to dwell in the line while it is not in use. Whenever the catheter is accessed, the heparin must first be removed before the line is flushed so that the patient does not receive a bolus of heparin. There is an increased risk of infection and thrombotic complications associated with the plasmapheresis catheter. Of note, this catheter resembles a hemodialysis catheter and should not be confused with a dialysis catheter. A dialysis catheter is a dedicated line specifically used for hemodialysis and is not accessed by nurses outside the dialysis center.

### **Surgical Management**

A surgical approach to the management of MG is thymectomy. Generally, thymectomy is performed within the first 3 years of diagnosis and in individuals less than the age of 65. This surgery is always performed for patients with thymoma. Although there are several approaches to performing this surgery, the standard approach is transsternal extended thymectomy. (These patients require postoperative care similar to that of patients undergoing open-heart surgery). However, transcervical and videoendoscopic procedures, including robotic-assisted surgery, are gaining popularity because of shorter hospital stays and improved cosmetic results. Patients undergoing surgery require IV neostigmine (Prostigmin) because of NPO status and management in an intensive care unit following surgery. Intravenous neostigmine, an IV anticholinesterase medication, is required to maintain muscle strength and respiratory function. Because oral pyridostigmine bromide (Mestinon) is discontinued for surgery, the patient must receive an IV equivalent of the medication.

### **Complications**

It can be extremely difficult to differentiate between worsening of MG and excessive anticholinergic medication in a rapidly deteriorating patient with muscular weakness and potential respiratory failure.

#### **Myasthenic Crisis**

**Myasthenic crisis** is an exacerbation of MG weakness that provokes an acute episode of respiratory failure that is often caused by a respiratory infection from viral or bacterial agents. Weakness may involve the respiratory or bulbar muscles and may affect the patient's ability to protect the airway. Additional features of myasthenic crisis include tachycardia, flaccid muscles, and pale and cool skin. Myasthenic crisis is an emergency that requires prompt recognition and treatment in an intensive care unit for optimal management. The crisis usually lasts for approximately 2 weeks. Intravenous immunoglobulin or plasmapheresis is used to manage the patient throughout the crisis.

#### **Cholinergic Crisis**

Another type of crisis that the MG patient may encounter is **cholinergic crisis**. This is due to excessive

anticholinesterase medication and is potentially secondary to the patient taking too much of the prescribed MG medication. Features of a cholinergic crisis include muscle bradycardia, **fasciculations** (muscle twitch), sweating, pallor, excessive secretions, and small pupils. It may be difficult to distinguish which crisis, cholinergic or myasthenic, the patient is experiencing because both crises have similar clinical features. The Tensilon (edrophonium) test is useful in distinguishing myasthenic from cholinergic crisis because it has a rapid onset and is short acting. This test may assist the provider in identifying the type of crisis the patient is experiencing and selecting the appropriate treatment course. When Tensilon is administered, if the patient demonstrates muscle strength improvement, it is determined to be a myasthenic crisis. If Tensilon is administered and the patient demonstrates fasciculations and muscle weakness, including the respiratory muscles, it is a cholinergic crisis. Anticholinesterase medications are temporarily discontinued in a cholinergic crisis.

### Diet

Patients with MG benefit from the professional evaluation of a speech language pathologist and registered dietitian. Because of the weakness of the oropharyngeal muscles, the patient may have difficulty with chewing and swallowing that increases the risk for aspiration. Modifications are made in the patient's diet so that adequate nutrition is provided and may include thickened liquids or enteral tube feedings.

## Connection Check 38.2

During the edrophonium or Tensilon test, a short-acting AChE inhibitor is administered intravenously, and the provider observes the patient for improvement in which function?

- A. Level of consciousness
- B. Muscle strength
- C. Muscle tone
- D. Hearing

## Nursing Management

### Assessment and Analysis

The patient with MG may experience clinical manifestations including respiratory deterioration and muscular weakness. The nurse performs a comprehensive neurological assessment of the patient with MG, including a detailed cranial nerve assessment. The nurse also carefully assesses motor strength to identify muscle weakness. Because of the potential for respiratory weakness, a bedside test known as the *vital capacity* is performed. Vital capacity is defined as the maximum amount of air exhaled following maximal inhalation. A patient has normal respiratory function with a value of 65 mL/kg. When a patient's value falls below 15 mL/kg or generally 1 L, respiratory deterioration may progress

rapidly, and mechanical ventilation will be required. Aside from bedside vital capacity measurements, which the nurse can perform, serial negative inspiratory force and positive expiratory force assessments are performed with the assistance of a respiratory therapist. The patient with MG is assessed for the following clinical manifestations:

- Muscle weakness that increases over the course of the day
- Fatigue
- Ptosis
- Diplopia
- Dysphagia
- Dysarthria

**Safety Alert** In patients with MG, it is important to carefully monitor vital capacity measurements. Pulse oximetry is not helpful in determining respiratory deterioration in a patient with MG because the failure is due to weakness of the diaphragm and intercostal muscles. The patient will develop hypoxemia and hypercarbia. Because the patient retains carbon dioxide (CO<sub>2</sub>), the provider needs to obtain an arterial blood gas to assess CO<sub>2</sub>.

### Nursing Diagnoses

- **High risk for ineffective breathing** related to respiratory muscle weakness
- **High risk for aspiration** related to bulbar weakness
- **Fatigue** related to muscular weakness

### Nursing Interventions

#### Assessments

- Assess breath sounds and observe the patient's respiratory effort.  
*Obtain vital capacity per provider's order. This is usually obtained immediately prior to a dose of pyridostigmine to obtain a trough value and then 1 hour post-dose to evaluate peak effect.*  
*If the value is below 1 L, the patient is at risk for respiratory compromise. Notify the provider. Respiratory deterioration may lead to respiratory arrest. Patients often require intubation and mechanical ventilation in an intensive care setting.*
- Vital capacity measurement  
*Vital capacity is an important respiratory function to monitor. If the value is below 1 L, notify the provider. In MG, the patient develops weakness of the diaphragm and intercostal muscles. Weakness of the respiratory muscles results in diminished forced vital capacity.*
- Cranial nerves IX, X, XI, and XII  
*Bulbar symptoms are the first to appear in about 16% of MG patients and place the patient at risk for aspiration due to difficulty swallowing.*
- Dysphagia  
*Weakness of the oropharyngeal muscles places the patient at risk for dysarthria and dysphagia.*

- Nutritional intake, intake and output, and daily weight  
*Cranial nerve weakness can make it difficult for the patient to chew and swallow. The patient may become fatigued during the meal.*
- Dysarthria  
*Patients may have a nasal quality to the speech and be at risk for aspiration because of weakness of these muscles. This is related to impairment of CNs V, VII, IX, X, XI, and XII.*

### ■ Actions

- Administer medications at prescribed times and prior to activities requiring swallowing.  
*Pyridostigmine must be administered exactly at the prescribed hour to maintain optimal muscle strength. Patients often take pyridostigmine 30 to 60 minutes before meals to minimize difficulty with chewing and swallowing.*
- Elevate the head of the patient's bed with eating or drinking.  
*Weakness of the oropharyngeal muscles increases the risk of aspiration, and elevating the head of the bed may decrease aspiration.*
- Establish effective communication method with the patient.  
*Consult with speech language pathology to obtain a picture communication board because verbal communication is impaired by dysarthria.*
- Plan meals when medications are at peak levels.  
*Timing the meals with peak medication levels decreases the risk of aspiration. Small, frequent meals will help maintain calorie intake. Weight loss may result from poor nutritional intake.*
- Offer soft foods and thickened liquids as recommended by the speech language pathologist.  
*A temporary feeding tube may be necessary if swallowing is impaired or if the patient deteriorates and requires intubation and mechanical ventilation.*
- Plan for rest periods between activities of daily living.  
*Use energy conservation techniques, such as sitting while activities of daily living are completed, to minimize fatigue and muscle weakness.*

### ■ Teaching

- Importance of taking medications as prescribed  
*It is important to teach the patient to adhere to the medication schedule at home because swallowing may be impaired if eating, drinking, brushing teeth, and other activities are not performed at peak levels of the medications.*
- Educate patient to keep medication with him or her at all times. Spare doses should be kept at the place of employment and in the car. When the patient travels, medication should remain with the patient in carry-on luggage.  
*The patient should not miss a dose of pyridostigmine bromide because this can lead to muscular weakness.*
- Instruct patient to purchase a MedicAlert bracelet and to wear it daily.  
*In the event of an emergency, the patient's diagnosis may be rapidly identified by emergency medical service providers.*

- Avoid public places such as theaters or concerts in the winter where there are large gatherings of people.  
*The patient may be exposed to colds and the flu where there are large gatherings of people, and this increases the risk of exacerbation.*
- Obtain vaccines to prevent the flu and pneumonia.  
*Vaccines decrease the risk of infection. Respiratory infections may lead to myasthenic crisis that requires hospitalization.*
- Prevent fatigue with frequent rest periods. Recognize physical limits, and plan activities during peak energy periods.  
*The risk of injury is decreased when activities are scheduled during peak times of medications.*
- Do not take any over-the-counter preparations without first checking with the provider.  
*Over-the-counter products may have ingredients that are contraindicated in MG.*
- Inform the patient and family about resources, such as the Myasthenia Gravis Foundation of America.  
*This organization provides detailed education and e-resources for patients and families.*

### Connection Check 38.3

The nurse assesses for which clinical manifestations in a patient admitted with MG? (Select all that apply).

- Ptosis
- Diplopia
- Hyperventilation
- Dysphagia
- Bitemporal headaches

### Connection Check 38.4

Which action is critical when administering a pyridostigmine 60-mg tablet to a patient with MG?

- Administer with milk and crackers to minimize gastrointestinal distress.
- Administer 2 hours after meals because food slows gastric absorption.
- Administer 30 to 60 minutes before meals to optimize the strength of the chewing and swallowing muscles.
- Administer with orange juice because vitamin C facilitates gastric emptying.

### Evaluating Care Outcomes

Patients with MG may be successfully managed with cholinesterase inhibitors. The patient and family must be aware of clinical manifestations of crisis and seek medical attention quickly. Patient education plays a crucial role in the successful management of the patient. With adherence to prescribed medications and the treatment plan, patients are able to actively participate in family activities and a career.

It is important for the patient and family to be educated on the disease process and the medications. Not only should the patient be educated about the action of medications required for the management of MG, but the patient should also be knowledgeable about medications to be avoided because they increase weakness. Information about the clinical manifestations of crises are included in a comprehensive teaching plan.

### Connection Check 38.5

The patient with MG needs to be educated about medications that should be avoided because they can increase weakness. Which medication should the patient avoid?

- A. Acetaminophen
- B. Prednisone
- C. Azathioprine
- D. Maalox

## GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS), another disorder of the PNS, is an acute inflammatory demyelinating **polyneuropathy** (simultaneous neuropathy of peripheral nerves). It often occurs after an infection and leads to a rapidly progressing flaccid paralysis. This syndrome was first identified about a century ago by French neurologists Guillain, Barré, and Strohl. They provided an account of two soldiers who developed acute paralysis with areflexia (absent reflexes) and then recovered spontaneously. It is important that health-care team members rapidly identify GBS as it presents in the provider's office or emergency department in order to ensure that appropriate treatment is implemented.

### Epidemiology

About two-thirds of patients who develop GBS demonstrate clinical manifestations of an infection 3 weeks prior to onset. Respiratory or gastrointestinal infections are the most common sources. *Campylobacter jejuni* is the most frequently identified cause, but cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae*, and *Haemophilus influenzae* are also causes. Guillain-Barré is a syndrome that affects the immune system and attacks the PNS.

Zika is a part of the mosquito-borne group of flaviviruses that are primarily transmitted by mosquitoes. As a virus, Zika had circulated for many decades with no reported epidemics until February 2016 when the World Health Organization declared it a major public health problem. There is recent evidence that supports a link between Zika virus and GBS. Guillain-Barré was the first reported complication of Zika in adults. A recent report suggests that Zika virus should be included in the list of infectious pathogens that can cause GBS. The pathogenesis of Zika virus-associated GBS is unknown. The typical treatment of

GBS, which includes plasmapheresis, IVIG, and intensive care can be challenging in remote regions of the world.

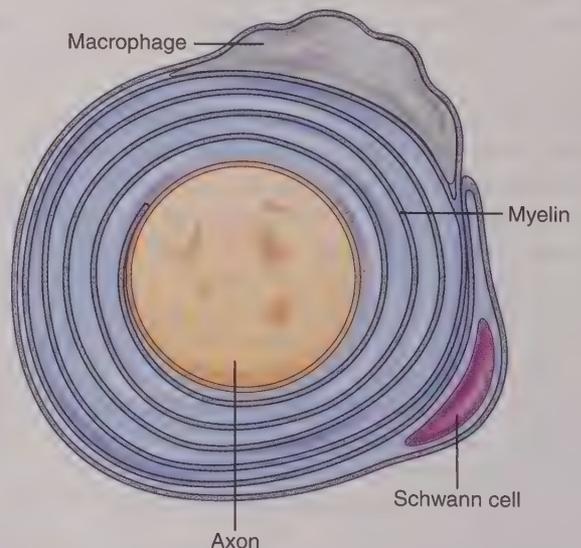

The incidence of GBS is about 1 case per 100,000 population, with men and women equally affected. Mortality rates range from 2% to 10% from autonomic dysfunction or complications of immobility and increase with age. Patients are more likely to die if they are over 60 years of age, have a rapidly progressing variant of GBS, develop axonal loss, and require an extended course of mechanical ventilation.

### Pathophysiology

Guillain-Barré syndrome is mediated by an immune response with acute lower extremity weakness with areflexia or diminished reflexes developing over several days. An infection usually precedes the development of GBS by about a month. In GBS, the patient's own immune system begins to destroy the myelin that surrounds the peripheral nerves. Destruction occurs between the nodes of Ranvier, which impairs **saltatory (jumping) conduction** and results in the slowing of impulses or a conduction block. There is infiltration of lymphocytes into the peripheral nervous system, which attracts macrophages; the macrophages penetrate the Schwann cell and invade the myelin, resulting in demyelination. Lymphocytes can be seen at points of myelin breakdown on microscopic exam. Axons usually remain intact (Fig. 38.3). In addition to affecting the myelin on cranial and motor nerves, sensory function is often impaired as well.

The patient's immune system produces antibodies in response to a viral or bacterial illness to fight the infection. Antibodies are also produced that attack the myelin of the peripheral nerves. Nerve damage results in numbness and tingling, muscle weakness, paralysis, and potential respiratory compromise.

There are three stages of GBS. The first stage is known as the *acute stage* and starts with the onset of clinical

**FIGURE 38.3** Guillain-Barré syndrome. Macrophages attach to and destroy myelin, leading to decreased nerve conduction.

manifestations of peripheral nerve **demyelination** (destruction of myelin sheath), edema, and inflammation. This phase lasts approximately 4 weeks. When demyelination ceases, the patient enters the *plateau stage*, which lasts from a few days to weeks. In the *recovery stage*, remyelination and axonal regeneration begin, and there is a gradual improvement in the patient's signs and symptoms.

## Clinical Manifestations

Although there are several subtypes of GBS, such as Miller-Fisher syndrome and acute motor axonal neuropathy, the most common form, acute inflammatory demyelinating polyneuropathy, is the focus of this chapter. The patient with GBS develops a symmetrical ascending motor weakness and paralysis that usually starts in the feet and extends to the trunk and arms. (Note: There is an easy way to remember the pattern of weakness in GBS: It starts in the toes, and up it goes.) There may be sensory involvement, and patients may complain of paresthesias and pain that involves the shoulders, back, buttocks, and upper legs. After the first few days of weakness, neurological assessment demonstrates diminished or absent deep tendon reflexes (areflexia). Areflexia is recognized as a key finding in GBS.

Additionally, there may be cranial nerve involvement in 85% of cases of GBS. Cranial nerve VII (facial nerve) is most commonly affected, and the patient may have difficulty with facial expressions such as smiling or frowning. Cranial nerves IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal) may also be involved, causing dysphagia. If CN X is affected, the patient may exhibit autonomic dysfunction with possible cardiac dysrhythmias, paroxysmal hypotension, orthostatic hypotension, paralytic ileus, urinary retention, and potential syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Up to 40% of patients with GBS develop respiratory impairment. Respiratory failure is caused by weakness of the diaphragm and intercostal muscles, and the patient may require intubation and mechanical ventilation to provide respiratory support. The patient's level of consciousness and cognitive function remain intact throughout the course of the illness. The pattern of recovery is the reverse of onset, and the nerves that were affected last are the first to improve.

## Connection Check 38.6

What pathophysiological processes occur in the first stage, or the acute phase, of GBS?

- Peripheral nerve demyelination, edema, and inflammation
- Depolarization of the spinal nerves
- Destruction of the myelin-producing oligodendrocytes
- Regeneration of the myelin sheath

## Management

### Medical Management

#### Diagnosis

The patient with GBS is admitted to the inpatient setting for a thorough evaluation. Established diagnostic criteria for GBS include progressive weakness of two or more limbs caused by neuropathy, areflexia, and history of recent viral or bacterial infection. Additionally, a lumbar puncture is performed to obtain cerebrospinal fluid (CSF). Cerebrospinal fluid findings include elevated protein and normal cell count. Electromyography results reveal slowed nerve conduction velocity soon after the patient develops paralysis.

#### Medications

Management of GBS focuses on supportive care and reducing the severity, potential complications, suffering, and recovery time. Although GBS is an autoimmune disorder, steroids have not been found to help speed recovery. The use of steroids is debatable, and current research is leaning toward patients with GBS *not* receiving corticosteroid therapy.

There are two main approaches used for treatment. These modalities are IVIG and plasmapheresis. Intravenous immunoglobulin therapy can shorten the length of the recovery phase by 50%, and this therapy is recommended for patients who need help to walk within 2 to 4 weeks of clinical presentation of GBS. This treatment may work by several mechanisms, which include blocking of macrophage receptors, the inhibition of antibody production, the inhibition of complement binding, and the neutralization of pathological antibodies. The dosing is 2 g/kg intravenously over 5 days. Typical adverse effects of this medication include flu-like symptoms. Rare adverse reactions are aseptic meningitis and acute renal failure. Fluid overload may occur in patients with heart failure or renal insufficiency.

The American Academy of Neurology recommends plasmapheresis for nonambulatory adult patients with GBS who start treatment within 4 weeks of onset of neuropathic symptoms. Plasmapheresis is also recommended for ambulatory patients who start treatment within 2 weeks of the onset of neuropathic clinical manifestations. This therapy can reduce recovery time, yet requires the insertion of a plasmapheresis catheter, skilled nursing staff, and specialized equipment that may not be available at all healthcare facilities. Plasmapheresis diminishes the length of hospitalization and the need for mechanical ventilation if initiated within the first week of clinical manifestations. There is an increased risk of infection and hemorrhage as a result of the removal of immunoglobulins and clotting factors. Adverse reactions the patient may experience include hypotension, bradycardia, fever, chills, and rash. Additional complications from this treatment include septicemia, pneumonia, cardiac arrhythmias, malaise, bleeding/clotting abnormalities, and hypocalcemia.

## Diet

Problems such as immobility, decreased gastric motility, and dysphagia place the patient at risk for inadequate nutrition. A speech language pathologist evaluates the patient for dysphagia and risk of aspiration. During the acute phase of the illness, a dietitian is consulted, and enteral feeding may be initiated to prevent aspiration (see Evidence-Based Practice). Feedings are individualized to meet the patient's caloric needs based on total body weight and laboratory values. Adequate nutrition is key throughout all phases of the illness, especially if the patient is intubated and placed on a mechanical ventilator. Decreased nervous innervation and ventilation support may contribute to muscle atrophy and inhibit the weaning process from the ventilator. Optimal nutrition plays a key role in the patient's recovery and prognosis.

## Evidence-Based Practice

### Nasogastric Tube Feeding for Patients With Guillain-Barré Syndrome

During the acute phase of Guillain-Barré syndrome (GBS), because of cranial nerve involvement, enteral tube feedings may be ordered to prevent malnutrition and aspiration. The nurse is responsible for insertion of the tube and residual and patency checks for proper positioning. The patient should be evaluated by the dietitian so that feedings meet the caloric and protein needs according to the patient's body weight and laboratory values.

The nurse is responsible for verifying nasogastric tube (NGT) placement after initial insertion, before medication administration, and every 8 hours with continuous enteral feedings. Traditional placement checks are validated by checking a mark at the nose that is placed following NGT insertion, auscultation (insufflation of 30 mL of air), and analysis of gastric contents. The literature supports that insufflation alone is not adequate. Although there are many methods by which tube verification may be accomplished (i.e., pH, enzyme, bilirubin, and carbon dioxide testing), none of these methods allows detection of a tube in the esophagus or gastroesophageal junction. X-ray placement is considered the gold standard. Radiography is the only reliable method to verify the initial placement of blindly inserted small- and large-bore feedings tubes.

Boullata, J. I., Carrera, A. L., Harvey, L., McGinnis, C., Wessel, J. J., Bajpai, S., ... Guenter, P. (2017). ASPEN safe practices for enteral nutrition therapy. *Journal of Parenteral and Enteral Nutrition*, 41(1), 15–103.

## Complications

In the patient with GBS, respiratory status is monitored in terms of breath sounds and forced vital capacity. Because ventilation is compromised by the loss of motor innervation to the skeletal muscles of respiration, the patient is at risk for respiratory compromise. The airway needs to be maintained, and the patient may require intubation and mechanical ventilation to prevent respiratory arrest.

During the course of GBS, the patient is also at risk for developing complications of immobility. Therefore, subcutaneous heparin may be ordered to prevent venous thromboembolism (VTE). Antiembolism stockings and sequential compression devices also play an important role in VTE prevention. The patient is also at risk for the development of pressure injuries, and a turning schedule should be implemented to prevent skin breakdown. Patients with GBS may perspire because of autonomic manifestations, and the patient's clothing and linens require frequent changes to prevent areas of moisture and to promote skin integrity.

## Connection Check 38.7

The nurse correlates respiratory compromise in GBS with which pathophysiological process?

- Decreased protein in the CSF
- Progressive limb weakness
- Diaphragmatic weakness
- Decreased acetylcholine at the neuromuscular junction

## Nursing Management

### Assessment and Analysis

It is important for the nurse to perform a thorough baseline assessment of the patient with GBS upon admission so that changes may be noted and the provider alerted. Nursing care is paramount in providing support to the patient during the acute phase of the illness so that complications are averted. Clinical manifestations of the disease include:

- Respiratory muscle weakness
- Skeletal muscle weakness (often ascending)
- Pain
- Autonomic manifestations such as sweating and tachycardia

It is important that complications such as aspiration, VTE, and skin breakdown are avoided so that the patient will be ready to fully participate in rehabilitation. In addition to the physical care the nurse provides, it is important to include the patient in as much decision making as possible. Although weak, the patient remains alert and cognitively intact. Some patients describe the course of their illness as

being locked in a body that will not work while being fully aware of their surroundings.

### Nursing Diagnoses

- **High risk for ineffective breathing patterns** related to respiratory muscle weakness
- **Pain** related to inflammation early in the acute phase; related to regeneration of sensory nerve fibers later in the course
- **Impaired physical mobility** related to muscle weakness secondary to decreased nerve conduction
- **Anxiety** related to course of illness, immobility, and dependency on others

### Nursing Interventions

#### ■ Assessments

- Perform respiratory assessment with vital capacity measurement.  
*Respiratory assessment is a priority because respiratory compromise secondary to weakness of the diaphragm and intercostal muscles may require intubation. Vital capacity measurement is an important function to monitor. The provider should be notified of a value below 1 L. Diaphragmatic weakness results in hypoxemia.*
- Cranial nerves VII, IX, X, XI, and XII  
*Cranial nerve assessment should be performed to identify deficits. Focus on facial expression, speech, gag, and swallow.*
- Motor and sensory assessment  
*Motor and sensory impairment may develop related to slowing of impulses or a conduction block secondary to demyelination of peripheral nerves.*
- Pain assessment  
*Patients often complain of pain. This may be due to sensory nerve fiber involvement.*

#### ■ Actions

- Turn frequently and perform range of motion every shift to maintain joint and muscle integrity.  
*Immobility places the patient at risk for contractures, skin breakdown, and VTE.*
- Consult with the provider on the need for VTE prevention (subcutaneous heparin, antiembolism hose, sequential compression devices).  
*Prolonged immobility leads to venous stasis and the development of VTE.*
- Reposition patient frequently.  
*Measures are implemented to promote comfort and prevent complications of immobility, including thromboembolism and impaired skin integrity.*
- Consult with provider regarding use of analgesics or nonopioids.  
*Carbamazepine or gabapentin may be used to relieve neuropathic pain.*
- Offer diversions such as music or other relaxation techniques.  
*Pain management is addressed with pharmacological as well as nonpharmacological methods.*

- Establish a method of communication, and provide a method to call the nurse (e.g., soft call bell).  
*Because of limb weakness, the patient may not have the strength to locate and use the call light. A soft squeeze call bell allows the patient to call the nurse with only a gentle squeeze.*

#### ■ Teaching

- Inform the patient and family about the importance of respiratory monitoring in the acute phase.  
*Provide encouragement that the disease course lasts several weeks to months and that rehabilitation will assist the patient in returning to pre-morbid functioning. In addition, it is important to inform the patient and family that recovery from this neurological disorder is possible.*
- Educate the patient and family about GBS at each stage of the illness.  
*Education allows the patient and family to anticipate that respiratory deterioration may occur. Having this information ahead of time may help to alleviate fear.*
- Inform the patient and family about resources, such as the GBS Foundation International ([www.gbs-cidp.org](http://www.gbs-cidp.org)).  
*Community and other resources provide additional support systems for the patient and family. Respite care may be available through some of these organizations.*

### Connection Check 38.8

Which nursing intervention is a priority for a patient with cranial nerve impairment from GBS?

- Perform sensory checks with the neurological examination below the level of the cervical spine.
- Consult with the provider for initiation of continuous positive airway pressure for breathing.
- Create a turning schedule with limited time in the side-lying position.
- Establish effective communication using eye blinks or a communication board.

### Evaluating Care Outcomes

The patient with GBS may enter the hospital system through the emergency department and remain in the hospital for several weeks to months. Aside from care in the inpatient setting, the patient may be moved to the intensive care setting for mechanical ventilation. Throughout the course of hospitalization, nursing care focuses on careful monitoring and interventions to avoid complications such as aspiration, skin breakdown, contractures, and VTE that can delay recovery. It is important for the patient to be ready to engage in rehabilitation when stabilized. Family involvement is important to help the patient reintegrate into family activities and work. Some patients recover completely, yet some may have residual numbness and weakness. With proper support and rehabilitation, the patient hopefully returns to baseline functioning within a few months.

## TRIGEMINAL NEURALGIA

Patients with trigeminal neuralgia, also referred to as *tic douloureux*, are treated in a variety of healthcare settings ranging from outpatient offices to surgical suites. As a review, the fifth CN is called the *trigeminal nerve*. It emerges from the pons of the brainstem and has three branches, namely, the ophthalmic, maxillary, and mandibular branches. It is a mixed cranial nerve, meaning this nerve has both motor and sensory innervation that is responsible for facial sensation and the strength of the jaw. Trigeminal neuralgia is a pain disorder, and the patient seeks medical attention for relief. It is not unusual for the patient to present to a primary care practitioner with a chief complaint of facial pain (Fig. 38.4).

### Epidemiology

There are approximately 15,000 Americans diagnosed with trigeminal neuralgia each year. It is more common in women than in men and rarely affects individuals less than 50 years of age. Risk factors for the development of trigeminal neuralgia are hypertension and multiple sclerosis (MS). In MS, there may be an area of demyelination along the

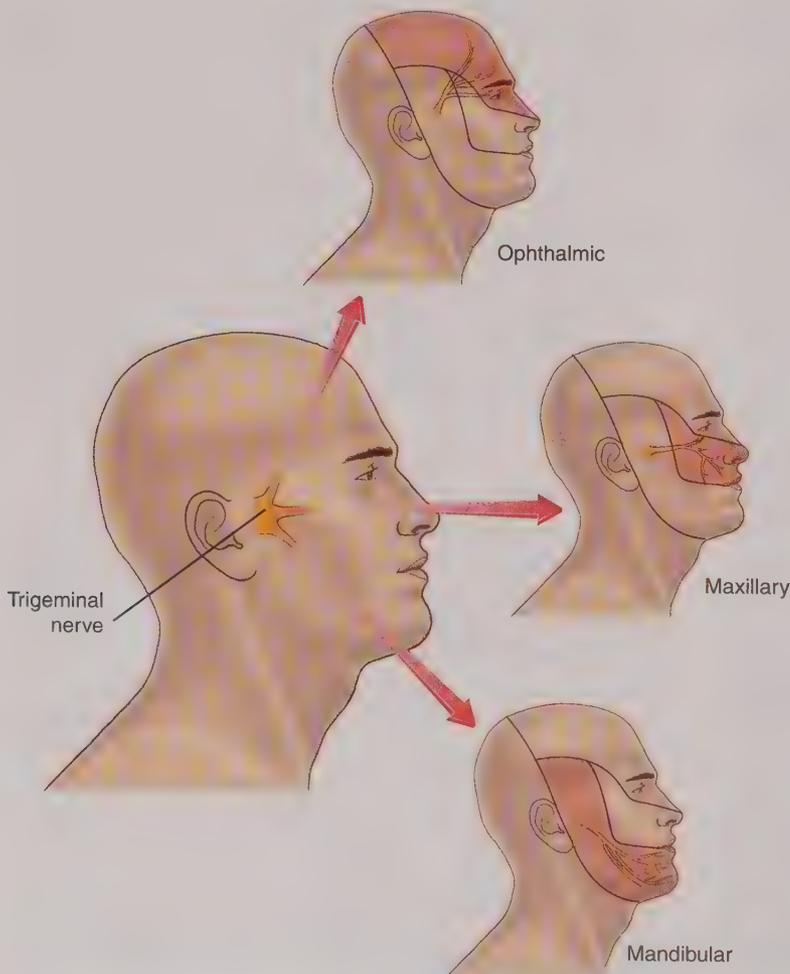

nerve that contributes to the increased incidence. However, for most cases, the cause remains unknown.

### Pathophysiology

Trigeminal neuralgia is described by the International Association for the Study of Pain as a sudden, usually unilateral, severe, brief, stabbing, recurrent pain in the distribution of one or more branches of the trigeminal nerve (CN V). In classic trigeminal neuralgia, the etiology is unknown or due to vascular compression. In some cases, it is associated with a tumor, a structural abnormality of the skull base, or MS. The second type of pain is atypical pain, which is a constant burning sensation that covers a more diffuse region of the face.

### Clinical Manifestations

Patients with trigeminal neuralgia often report that their pain began spontaneously, whereas others relate that their onset of clinical manifestations followed dental surgery, facial trauma, or a motor vehicle accident. The patient complains of sharp, throbbing, and shock-like pain. Triggers may include touching an area of the skin or an activity such as

**FIGURE 38.4** Branches of the facial nerve (CN V). There are three branches of CN V, and pain manifestations correlate to the sensory distributions of these branches.

brushing the teeth, drinking a beverage, smiling, or talking. Patients may also report that just the breeze from opening the door triggers the pain. Hygiene activities such as brushing the teeth, bathing, and shaving may be neglected because they trigger pain. A patient may have 1 attack per day or as many as 10 to 15 attacks an hour.

## Management

### Medical Management

#### Diagnosis

The diagnosis of trigeminal neuralgia is primarily based on the clinical presentation and ruling out other pathophysiological processes, such as direct injury to CN V or tumors. In addition to a comprehensive neurological assessment, including trigeminal reflex testing, a magnetic resonance imaging (MRI) scan of the head is also performed. Blood work may include a sedimentation rate (ESR), antinuclear antibody titer (ANA), or complete blood cell (CBC) count to look for hematological abnormalities.

#### Treatment

Medications are used in the treatment of trigeminal neuralgia, including the use of antiepileptic drugs (AEDs) such as carbamazepine, oxcarbazepine, or gabapentin. Carbamazepine is the first line of medication therapy used in the treatment of trigeminal neuralgia, and it works by reducing the excitability of neurons by inhibiting neuronal sodium channels. Additionally, baclofen may also be prescribed, particularly in patients with MS, because it works as a muscle relaxant. Although medications can be helpful in abating the pain, some patients do not receive optimal relief and seek surgery. Table 38.4 presents a summary of the surgical approaches for the management of trigeminal neuralgia. Microvascular decompression is the most effective surgical treatment for this disorder; facial pain is usually relieved within 24 to 48 hours, and the patient does not have residual facial numbness.

### Connection Check 38.9

The nurse recognizes which class of medications as most effective in the management of trigeminal neuralgia?

- Anticholinergics
- Antihistamines
- Antibiotics
- Antiepileptics

### Nursing Management

#### Assessment and Analysis

Examination of the cranial nerves identifies the area of the face that is affected. It is important to note the branches of the trigeminal nerve that are affected. Usually the clinical manifestations (e.g., short, stabbing attacks of pain) are unilateral and may correlate to the sensory distribution of a specific CN V branch. The nurse also

**Table 38.4** Procedures to Treat Trigeminal Neuralgia

Type of Procedure	Description
<b>Percutaneous rhizotomy</b>	In this procedure, a needle is inserted through the cheek into the foramen ovale. The nerve fibers are damaged or destroyed by radiofrequency, glycerol injection, or balloon compression. Patients will have permanent facial numbness in the region supplied by the branch.
<b>Stereotactic radiosurgery</b>	In this procedure, a single, high-concentrated dose of ionizing radiation is delivered to a precise target at the trigeminal nerve root. This dose of radiation causes a lesion to form, which interrupts pain transmission to the brain.
<b>Microvascular decompression</b>	This is the most invasive procedure. A craniotomy is performed to the suboccipital region. The neurosurgeon performs neurovascular decompression by placing a shredded fluorocarbon resin pad between the vessels and the nerve. The most common vessel to cause compression is the superior cerebellar artery.

assesses for any exacerbating and relieving factors for the patient's pain.

#### Nursing Diagnoses

- **Pain** related to impairment of CN V function
- **Fear** related to chronic and unpredictable pattern of remissions and attacks of pain
- **Impaired nutrition** related to inability to eat and drink associated with pain of trigeminal neuralgia

#### Nursing Interventions

##### ■ Assessments

- Pain, including onset, character, and exacerbating factors  
*It is important to identify the pain rating as well as aggravating factors. The pain is believed to be related to irritation of the nerve fibers in CN V.*
- Oral intake  
*Pain may impair oral intake, so it is important to assess oral intake and fluid-volume status.*
- Weight  
*If pain significantly interferes with nutritional intake, the patient may have weight loss.*
- History of exacerbations and remissions  
*Because the time between attacks appears to shorten as the patient ages, it is important to establish any pattern of attacks.*

### ■ Actions

- Administer medications as ordered.  
*Medication is taken at prescribed intervals to assist with pain relief. Antiepileptic medications have been found to have an analgesic effect on neuropathic pain.*
- Nonpharmacological strategies including meditation, diversional activities, support groups, and acupuncture.  
Suggest meditation or diversional activities.  
Seek a support group so that members may share their experiences.  
Acupuncture has been found to have efficacy similar to that of carbamazepine.  
*These interventions are implemented to address pain management through alternative measures. Acupuncture has been found to have efficacy similar to that of carbamazepine in some patients.*

### ■ Teaching

- Identify and avoid exacerbating factors (cold weather, drafts, etc.).  
*Because the pain can be severe and interfere with activities of daily living, it is important to minimize factors that cause or exacerbate the pain associated with this disorder.*
- The pain from trigeminal neuralgia can affect the patient's quality of life.  
*The nurse educates the patient about the medications that are prescribed, including side effects. Although AEDs are used for pain management, the patient should be educated that the indication is neuropathic pain, not epilepsy. The nurse may also suggest alternative methods of hygiene that may not aggravate an attack.*

### Connection Check 38.10

Which surgical approach is most effective for the patient with trigeminal neuralgia?

- Stereotactic radiosurgery
- Cervical decompression
- Microvascular decompression
- Percutaneous ablation

### Evaluating Care Outcomes

The patient may pursue medical management for trigeminal neuralgia due to the effects of pain on daily activities of daily living and quality of life. If medications do not prove to be effective, the patient may seek surgical evaluation. Proper pain management, either medical or surgical, allows the patient to achieve pain control and have improved quality of life. Inform the patient and family about resources, such as the Facial Pain Association.

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Jordan demonstrates increasing weakness and requires two nurses to assist her to the bathroom. Her speech remains slurred and is now incomprehensible. The nurse performs a neurological assessment and obtains a forced vital capacity. The vital capacity measurement is 0.8 L. Oxygen saturation is 95% on room air. The provider is notified of the vital capacity, and an arterial blood gas is drawn. The results are pH 7.28, PaCO<sub>2</sub> 70 mm Hg, PaO<sub>2</sub> 85 mm Hg, HCO<sub>3</sub> 25 mEq/L. The patient is moved to an intensive care setting, where she is intubated and placed on a mechanical ventilator. A neostigmine infusion is initiated in order to determine her anticholinesterase requirements during this acute phase of illness. The healthcare provider decides that Ms. Jordan will have five plasmapheresis treatments, and a dual-lumen plasmapheresis catheter is placed. She is scheduled to have her first plasmapheresis treatment performed at her bedside tomorrow.

After three additional plasmapheresis treatments, Ms. Jordan is able to be extubated and returns to the inpatient unit. Her vital capacity at this time is 1.5 L. She completes her final plasmapheresis treatment and is discharged home under the care of her husband. The nurse ensures that Ms. Jordan is knowledgeable of her medications and the importance of taking her medications at the exact time prescribed. Discharge teaching also focuses on clinical manifestations of myasthenic and cholinergic crises.

### Case Study Questions

- Ms. Jordan has been taking prednisone 20 mg daily for management of her MG. What side effects should she be monitored for during her hospitalization? (*Select all that apply.*)
  - Hyperglycemia
  - Weight gain
  - Cardiomegaly
  - Heart failure
  - Insomnia
- The autoimmune dysfunction in MG results from which process?
  - An overabundance of acetylcholine (ACh)
  - An inadequate amount of ACh
  - An inadequate amount of serotonin
  - Destruction of the postsynaptic membrane
- While caring for Ms. Jordan, the nurse monitors for which manifestations of a cholinergic crisis? (*Select all that apply.*)
  - Bradycardia
  - Angioedema
  - Diarrhea
  - Increased heart rate
  - Decreased saliva

4. During her hospitalization, Ms. Jordan receives plasmapheresis treatments. Following the plasmapheresis treatments, the nurse monitors Ms. Jordan for which complications? (*Select all that apply.*)
  - A. Hypotension
  - B. Stevens-Johnson syndrome
  - C. Galactorrhea
  - D. Hypocalcemia
  - E. Hypoglycemia
5. After the nurse provides patient education to Ms. Jordan, the patient states that by taking her medications as instructed and planning frequent rest periods in her day, she should expect which outcome?
  - A. She will succumb to her disease within 5 years.
  - B. Her symptoms will be controlled, and she can consider the disease cured.
  - C. She will be able to manage her disease and have quality of life.
  - D. She will not develop any respiratory complications.

## CHAPTER SUMMARY

The patient with a disorder of the peripheral nervous system (PNS) presents with many challenges and may be encountered in outpatient, inpatient, or intensive care settings. Careful neurological and respiratory assessments allow the nurse to identify deficits in order to prioritize care. It is important that the nurse is able to correlate the pathophysiology of the disorders to the patient's clinical presentation and rationales for treatment modalities.

Myasthenia gravis, an acquired autoimmune neuromuscular junction disorder, is caused by antibodies that are directed toward skeletal muscle nicotinic acetylcholine (ACh) receptors and muscle-specific kinase (MuSK). Patients with MG may be successfully managed with cholinesterase inhibitors. The patient and family must be aware of the clinical manifestations of both myasthenic and cholinergic crises and the importance of seeking medical attention quickly. Patient education plays a crucial role in the successful management of the patient. With adherence to prescribed medications and the treatment plan, patients are able to actively participate in family activities and a career.

Guillain-Barré syndrome (GBS), another disorder of the PNS, is an acute inflammatory demyelinating polyneuropathy. It often occurs after an infection and leads to a rapidly progressing flaccid paralysis due to peripheral nerve demyelination. The management of GBS focuses on supportive care and reducing severity, potential complications, suffering, and recovery time. Although GBS is an autoimmune disorder, steroids have not been found to help speed recovery. The two primary treatment modalities for GBS are intravenous immunoglobulin therapy (IVIg) and plasmapheresis.

Patients with trigeminal neuralgia are treated in a variety of healthcare settings ranging from outpatient offices to surgical suites. This disorder involves the fifth cranial nerve (CN), the trigeminal nerve, which is a mixed CN, meaning this nerve has both motor and sensory innervation that is responsible for facial sensation and the strength of the jaw. Trigeminal neuralgia is a pain disorder, and the patient seeks medical attention for relief. Medications are used in the treatment of trigeminal neuralgia. This includes the use of antiepileptic drugs (AEDs) such as carbamazepine, oxcarbazepine, or gabapentin. Microvascular decompression is the most effective surgical treatment for trigeminal neuralgia, with facial pain typically relieved within 24 to 48 hours, with no residual facial numbness.

## Coordinating Care for Critically Ill Patients With Neurological Dysfunction

*Elizabeth Zink*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of disorders of the nervous system requiring critical care management
2. Correlating the clinical manifestations to pathological processes of:
  - a. Increased intracranial pressure (ICP)
  - b. Stroke
    - Ischemic
    - Hemorrhagic
  - c. Traumatic brain injury
  - d. Neurogenic shock
3. Describing the indications and nursing implications for ICP monitoring in the critically ill patient
4. Explaining the rationales for relevant medical interventions in the treatment of patients with increased ICP, stroke, traumatic brain injury, and neurogenic shock
5. Discussing the nursing management of patients with increased ICP, stroke, traumatic brain injury, and neurogenic shock
6. Developing a teaching plan for patients with stroke and traumatic brain injury

### CONCEPTS

- Assessment
- Cognition
- Medication
- Neurological Regulation
- Oxygenation
- Perioperative

### ESSENTIAL TERMS

Agnosia  
Aneurysm  
Apraxia  
Arteriovenous malformation (AVM)  
Autoregulation

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mr. George Stewart, a 58-year-old male, begins slurring his speech, drooling from the left side of his mouth, and leaning to the left side during a meeting at work. His colleagues notify emergency medical services (EMS), and he is transported to the closest hospital. The EMS crew establishes that Mr. Stewart was last witnessed without stroke signs and symptoms at 12:15. He has a history of hypertension, high cholesterol, and smoking. He takes metoprolol (Lopressor or Toprol XL) and simvastatin (Zocor)...

## INTRODUCTION

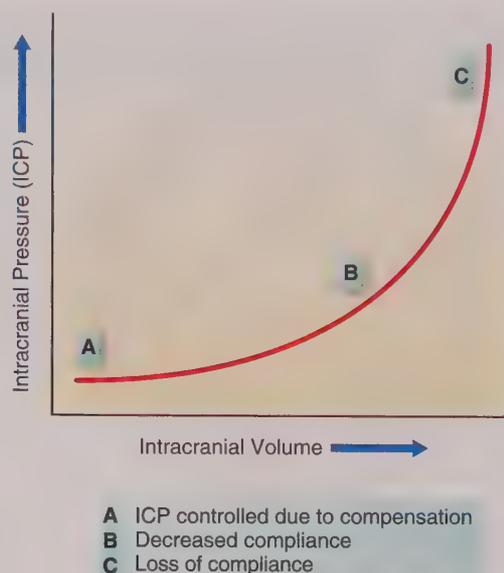

The emergent care of patients with injury or disease of the central nervous system requiring intensive care management is a subspecialty of critical care focused on the preservation of neurological function. Patients with disorders of the central nervous system often encounter or present with complications in other body systems; therefore, neuroscience critical care combines interprofessional neurological expertise with general critical care to treat this vulnerable patient population. Acute and critical care nurses working in the neurosciences are experts in performing and trending serial neurological assessments in order to detect neurological deterioration and facilitate rapid medical interventions to prevent further brain injury. Nursing expertise in general critical care and the neurosciences is necessary to optimize patient outcomes.

## INCREASED INTRACRANIAL PRESSURE

### Pathophysiology and Clinical Manifestations

Increased **intracranial pressure (ICP)** is best illustrated by the **Monro–Kellie doctrine**, which states that three components—brain tissue, blood, and cerebrospinal fluid (CSF)—occupy a rigid box, the skull. When one of these three components increases, the other components must decrease to maintain equilibrium, preventing further injury to the brain through compression of the tissue within the fixed box. The ability of the body to compensate by adjusting the levels of the components is called **intracranial compliance**.

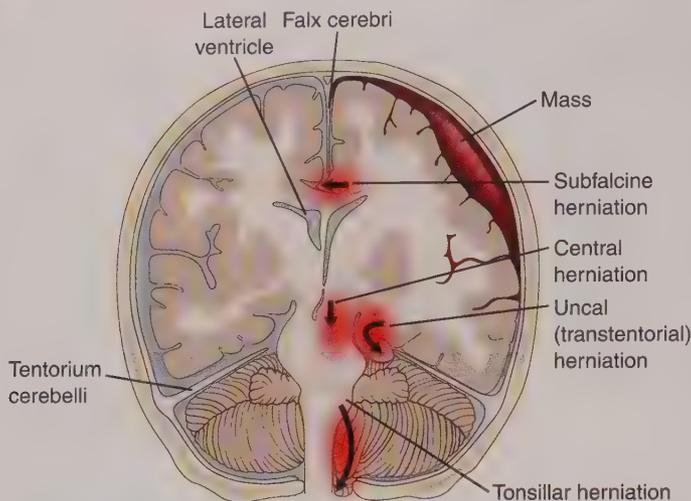

Brain tissue is composed primarily of water and makes up 80% of the intracranial contents, and blood and CSF each make up 10% of the remaining contents within the cranium. The most common initial method of intracranial compensation involves the displacement of CSF from the cranial vault down through the foramen magnum at the base of the skull and around the spinal cord. The pressure–volume curve (Fig. 39.1) depicts the body's ability to compensate for the

**FIGURE 39.1** Pressure–volume curve. Section A represents an incremental increase in volume where intracranial pressure is maintained and does not increase; this implies that compensation is occurring within the cranial vault to accommodate the increased volume. Section B represents an incremental increase in volume where intracranial pressure begins to rise with the addition of volume, implying a decrease in the ability to compensate for additional volume. Section C represents an incremental increase in volume where intracranial pressure rises disproportionately in response to the continued addition of volume. On this portion of the curve, compliance is extremely limited, and herniation may occur with the continued addition of volume.

addition of one or more of the three intracranial components without a significant increase in ICP until a critical volume is reached (A). At this point, continued accumulation of volume causes a disproportionate increase in ICP referred to as decreased compliance (B). Finally, on the last section of the curve, any addition in volume causes a sustained increase in ICP, which represents a loss of compliance (C). Loss of intracranial compliance leads to cerebral herniation syndrome, in which brain tissue is displaced, and if the displacement is not resolved, the brainstem becomes compressed, eventually causing brain death.

Cerebral **herniation syndromes** are classified according to the region of tissue that is displaced (Fig. 39.2). The most often recognized signs of cerebral herniation, increased systolic blood pressure (BP) with decreased diastolic BP (widened pulse pressure), bradycardia, and irregular respiratory pattern, actually occur late in the herniation process as the brainstem is compressed and are referred to as “**Cushing’s triad**.” Another frequently recognized late sign of increased ICP is a unilateral fixed and dilated pupil. This phenomenon occurs as the bottom portion of the temporal lobe or **uncus** is displaced through the tentorium cerebelli and compresses cranial nerve (CN) III (oculomotor nerve) and is called **uncal** or **transtentorial** (temporal lobes into the tentorium) herniation. Compression of the third cranial nerve produces pupillary dilation on the same side as the cranial nerve compression, or **ipsilateral** to the cranial nerve compression. Motor paresis accompanies pupillary

**FIGURE 39.2** Cerebral herniation syndromes: regions of tissue.

dilation on the opposite side, or **contralateral** to the site of herniation. Table 39.1 summarizes the types of cerebral herniation.

There are three types of cerebral edema—vasogenic, cytotoxic, and transependymal—which can impact intracranial pressure (Table 39.2). **Vasogenic edema** occurs when the **blood-brain barrier (BBB)** is disrupted. The BBB is made up of endothelial cells and astrocytes, which form tight junctions around capillaries, reducing the permeability of substances into the brain. Vasogenic edema primarily impacts white matter and is caused by leakage of fluids out of capillaries into the interstitial space. **Cytotoxic edema** does not impact the BBB and primarily involves individual cellular swelling caused by failure of the sodium-potassium pump. **Transependymal edema** is caused by increased pressure in the ventricular system that results in CSF moving into the brain parenchyma.

**Table 39.1** Cerebral Herniation Syndromes

Description	Clinical Manifestations
<p><b>Subfalcine or cingulate herniation</b></p> <p>In this type of herniation, brain tissue is shifted over and underneath the falx cerebri. One of the main concerns in this type of herniation is the risk of compression to the anterior cerebral artery, which could cause a stroke in this region of brain tissue.</p>	<p>Specific clinical manifestations of subfalcine herniation do not exist; however, this type of herniation may be found on a CT scan when evaluating clinical manifestations of increased ICP, such as decreased level of consciousness, unilateral weakness of extremities, or a change in pupillary assessment, and places the patient at risk for further herniation.</p>
<p><b>Central herniation</b></p> <p>Central herniation occurs when the structures of the diencephalon (e.g., thalamus, hypothalamus, pituitary gland) and the tips of both temporal lobes are displaced in a downward direction through the tentorium (portion of the dura that creates a separation between the occipital lobes and the cerebelli), compressing the brainstem.</p>	<ul style="list-style-type: none"> <li>● Abnormal flexion or extension (posturing)</li> <li>● Bilateral pupillary dilation</li> <li>● Abnormal eye movements such as downward and outward eye movements as cranial nerves controlling eye movements are compressed</li> <li>● Positive Babinski reflex</li> <li>● Coma</li> <li>● Cushing's triad (increased systolic blood pressure, bradycardia, and irregular respiratory pattern)</li> </ul>
<p><b>Uncal herniation</b></p> <p>In uncal herniation, an expanding lesion causes the tip of the temporal lobe (uncus) to shift downward and inward toward the midbrain and through the tentorium (portion of the dura that creates a separation between the occipital lobes and the cerebelli), compressing CN III. CN III is innervated by the parasympathetic nervous system, and stimulation of this nerve causes pupillary constriction. Compression of this cranial nerve causes dilation of the pupil and an inability to constrict (fixed and dilated pupil).</p>	<ul style="list-style-type: none"> <li>● Unilateral dilated pupil</li> <li>● Contralateral motor weakness or flexion/extensor posturing</li> <li>● Positive Babinski reflex</li> <li>● Coma</li> </ul>
<p><b>Tonsillar herniation</b></p> <p>Tonsillar herniation occurs, and the bottom portion of the cerebellar hemispheres (tonsils) descends through the foramen magnum, damaging the medulla.</p>	<ul style="list-style-type: none"> <li>● Abnormal flexion or extension (posturing)</li> <li>● Bilateral pupillary dilation</li> <li>● Positive Babinski reflex</li> <li>● Coma</li> <li>● Cushing's triad (increased systolic blood pressure, bradycardia, and irregular respiratory pattern)</li> </ul>

**Table 39.2** Types of Cerebral Edema

	Description	Treatment
<b>Vasogenic edema</b>	Vasogenic edema occurs when the blood–brain barrier (BBB) has been disrupted. The BBB is made up of endothelial cells and astrocytes, which are arranged around capillaries and between the capillary and extracellular fluid. Tight junctions between these cells regulate substances going in and coming out of the brain. For example, bacteria and hydrophilic molecules are not able to pass through the BBB. Active transport mechanisms allow substances such as glucose and some proteins to cross the BBB into the brain. Brain tumors cause disruption of the BBB by production of a substance called <i>vasogenic endothelial growth factor</i> (VEGF) that causes separations between the endothelial cells, resulting in increased permeability of the BBB.	Osmotic therapy (mannitol and/or hypertonic saline), hyperventilation, or surgical decompression
<b>Cytotoxic edema</b>	Cytotoxic edema occurs as a result of a decrease in oxygenation where cellular energy reserves are depleted and the sodium–potassium pump fails, causing an influx of sodium and water across the cell membrane. Accumulation of intracellular fluid can cause cell death. In this type of edema, the BBB is intact, and the damage may be reversible if oxygenation is restored.	Same interventions as vasogenic shock
<b>Transependymal edema</b>	This type of cerebral edema is caused by an increase in hydrostatic pressure in the ventricular system associated with hydrocephalus, which results in a leakage of cerebrospinal fluid out of the ventricles and into surrounding brain tissue.	Drainage of cerebrospinal fluid is the primary method of decreasing this type of edema.

Increased ICP is detected by performing serial neurological assessments, including the elements of wakefulness, arousal, cranial nerves, and motor function. The most sensitive indicator of ICP is a decrease in level of consciousness. In order to detect subtle changes in level of consciousness, it is imperative to establish an accurate baseline of functioning from which to judge deterioration. A series of questions that go beyond the basic elements of orientation to person, place, and time help to establish this baseline and include specifics of place or location and specifics about the patient's current state or situation (see Box 39.1 for additional orientation questions).

The clinical presentation of increased ICP may be subtle, particularly in the early stages, and is in sharp contrast to the presentation of cerebral herniation (Table 39.3). The clinical manifestations of increased ICP must be detected early in order to implement treatment and prevent herniation

syndrome. It is important to note that changes in vital signs reflect late changes as herniation occurs.

### Intracranial Pressure Monitoring

Intracranial pressure can be monitored using a catheter or sensor placed in one of the lateral ventricles of the brain, in the brain tissue or parenchyma, or in the subarachnoid space (Fig. 39.3). Intracranial pressure monitoring is an additional assessment tool used to trend a patient's response to medical treatments and progression of an intracranial process causing increased ICP (see Table 39.4 for types of ICP-monitoring devices). Recognized guidelines suggest that patients with traumatic brain injury (TBI) and a Glasgow Coma Scale (GCS) score of 8 or less have an ICP monitor placed. Normal ICP is 0 to 15 mm Hg and is typically treated in a stepwise approach when the pressure exceeds 15 mm Hg; however, this threshold is individualized to each patient depending on specific causes of increased ICP. **Cerebral perfusion pressure (CPP)** is a commonly used parameter to indirectly measure cerebral blood flow and is generally maintained above 60 mm Hg. Cerebral perfusion pressure is measured by subtracting ICP from mean arterial pressure (MAP):  $MAP - ICP = CPP$ .

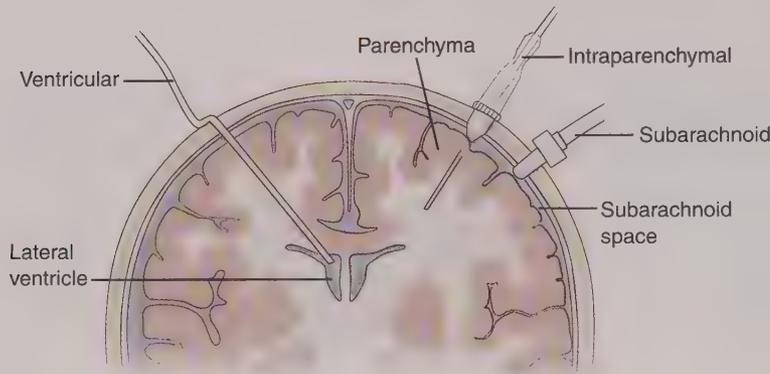

There are several different methods of monitoring ICP. The subarachnoid bolt (SAB), one of the oldest methods of ICP monitoring, uses a metal bolt, also referred to as a screw, inserted through a hole drilled in the skull and threaded into place at the inner table of the skull. The dura

### Box 39.1 Asking Expanded Orientation Questions

- What state are you in right now?
- What city are you in right now?
- What kind of place are we in right now?
- What floor are we on right now?
- Why are you here today?
- What are your children's/family members' names?

**Table 39.3 Increased Intracranial Pressure Versus Cerebral Herniation**

	Increased Intracranial Pressure	Cerebral Herniation
<b>Level of consciousness</b>	Progressive confusion and increasing lethargy	Unresponsive
<b>Pupillary assessment</b>	Sluggish reaction and ovoid shape	Unilateral or bilateral pupillary dilation (depending on type of herniation) without reaction
<b>Motor assessment</b>	Focal contralateral motor weakness	Contralateral hemiparesis including flexor or extensor posturing
<b>Vital signs</b>	No change	Cushing’s triad (increase in systolic pressure, widening of pulse pressure, bradycardia, and change in respiratory pattern)

**Table 39.4 ICP Monitoring Devices**

Monitoring Device	Advantages	Disadvantages
<p><b>Intraventricular catheter</b></p> <ul style="list-style-type: none"> <li>● This device and procedure are also commonly known as a ventriculostomy or external ventricular drain (EVD).</li> <li>● May be connected to a filled transducer system</li> <li>● May have an embedded ICP monitoring sensor/probe</li> </ul>	<ul style="list-style-type: none"> <li>● Ability to monitor pressure and drain CSF</li> <li>● Considered “gold standard” for ICP measurement because of the location of the tip of the catheter in the lateral ventricle</li> <li>● Can be inserted at the bedside or in the operating room (OR)</li> </ul>	<ul style="list-style-type: none"> <li>● Increased risk of infection, particularly when the catheter dwells for greater than 7 days</li> <li>● Measurement drift exists over time when pressure is transduced with a fluid-filled transducer system.</li> </ul>
<p><b>Intraparenchymal sensor/probe</b></p> <ul style="list-style-type: none"> <li>● Micro-strain gauge attached to the tip of a small catheter used to measure ICP</li> <li>● Fiberoptic technology used to measure ICP</li> </ul>	<ul style="list-style-type: none"> <li>● Accurate measurement of ICP with less mechanical drift of the measurement over time when compared to devices using a fluid-filled transducer to measure pressure</li> <li>● Can be inserted at the bedside or in the OR</li> </ul>	<ul style="list-style-type: none"> <li>● Inability to drain CSF</li> </ul>
<p><b>Subarachnoid bolt (SAB)</b></p> <ul style="list-style-type: none"> <li>● Bolt or screw connected to a fluid-filled transducer system</li> </ul>	<ul style="list-style-type: none"> <li>● Can be inserted at the bedside or in the OR</li> <li>● Lower rate of infection when compared to the IVC because the SAB does not have a fluid reservoir</li> </ul>	<ul style="list-style-type: none"> <li>● Inability to drain CSF</li> <li>● Inaccuracy of measurement due to measurement drift that is inherent with a fluid-filled transducer system</li> </ul>

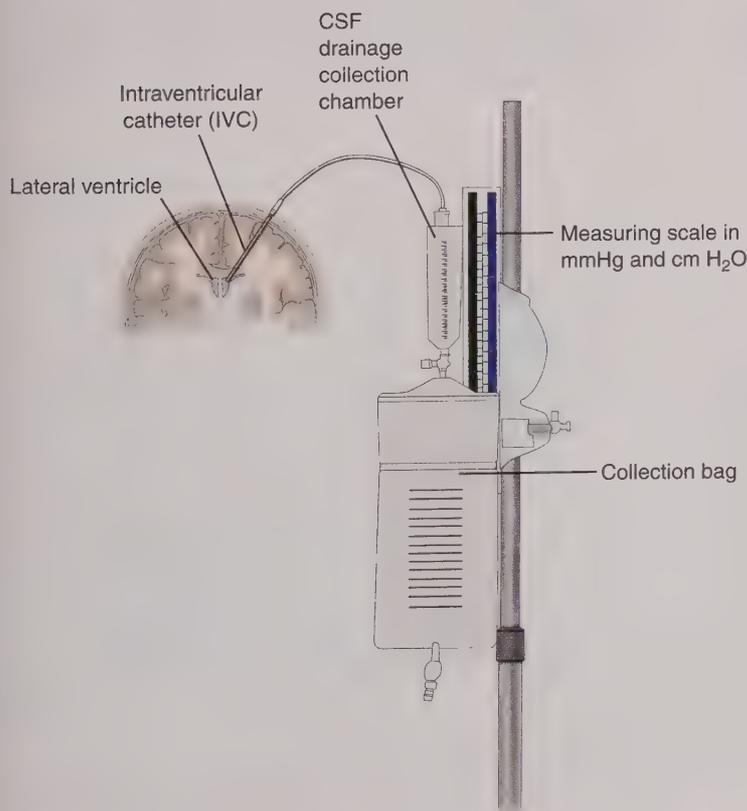

CSF, Cerebrospinal fluid; ICP, intracranial pressure.

is incised so that when the bolt is connected to a pressure transducer, pressure is transmitted from the subarachnoid space to the monitor via the transducer. The bolt may be placed in the operating room or at a patient's bedside under sterile conditions. The advantage of this device is that it has a decreased risk of infection when compared to ICP-monitoring systems that also drain fluid. The disadvantages of this device relate to its inability to drain CSF; the system's susceptibility to significant measurement drift (ability to maintain accurate measurements over time); and the risk of the bolt becoming occluded with blood, tissue, or dura. The pressure transducer is typically leveled to the insertion site of the bolt and zero balanced according to specific facility policies. The purpose of leveling the transducer to the insertion site of the SAB is to ensure that pressure is measured near the tip of the device in the brain in order to obtain an accurate reading. The leveling process with the SAB and transducer is similar to the process of leveling a transducer at the phlebostatic axis to measure central venous pressure. Subarachnoid bolt placement is also used in order to introduce probes into the brain parenchyma for monitoring. The bolt in this case provides a secure method for insertion and maintenance of probes that may measure multiple parameters, including ICP, temperature, brain oxygen, cerebral blood flow, and brain metabolism.

Intraparenchymal probes are inserted below the dura into the white matter in one of the frontal lobes of the brain to monitor ICP. The right frontal lobe is often chosen in

order to avoid interference with the language center, housed in the left hemisphere for many patients. This type of monitor also may be inserted in the operating room or at a patient's bedside. The technology used in these ICP-monitoring devices is reported to have less measurement drift over time than the SAB, which improves the accuracy of ICP measurement. This type of monitor does not have an external transducer that must be leveled in order to obtain an accurate pressure because the monitor is calibrated prior to insertion. Because of the placement in the brain tissue, CSF drainage is not possible.

The intraventricular catheter (IVC) with external ventricular drain (EVD), or ventriculostomy, is used for monitoring ICP and draining CSF (Fig. 39.4). The tip of the IVC is placed into one of the lateral ventricles in the brain using external landmarks or image guidance in some cases. The catheter is placed under sterile conditions at the bedside or in the operating room and is connected to an external drainage system with a pressure transducer for ICP monitoring. An alternative method of monitoring ICP is to place an intraparenchymal ICP-monitoring probe with the IVC, eliminating the need for attachment of a pressure transducer. The CSF drainage system is leveled to the external auditory meatus of the ear, which approximates the foramen of Monro or the tip of the IVC in the ventricle. Drainage of CSF is controlled by raising or lowering a collection burette above or below this leveling point.

**FIGURE 39.4** Cerebrospinal fluid drainage using an external ventricular drainage system (ventriculostomy).

Most external ventricular drains have a measuring scale printed on the device allowing measurements in millimeters of mercury (mm Hg) or centimeters of water (cm H<sub>2</sub>O). If the drainage burette is set to 5 mm Hg while leveled at the external auditory meatus, CSF will drain when ICP reaches 5 mm Hg. The CSF can be drained continuously using the method of setting a pressure threshold described previously, or the drain may be closed until ICP reaches a predetermined level, and then the drain is opened to drain at a specific level in relation to the leveling point. When a pressure transducer is attached to the drainage system, a stopcock controls whether CSF is drained or pressure is monitored. An accurate ICP can be monitored only when the drainage system is closed to CSF drainage. The drainage system must be correctly leveled after the head of the bed is repositioned to safely drain CSF. Prior to connection to the patient, the external ventricular drain is flushed with preservative-free normal saline and purged of all air bubbles. Preservative-free saline solution rather than bacteriostatic normal saline is used to flush the system because of a concern for meningeal inflammation, as bacteriostatic saline contains benzyl alcohol. It is important to maintain the system as a closed system to prevent infection.

The drainage system and catheter are generally not changed on a routine basis in order to maintain the sterility of the system. Cerebrospinal fluid cultures may be drawn through a designated port or stopcock located near the insertion point on the head when indicated. The major advantage of the IVC is that it is a monitor and a method of treatment for ICP. The major disadvantages include a higher rate of infection than other methods (approximately 6%) and a risk of bleeding along the catheter tract. A higher incidence of infection in patients with an IVC with external drain may be explained by the connection of the fluid-filled ventricular system to the external environment, which can act as a reservoir for microorganisms.

Complications of CSF drainage include infection, overdrainage of CSF, and introduction of air into the ventricular system if proper leveling is not maintained. If an excessive amount of CSF is drained rapidly through an IVC, a **subdural hematoma** (collection of blood in the subdural space) can result because of contraction of brain tissue that stretches the small bridging blood vessels traversing the space between the dura and brain tissue. When these bridging blood vessels are stretched, tearing can occur, causing a subdural hematoma. Overdrainage of CSF through an IVC may also cause the cerebellar tonsils to “sag” into the foramen magnum, resulting in pressure on the brainstem. Overdrainage of CSF can be prevented by maintaining proper leveling of the drainage system (0 point on drainage system leveled at the external auditory meatus) and proper adjustment of the drainage burette at the ordered level above the external auditory meatus.

It is important to note that ICP values may not always be representative of ICP in all areas or compartments of the brain. For example, most ICP-monitoring devices are

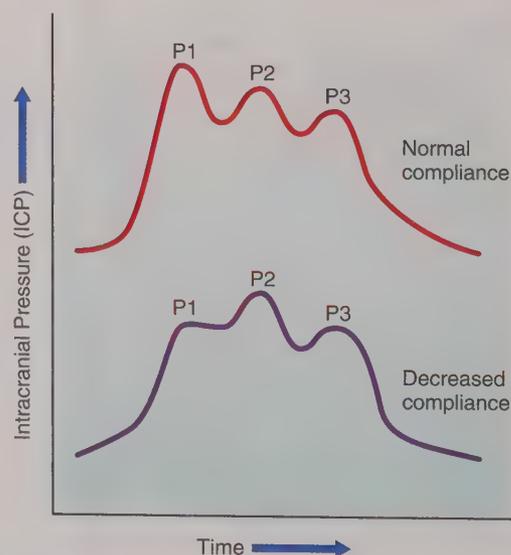

placed in the **supratentorial** (above the tentorium cerebelli) space; cerebral edema may cause the **infratentorial** (below the tentorium cerebelli) space to be compartmentalized such that pressures are higher than those measured in the supratentorial space. For this reason, cerebral herniation may occur in the presence of normal ICP.

The ICP waveform produced by all three of the previously described monitoring methods is a pulsatile waveform made up of three waves, numbered P1, P2, and P3 (Fig. 39.5). In cases of decreased intracranial compliance, the P2 wave is elevated above the P1 and P3 waves.

### Connection Check 39.1

The nurse is caring for a patient status post-craniotomy for resection of a right frontal tumor. Upon admission, the patient was alert and oriented to person, place, and time and moving all extremities symmetrically, and the cranial nerves were intact. Three hours after admission, the nurse notes that the patient is slower to awaken than during previous assessments, requiring vigorous shaking, and cannot recall location. The patient also exhibits a left pronator drift. What are the nurse's next actions?

- Notify the patient's provider and prepare the patient for a computed tomography (CT) scan.
- Record vital signs and prepare to draw blood for serum osmolality.
- Notify the patient's provider and prepare the patient for a magnetic resonance imaging (MRI) scan.
- Prepare to hang a fluid bolus and notify the patient's provider.

**FIGURE 39.5** Intracranial pressure (ICP) waveform. The ICP waveform produces three waves, numbered P1, P2, and P3. In cases of decreased intracranial compliance, the P2 wave is elevated above the P1 and P3 waves.

## Management

### Medical Management

Treatment of increased ICP is based on decreasing the volume of brain water, blood, or CSF in the intracranial space. The initial approach to the emergency management of increased ICP consists of airway management and therapies to decrease intracranial contents, such as administration of an osmotic diuretic and hyperventilation (see following discussion of specific therapies). Vigilant monitoring of the patient's neurological status is critical during treatment because there may be subtle changes in level of consciousness that may indicate further compromise. Research in the area of additional bedside neuromonitoring technologies, such as brain oxygen probes, digital quantitative pupillary assessment, cerebral blood flow probes, microdialysis probes sampling extracellular fluid metabolites, and cerebral oximetry, is emerging. It is thought that these therapies may complement traditional monitoring methodologies, such as the clinical assessment, ICP, and CPP, and could be helpful in helping the interprofessional team customize therapy to each patient.

### Connection Check 39.2

A patient is admitted to the neuroscience intensive care unit (NICU) after a TBI. If the goal of ICP monitor insertion is to measure ICP and drain CSF to control ICP, what device should the nurse anticipate being inserted?

- Intraparenchymal sensor
- Epidural sensor
- Intraventricular catheter
- Subarachnoid bolt

### Diagnosis

Radiographic imaging of the brain, typically a computed tomography (CT) scan, is necessary to determine the cause of increased ICP (e.g., collection of blood, cerebral edema). Laboratory testing such as serum osmolality and arterial blood gas (ABG) testing is necessary to guide medical treatments (Table 39.5).

**Table 39.5 Diagnostic Tests Used in the Management of Increased Intracranial Pressure (ICP)**

Diagnostic Test	Explanation	Nursing Considerations
<b>Computed tomography* (CT) scan of the head</b>	The CT scan uses x-rays to obtain many cross sections or slices of the head and brain. A computer is used to sequence the delivery and position of x-ray beams and movement of the patient through the machine to allow detailed views of the skull, brain structures and tissue, facial bones, or sinuses depending on the reason for obtaining the CT scan. Reducing the thickness of the cross-sectional images and increasing the number of images enhance the detail of the scan. A disadvantage of the CT scan is the reduced ability to visualize the lower portion of the cerebellum and the brainstem structures (midbrain, pons, and medulla). Magnetic resonance imaging (MRI) is an imaging tool used to visualize these structures (see below for information on MRI). A CT scan is the most common test performed in critically ill patients with a deterioration of neurological status, such as a decrease in level of consciousness, new motor deficit, or new cranial nerve deficit, because the test can be performed quickly. The CT scan is first obtained without the injection of IV contrast material to visualize brain structures and detect bleeding. Images may be obtained after IV contrast is administered if a mass (brain tumor, abscess) is suspected because IV contrast material travels into brain tissue where the blood–brain barrier has been disturbed. A mass is said to “light up” on a	<ul style="list-style-type: none"> <li>Transport of a patient with increased ICP is a challenge and must be performed with the right team and the right equipment. Depending on the stability of the patient, providers, nurse practitioners, or respiratory therapists may have to accompany the nurse to ensure continuity of care from the intensive care unit (ICU) to the procedure area. See Evidence-Based Practice Box regarding patient transport for more information on best practice for transporting a critically ill patient.</li> <li>If contrast material is expected to be given, risk factors for contrast-induced nephropathy (CIN), such as hypotension, diabetes, and chronic kidney disease, should be assessed and serum creatinine (within 24 hours of test) should be evaluated because contrast can damage the kidney. If a patient is at risk for CIN, strategies to prevent CIN, including prehydration with IV saline, administration of a bicarbonate-based IV solution, or administration of <i>N</i>-acetylcysteine (Mucomyst) IV, may be employed. In emergent situations, full assessment of risk factors and prevention strategies may not be undertaken because of the urgency of obtaining needed scans to guide further care. The serum creatinine should be monitored at least once after the contrast administration in the critically ill patient and more often if acute kidney injury is suspected. Typically, an increase in serum</li> </ul>

*Continued*

**Table 39.5 Diagnostic Tests Used in the Management of Increased Intracranial Pressure (ICP)—cont'd**

Diagnostic Test	Explanation	Nursing Considerations
	<p>contrasted CT scan because the blood–brain barrier has been disrupted and contrast material has infiltrated the interstitial space in and around the mass. A noncontrast CT scan must be performed before the administration of contrast if bleeding is suspected because the contrast material and blood appear the same color (white) in the brain tissue, making detection of blood very difficult for a period of time after contrast has been administered.</p>	<p>creatinine of at least 0.5 mg/dL is expected, which will decrease over 24–48 hours.</p> <ul style="list-style-type: none"> <li>● Because of the exposure to ionizing radiation, a pregnancy test should be performed in women of childbearing age, and the abdomen should be shielded if no alternative to the CT scan exists.</li> <li>● Assess the patient's ability to remain still during the procedure because movement of the head causes decreased clarity (artifact) of the images, which could obscure an abnormality. Patients with increased ICP may be confused, restless, or agitated, requiring sedation or anxiolysis to ensure capture of high-quality images.</li> <li>● Assess the patient's ability to lie flat during the scan. Patients with congestive heart failure or lung disease may not be able to maintain adequate oxygenation while lying flat, as evidenced by decreased oxygen saturation and increases in work of breathing and restlessness. If the patient cannot lie flat for at least 5 minutes, the healthcare team should be made aware to consider another test or a strategy to manage the patient during the test.</li> <li>● Assess allergy to iodine or shellfish because a patient with these allergies may also be allergic to some contrast agents.</li> <li>● Assess the patient's IV access if IV contrast will be administered during the CT; a larger-gauge peripheral IV catheter (typically an 18-gauge) is required for administration of the contrast through a device called a <i>power injector</i>. Certain types of central lines called <i>power injectable lines</i> may also be able to be utilized for this type of contrast injection.</li> </ul>
<p><b>Computed tomography angiography (CTA)</b></p>	<p>A CTA scan uses the radiographical technique described above to visualize cerebral arteries, such as the carotid and vertebral arteries, as they enter the skull and join the circle of Willis. The circle of Willis is also visualized. A computer is used to reconstruct the images obtained to create three-dimensional representation of the cerebral vasculature. This type of scan may be obtained if injury to a blood vessel or blockage of the blood vessel is suspected. A CTA scan requires the administration of IV contrast material.</p>	<ul style="list-style-type: none"> <li>● See above for nursing considerations.</li> </ul>
<p><b>Computed tomography perfusion (CTP) scan</b></p>	<p>A CTP scan may be used to detect evidence of reduced blood flow (ischemia) to a region of brain tissue supplied by a particular blood vessel; a CTP scan requires the administration of IV contrast material.</p>	<ul style="list-style-type: none"> <li>● See above for nursing considerations.</li> </ul>

**Table 39.5 Diagnostic Tests Used in the Management of Increased Intracranial Pressure (ICP)—cont'd**

Diagnostic Test	Explanation	Nursing Considerations
<b>Magnetic resonance imaging (MRI)</b>	An MRI scan uses a magnetic field and radiofrequency waves to change the alignment of protons in water molecules, which then release energy (photons) that can be detected by the scanner and sent to a computer for reconstruction of images in different planes and in three dimensions. This type of scan does not utilize ionizing radiation and produces detailed images of soft tissue structures such as the brain, spinal cord, blood vessels, and ligaments. Different protocols containing different scanning modalities can be programmed into the scanner by a technologist to target specific organ systems or disease processes.	<ul style="list-style-type: none"> <li>● Patients must be screened for metal that may be embedded in and around the eyes (metal workers and welders) or in any other part of the body, including joint implants, cardiac stents, pacemakers, and other implanted devices. If the patient has a history of working with metal, x-rays may be requested by a radiologist to locate or rule out the existence of metal fragments. During MRI, implanted metal can heat up, causing tissue damage. Certain implanted devices, such as a pacemaker or deep brain stimulator (used in patients with movement disorders), may malfunction. Patients may not be able to have MRI because of these factors. An MRI clearance form is often used by MRI technicians to ensure that a patient is safe to be scanned.</li> <li>● Transport of critically ill patients to MRI requires planning because the time to acquire the images is longer than a CT scan, and cardiorespiratory monitoring has to be changed to an MRI-compatible monitoring system. Additionally, IV fluids or other necessary infusions have to be changed to an MRI-compatible infusion pump or lengthened with extension tubing so that the pump does not enter the room. Patients receiving mechanical ventilation must be changed over to an MRI-compatible ventilator. Conventional medical equipment, including cardiac monitors, ventilators, infusion pumps, oxygen tanks, and IV poles, may not enter the MRI scanning room because the strong magnetic field may pull metal equipment into the magnet, which could injure a patient or staff in the room. Many devices do not operate properly in the strong magnetic field.</li> <li>● Assess the patient's ability to remain still during the procedure because movement of the head causes decreased clarity (artifact) of the images, which could obscure an abnormality. Patients with increased ICP may be confused, restless, or agitated, requiring sedation or anxiolysis to ensure capture of high-quality images. Many patients know that they are claustrophobic and require anxiolysis (benzodiazepines are commonly used for this purpose) in order to enter the small scanning tube of the MRI scanner. A pregnancy test should be performed prior to scanning a woman of childbearing age so that appropriate precautions may be applied depending on the stage of pregnancy and in consultation with a radiologist.</li> </ul>
<b>Electroencephalogram (EEG)</b>	An EEG records electrical activity in different regions of the cerebral cortex. An EEG is commonly used to detect seizure activity but can also be used to identify areas of abnormal wave patterns indicating brain	<ul style="list-style-type: none"> <li>● A patient must be completely still for an EEG because any movement, including shivering, is recorded as artifact and obscures the electrical tracing. Some patients may require mild sedation to reduce movement artifact on the</li> </ul>

Continued

**Table 39.5 Diagnostic Tests Used in the Management of Increased Intracranial Pressure (ICP)—cont'd**

Diagnostic Test	Explanation	Nursing Considerations
<b>Serum osmolality</b>	<p>tissue dysfunction from a variety of causes. Continuous EEG monitoring is frequently used in the ICU to detect seizure activity on an ongoing basis and to guide treatment for status epilepticus. An EEG may be used as a test to confirm the cessation of electrical activity in the brain when brain death is suspected. A neurologist with specialized training in the interpretation of EEGs provides an official reading of the EEG tracing.</p> <p>This blood test is used to monitor the diuretic effect of osmotic diuretics such as mannitol (Osmitol). Osmotic diuretics cause interstitial fluid throughout the body to shift into the vascular space, where it is filtered and eliminated by the kidneys, causing dehydration. This action is necessary to treat edema in the brain; however, severe dehydration, as indicated by a rising serum osmolality, can cause renal failure. Mannitol is typically not given if the serum osmolality reaches 320 mOsm/kg in order to prevent acute kidney injury.</p>	<p>EEG recording. The EEG technician records the amount of medication given so that the tracing can be interpreted in the context of sedation administration.</p> <ul style="list-style-type: none"> <li>● During continuous EEG monitoring, the scalp electrodes are typically placed by an EEG technician, and the patient's head is wrapped in a bandage to keep the electrodes in place. It is important that the nurse inspects the head to ensure that all electrodes are in place so that the EEG recording is continuous.</li> <li>● Ensure that the blood sample for serum osmolality is drawn within 1–2 hours of osmotic diuretic administration.</li> </ul>
<b>Serum sodium</b>	<p>Serum sodium is monitored when targeting a specific level of solute concentration (sodium concentration) in the blood with the administration of hypertonic saline solutions. A target above the normal sodium range (135–145 mEq/L) is chosen on the basis of the severity of cerebral edema and the specific disease process. A goal sodium range above 145 mEq/L and typically less than 160 mEq/L is set, and serum sodium is measured every 4–6 hours to ensure that the goal is achieved and not exceeded. Disorders of sodium imbalance occur frequently in the neurosurgical population for reasons that are not clearly understood. Common disorders of sodium imbalance in this population are syndrome of inappropriate antidiuretic hormone (SIADH), diabetes insipidus (DI), and cerebral salt-wasting syndrome (CSW, also called renal salt-wasting syndrome). See Chapter 8 for more information on electrolyte imbalance.</p>	<ul style="list-style-type: none"> <li>● Serum sodium should not rise by more than 10 mEq/L in 24 hours for patients who have chronic hyponatremia. If sodium levels rise too quickly in a patient with chronic hyponatremia, a disorder called <i>central pontine myelinolysis</i> may result. Central pontine myelinolysis causes damage to myelin (the sheath covering neurons to enhance speed of impulse transmission) in the pons, resulting in a decrease in neuronal transmission in the pons. Features of this disorder may include generalized weakness on both sides of the body, quadriplegia in severe cases, lethargy, and paralysis of eye movements.</li> <li>● In patients with cerebral edema, a decrease in serum sodium may affect the level of consciousness because of an exacerbation of cerebral edema.</li> </ul>

\*Computed tomography (CT) and computed axial tomography (CAT scan) refer to the same type of diagnostic examination; *CT scan* is the newer term, and *CAT scan* is the older term. The CT scan is completely known as *computed tomography*, whereas the CAT scan, in full, is *computed axial tomography*. In some references, CAT can also be the acronym for *computerized axial tomography*, but it still refers to the same test.

## Medications

The volume of water in brain tissue observed in cerebral edema is reduced by increasing the osmolality of the blood (increasing solute in the blood), thereby changing the osmotic gradient, resulting in diffusion of water from an

area of low concentration (brain tissue) to an area of high concentration (the blood). Medications such as mannitol (Osmitol) and high-concentration sodium chloride solutions (e.g., 3%) are used to increase the osmolality in the blood in order to pull water from the interstitial space

of the brain and other tissues into the vascular space. Mannitol pulls water from the interstitial spaces into the vascular space, and then diuresis occurs at the level of the kidney (see Evidence-Based Practice: Mannitol for Treatment of Traumatic Brain Injury). High-concentration sodium chloride solutions pull water from the interstitial spaces into the vascular space without the dramatic fluid shifts caused when osmotic diuretics are utilized. In order to compensate for the systemic dehydration and hypovolemia that occur with the administration of mannitol, IV fluid should be administered to replace losses. It is important to note that there are advantages and disadvantages in using osmotic diuretics and high-concentration sodium solutions; however, studies have not yet demonstrated an advantage of one regimen over the other, which results in differing practices to accomplish the removal of excess fluid volume from brain tissue.

### Evidence-Based Practice

#### Mannitol for Treatment of Traumatic Brain Injury

Mannitol has been used for more than 50 years to manage intracranial pressure (ICP). This study used the Medline, Embase, and PubMed databases to systematically search for randomized controlled studies (RCTs) that focused on the use of mannitol in critical care and perioperative areas. Meta-analyses examined mannitol's effects on ICP, cerebral perfusion pressure (CPP), mean arterial pressure (MAP), brain relaxation, fluid intake, urine output, and serum complications, as well as complications associated with mannitol administration. A total of 55 RCTs were identified, and 7 meta-analyses were conducted. In traumatic brain injury, mannitol was found to cause differences in sodium levels, but it had little impact on MAP when compared with the administration of hypertonic saline. Hypertonic saline was also more effective in leading to satisfactory brain relaxation in patients after craniotomy in comparison to mannitol. Complications associated with mannitol administration included hyponatremia, hyperkalemia, and acute kidney injury. Although the use of mannitol is effective in accomplishing short-term clinical goals, more research is needed, particularly in comparison with hypertonic saline and regarding the long-term outcomes for mannitol.

Zhang, W., Neal, J., Lin, L., Dai, F., Hersey, D. P., McDonagh, D. L., ... Meng, L. (2018). Mannitol in critical care and surgery over 50+ years: A systematic review of randomized controlled trials and complications with meta-analysis. *Journal of Neurosurgical Anesthesiology*. Advance online publication. doi:10.1097/ANA.0000000000000520.

### CASE STUDY: EPISODE 2

Mr. Stewart's presenting signs and symptoms and time course of symptoms (abrupt) are indicative of acute ischemic stroke. However, these signs can also indicate increased ICP due to a mass lesion, in particular, an intracerebral hemorrhage (ICH) that involves bleeding into the brain tissue. Exclusion of hemorrhage as a cause of presenting signs and symptoms can be undertaken with a noncontrast head CT scan that can enable a provider to detect a haemorrhage...

#### Physical Interventions

Blood volume in the intracranial space may be decreased by raising the head of the bed to greater than 45 degrees to facilitate drainage of venous blood through the jugular venous system. Positioning a patient so that the neck is in a neutral position and hip flexion is minimized also assists in facilitating venous drainage from the head. Further reduction of blood volume in the intracranial space may be accomplished through hyperventilation. Increasing the respiratory rate either through manual ventilation or the use of a resuscitation bag or mechanical ventilator causes an increased clearance of carbon dioxide and constriction of cerebral blood vessels. The consequence of hyperventilation is global cerebral vasoconstriction, which may result in ischemia to uninjured brain tissue. Established guidelines used for the management of patients with severe TBI recommend that arterial carbon dioxide ( $\text{PaCO}_2$ ) be maintained in the range of 30 to 35 mm Hg when hyperventilation is employed to decrease ICP. The external drainage of CSF is an effective method for rapidly decreasing increased ICP (see previous discussion). Drainage of CSF may be continuous or intermittent according to the patient's specific needs.

#### Safety Alert Patient Care Activities in Patients With Increased Intracranial Pressure

When caring for a patient with increased ICP, it is important for the nurse to evaluate the patient's response to movements such as turning, side-lying, and lying flat. The optimal position for a patient with increased ICP and *decreased intracranial compliance* (inability to compensate for increase in intracranial contents) is thought to be 45 to 90 degrees with the neck in a neutral position in order to promote drainage of venous blood through jugular veins in the neck. The nurse can evaluate the patient's response by assessing the patient's ICP during a given activity and noting how quickly the ICP value returns to baseline after the activity is completed. Patients may tolerate routine patient care activities such as bathing, turning, and lying flat for diagnostic

tests such as x-rays, and other patients may not. In situations where increased ICP does not respond to standard treatments, barbiturates such as pentobarbital can be used to induce a coma, significantly reducing metabolic demands in the brain (Table 39.6). When a barbiturate coma is initiated, other sedatives and analgesic medications are discontinued. Pentobarbital often causes vasodilation of the peripheral blood vessels and myocardial depression, requiring management with vasoactive medication to regulate blood pressure. Advanced hemodynamic monitoring such as a pulmonary artery catheter may also be initiated.

### Surgical Management

Refractory increased ICP may also be managed by removing a section of the cranium and dura in order to create space for the swelling brain. This neurosurgical procedure is called a **hemicraniectomy** with a **durotomy** and involves the removal of a section of the skull and opening of the dura. The skull is removed and typically stored in a tissue bank or stored in a tissue pocket within the patient's abdomen. The dura is replaced with a synthetic material that allows for brain tissue expansion and watertight closure of the meningeal layer.

### Nursing Management

#### Assessment and Analysis

Vigilant serial assessments of a patient's neurological status are necessary to identify neurological deterioration that places a patient at risk for increased ICP and cerebral herniation syndrome. Assessments of oxygenation, ventilation, and hemodynamic parameters are necessary to optimize therapy and prevent or mitigate brain injury. Performing a full systems assessment assists the nurse in identifying signs of complications or conditions that may negatively impact the patient with increased ICP, such as respiratory compromise. Assessment of laboratory values such as serum electrolytes and serum osmolality is necessary to detect electrolyte imbalance and dehydration, which can lead to renal insufficiency or failure.

Patients in a barbiturate coma are monitored using ICP monitoring, and in some cases electroencephalogram (EEG) recordings are used to document suppression of electrical activity in the brain. Medication levels may also be monitored, particularly when the dosage is decreased. The ability to elicit a neurological assessment from a patient in a barbiturate coma is limited because of the suppression caused by the medication; therefore, other parameters, such as pupillary size and reaction and corneal reflexes, must be trended. The nurse must ensure that the following safety measures are performed: application of moisture chambers with artificial tears to prevent corneal

**Table 39.6 Common Sedatives Used in the Treatment of Increased ICP**

Medication	Usual Dosage	Nursing Considerations
<b>Morphine sulfate</b>	Continuous infusion, 2–10 mg/hr and titrated to a pain and sedation scale target	<ul style="list-style-type: none"> <li>● Patients should have a secure airway (typically an endotracheal tube) in place when any one of these continuous infusions is initiated in order to ensure that retention of carbon dioxide (hypercarbia) does not occur. Hypercarbia causes cerebral blood vessel dilation, resulting in increased cerebral blood volume and increased ICP.</li> </ul>
<b>Midazolam (Versed)</b>	Continuous infusion, 2–4 mg/hr and titrated to a sedation scale target	<ul style="list-style-type: none"> <li>● These infusions should be titrated to the desired effect, either a goal ICP measurement or a specific rating on a validated sedation scale such as the Nursing Instrument for the Communication of Sedation Scale (NICS) or the Richmond Agitation Sedation Scale (RASS).</li> </ul>
<b>Fentanyl (Sublimaze)</b>	Continuous infusion, 25–100 mcg/hr and titrated to a sedation scale target	<ul style="list-style-type: none"> <li>● Propofol infusion syndrome (PrIS) may occur in patients receiving propofol for greater than 48 hours or in patients receiving high doses of propofol (greater than 75 mcg/kg/min). Clinical manifestations of PrIS include acidosis, hyperkalemia, hyperlipidemia, and rhabdomyolysis causing acute kidney injury.</li> </ul>
<b>Propofol (Diprivan)</b>	Continuous infusion, 50–200 mcg/kg/min and titrated to a target sedation goal or ICP threshold	<ul style="list-style-type: none"> <li>● It is important to note that propofol is not an analgesic; therefore, if the patient is suspected to be in pain, it is important to advocate for medication to treat pain in addition to the sedative.</li> <li>● These infusions should be titrated to the desired effect, either a goal ICP measurement or a specific rating on a validated sedation scale such as the NICS or RASS.</li> </ul>

ICP, Intracranial pressure.

From Brain Trauma Foundation, American Association of Neurological Surgeons, & Congress of Neurological Surgeons. (2017). Guidelines for the management of severe traumatic brain injury, 4th edition. *Journal of Neurosurgery*, 80(1), 6–15.

injury and frequent repositioning to prevent pressure injury.

Continued monitoring of ICP, neurological assessment, and vital signs continues after hemicraniectomy. Nursing and medical management of increased ICP requires the collection and synthesis of many data points in order to adjust and optimize treatment and a positive functional outcome. Clinical manifestations of increased ICP, including subtle changes in level of consciousness, increased blood pressure, decreased pulse rate, widening pulse pressure, changes in respiratory pattern, and pupillary changes, are reported immediately to the healthcare provider in order to ensure prompt intervention to decrease chances of permanent neurological injury.

### Nursing Diagnoses

- **Ineffective airway clearance** related to diminished protective reflexes (cough, gag)
- **Ineffective breathing patterns** related to neurological dysfunction (brainstem compression, structural displacement)
- **Ineffective cerebral tissue perfusion** related to cerebral edema, hemorrhage, or hydrocephalus
- **Fluid volume deficit** related to osmotic diuretic administration
- **Ineffective thermoregulation** related to damage to the hypothalamus
- **Interrupted family processes** related to unresponsiveness of the patient; unpredictability of the outcome; prolonged recovery period; and the patient's uncertain residual physical, emotional, and cognitive disabilities

### Nursing Interventions

#### ■ Assessments

- Serial neurological assessments every 1 to 2 hours in the critical phase, decreasing in frequency as the risk of cerebral edema and secondary brain injury decreases  
*Serial neurological assessments are necessary to trend a patient's response to injury and to detect subtle neurological changes, such as a decrease in level of consciousness or new motor weakness, signaling increased ICP. Changes in level of consciousness are earlier clinical manifestations of increased ICP as compared with changes in vital signs (Cushing's triad) and motor activity. At change of shift, it is important for the oncoming nurse to complete a neurological assessment with the nurse leaving so that subtle patient findings are consistently trended and documented.*
- Vital signs and oxygen saturation (SpO<sub>2</sub>) every 1 to 2 hours  
*Trending of vital signs is necessary to detect changes that may signal hemodynamic or neurological instability. In herniation syndrome, the systolic BP rises, and the diastolic remains normal or is lowered, resulting in a widened pulse pressure. The HR is decreased, and the respiratory pattern is irregular. Prompt identification of hypotension and decreased oxygenation (SpO<sub>2</sub>) is important in preventing further brain injury resulting from decreased perfusion and oxygenation.*

- Temperature every 1 to 2 hours  
*Temperature elevations may indicate damage to the hypothalamus. Increasing cerebral metabolism may exacerbate existing brain injury by increasing the demand for oxygen and nutrients where there is existing poor blood flow (ischemia).*
- Intracranial pressure and CPP every 1 to 2 hours or more frequently if the patient is experiencing an increase in ICP and/or a deterioration of neurological assessment  
*Intracranial pressure and CPP are measured frequently in order to trend the values and to rapidly identify trends (increase in ICP and/or decrease in CPP) that require medical interventions in order to prevent herniation syndrome or secondary brain injury due to inadequate cerebral perfusion.*
- Cardiac rhythm; serum markers of myocardial injury (creatinine kinase, creatinine kinase specific to cardiac muscle, and troponin)  
*Myocardial ischemia, injury, or dysrhythmias may occur as a result of neurological injuries such as TBI or aneurysmal subarachnoid hemorrhage (SAH). The cause of myocardial ischemia is most likely due to a sudden release of catecholamines (epinephrine and norepinephrine) in the body at the time of injury because of activation of the sympathetic nervous system.*
- Intake and output every 1 to 2 hours  
*Fluid balance may be affected as treatments such as osmotic diuretics are administered. Hypovolemia may result in hypotension that adversely affects cerebral perfusion.*
- Serum sodium and/or serum osmolality  
*Serum osmolality is monitored after administration of mannitol to quantify the degree of systemic dehydration that has occurred as a result of diuresis. The purpose of monitoring serum sodium is to determine whether a patient is meeting the target to maintain a continuous concentration gradient favoring the pull of water out of the brain tissue. The typical maximum sodium level tolerated is 160 mEq/L.*
- Serum electrolytes  
*Electrolyte imbalance can occur with osmotic diuresis, and monitoring and replacement of electrolytes are required to prevent complications of electrolyte disturbances such as dysrhythmias and muscle weakness.*
- Blood urea nitrogen (BUN) and creatinine  
*In patients receiving hypertonic saline, the serum osmolality increases, and the risk of acute renal failure increases as serum osmolality rises above 320 mOsm/kg. Creatinine and BUN are monitored for indications of renal insufficiency.*
- Arterial blood gas samples  
*Monitoring ABG allows precise measurement of gases dissolved in the plasma and is particularly useful in the patient with increased ICP because it allows evaluation of the PaCO<sub>2</sub>, which causes vasoconstriction (decreased PaCO<sub>2</sub>) or vasodilation (increased PaCO<sub>2</sub>) of cerebral blood vessels. Cerebral vasoconstriction can reduce ICP, and vasodilation of the cerebral blood vessels can increase ICP in brain injury.*

- End-tidal carbon dioxide (EtCO<sub>2</sub>) continuously to guide hyperventilation therapy during treatment of increased ICP

*When hyperventilation therapy is employed, EtCO<sub>2</sub> is monitored in order to maintain carbon dioxide in a specified range (30–35 mm Hg). End-tidal carbon dioxide values may be higher or lower than PaCO<sub>2</sub>; therefore, it is necessary to document the EtCO<sub>2</sub> value at the time that a blood sample for an ABG is performed so that a correlation can be made between the EtCO<sub>2</sub> and the PaCO<sub>2</sub> measured in the arterial blood sample.*

### ■ Actions

- The head of the bed should be maintained at greater than 30 degrees, with the patient's head in midline. Avoid sharp hip flexion.

*Elevating the head of the bed and ensuring that the head is in midline facilitates drainage of blood from the jugular venous system, decreasing ICP. Avoiding sharp hip flexion ensures that large veins in the abdomen are not compressed, decreasing venous return.*

- Avoid placing the patient in a position that allows pressure directly on the operative side after craniectomy.

*Direct pressure on the operative site may lead to injury to brain tissue that is not protected by the bone that has been removed. Additionally, placement on the operative side may increase ICP.*

- Perform endotracheal suction only as necessary; pre-oxygenate with 100% oxygen for 1 to 2 minutes prior to suctioning.

*Suctioning a patient with increased ICP can introduce the risk of further elevation of ICP because the act induces coughing, which raises pressure inside the chest and may transiently reduce drainage of blood from veins in the neck, causing a spike in ICP in some patients. Suctioning should be performed when the patient demonstrates mucus in the endotracheal tube or every 4 to 6 hours to maintain patency of the tube. Administering 100% oxygen just prior to suctioning is performed to prevent hypoxia, which can occur during the interruption of mechanical ventilation.*

- Administer sedative medications as prescribed. Sedation is used in patients with acutely increased ICP to treat pain, anxiety, and restlessness because it decreases ICP when titrated to an appropriate level for a particular patient. When given as a continuous infusion, sedative medications should be interrupted for a time adequate for a patient's neurological assessment to be evaluated. These medications are used judiciously in patients at risk for increased ICP so that subtle changes in the neurological assessment may still be identified.
- Administer osmotic agents (mannitol and hypertonic saline).

*Osmotic diuretics decrease ICP by pulling water from the interstitial spaces into the vascular space, and then diuresis occurs through the distal renal tubules. High-concentration*

*sodium chloride solutions pull water from the interstitial spaces into the vascular space without associated fluid shifts.*

- Ensure continuous drainage of CSF through the external ventricular drainage system when applicable. Kinks in the ICP monitoring tubing decrease drainage and may result in increased ICP.

- Administer antipyretics and/or implement cooling measures.

*These interventions prevent an increase in cerebral metabolism that accompanies elevated body temperature. Cooling can be achieved using water-cooled blankets or pads, ice packs placed in the axilla and groin, or a centrally placed catheter allowing for cool water to circulate around the catheter (endovascular cooling).*

### ■ Teaching

- Devices used during the course of treating increased ICP. Devices such as central lines, ICP-monitoring devices, endotracheal tubes, and gastric tubes may be placed in order to manage patients with increased ICP.

- Medications used to treat increased ICP

*Several medications are used to treat increased ICP, and a patient's routine home medications may be significantly different in the hospital.*

- Complications of increased ICP

*Many complications of increased ICP may occur and are closely associated with the primary cause of elevated ICP.*

- Rationale for helmet after craniectomy

*As the patient progresses, a helmet is often fitted and placed on the patient's head whenever he or she is out of bed to prevent injury to the unprotected portion of the head.*

- Importance of allowing the patient to rest

*Family members need to be instructed on the importance of allowing the patient rest periods because constant stimulation may exacerbate increased ICP.*

## Evaluating Care Outcomes

The effects of increased ICP on functional outcomes can be diminished with early recognition of deterioration and rapid treatment. Identification and control of the primary problem are also essential. The initial goal in managing increased ICP is to prevent cerebral herniation. The role of the nurse in performing, trending, and communicating neurological assessment findings is critically important to the preservation of neurological function. Positive patient outcomes are related to maximizing neurological function and minimizing the complications associated with increased ICP.

## STROKE

### Epidemiology

A person experiences a stroke every 40 seconds in the United States, resulting in approximately 6,400,000 Americans living with the effects of a stroke. Each year,

795,000 Americans are diagnosed with a stroke; the majority of these people have a stroke for the first time (610,000), and the remaining 185,000 people have a recurrent stroke. Additionally, 1 in 19 deaths is caused by stroke. The incidence of stroke is greater in men than women until age 55, at which time the incidence of stroke is greater in women than men. Death from stroke is greater in women and African Americans. Particularly concerning is an increase in the incidence of stroke and death rates in minorities aged less than 55 years in the United States. Stroke represents a significant public health threat that must be made a priority by all healthcare providers. Nurses have a unique and important role in their ability to educate patients on stroke risk factors, prevention, and treatment strategies across the continuum of care, from the community to acute care and back into their communities.

The term *stroke* is a general term used to describe a disruption in blood flow to the brain, which can be caused by a blockage of a blood vessel, ischemic stroke, or bleeding into the brain, hemorrhagic stroke. Ischemic strokes comprise 87% of strokes; 10% are caused by intracerebral hemorrhage (ICH), and 3% are caused by aneurysmal SAH (Box 39.2). A significant risk factor for stroke is hypertension, followed by cigarette smoking. Other modifiable risk factors include hypercholesterolemia and illicit drug use (cocaine use is associated with ICH). Major non-modifiable risk factors include age greater than 55, gender, and race. The National Institutes of Health Stroke Scale (NIHSS) may be used to quantify and trend neurological dysfunction in patients presenting with a suspected stroke (Fig. 39.6).

### Connection Check 39.3

The nurse recognizes that which patient is at greatest risk for death secondary to stroke?

- A 36-year-old Caucasian male
- A 45-year-old Asian male
- A 56-year-old African American female
- A 62-year-old Hispanic female

### Box 39.2 Types of Stroke

#### Ischemic Stroke (87%)

- Large vessel
- Small vessel (lacunar)
- Embolic
- Cryptogenic

#### Hemorrhagic Stroke (13%)

- Intracerebral hematoma (ICH; 10%)
- Subarachnoid hemorrhage (SAH; 3%)

### CASE STUDY: EPISODE 3

The EMS crew alerts the hospital during transport about the arrival of a patient with stroke signs and symptoms, and the emergency department (ED) staff notifies the stroke team. Once he arrives in the ED at 12:55, Mr. Stewart is examined, and his stroke signs are quantified using the NIHSS, where he scores 22 points, indicating severe stroke symptoms. Mr. Stewart's time of stroke symptom onset is confirmed to be 12:15. Vital signs are recorded to be BP: 170/90 mm Hg, HR: 80 bpm, rhythm: atrial fibrillation, RR: 14. Two IV catheters are placed, and blood work is drawn to evaluate electrolytes and a complete blood cell (CBC) count. A finger-stick glucose is performed, and the result is 100 mg/dL. An emergent CT scan is arranged, revealing no intracerebral hemorrhage. After discussing the risks and benefits of IV recombinant tissue plasminogen activator (rt-PA) therapy with Mr. Stewart's wife and daughter and evaluating all laboratory work, the stroke team leader orders the following:

- rt-PA 0.9 mg/kg 0.9 mg × 82 kg (weight reported by wife) = 73.8 mg (rounded to nearest whole mg) = 74 mg
- Administer 7.4-mg IV push over 1 minute.
- Administer the remaining 66.6 mg over 1 hour using an infusion pump.

The rt-PA bolus is administered by the nurse at 1:50 p.m., and the continuous infusion is started at 1:52 p.m. . .

## Ischemic Stroke

### Pathophysiology and Clinical Manifestations

A sudden blockage of a cerebral blood vessel causes a reduction in the supply of oxygenated blood to the region of the brain fed by the involved artery, resulting in an abrupt onset of clinical manifestations. These clinical manifestations are grouped into stroke syndromes, which can be correlated or localized to a particular cerebral blood vessel (Table 39.7). When blood flow is disrupted, an area of brain tissue suffers irreversible damage, and this is referred to as an infarction (similar to cardiac tissue damage with a myocardial infarction [heart attack]). There is often a zone of tissue surrounding an infarction called the **ischemic penumbra** that contains ischemic tissue that is not irreversibly damaged. The ischemic penumbra is the target of therapies aimed at opening blocked cerebral blood vessels and reestablishing blood flow to ischemic brain tissue, providing the optimal chance for functional recovery. The abrupt nature of stroke symptom onset led to coining of the term "**brain attack**" as a tool to raise the level of urgency surrounding stroke to that of a "heart attack," which has provided a foundation for urging the lay public to seek immediate medical care for myocardial infarction and now stroke symptoms.

Category	Scale Definition	Score
<b>1a. Level of Consciousness</b> (Alert, drowsy, etc.)	0 = Alert 1 = Drowsy 2 = Stuporous 3 = Coma

**FIGURE 39.6** National Institutes of Health Stroke Scale (NIHSS). The NIHSS quantifies and trends neurological dysfunction in patients presenting with a suspected stroke.

Occlusion of large cerebral blood vessels (e.g., carotid arteries, vertebral arteries) by atherosclerotic plaque occurs when the plaque ruptures, causing a blood clot to form and block the vessel (Fig. 39.7), or when atherosclerotic plaque accumulates to a point that it critically narrows and then completely obstructs blood flow. The occlusion of a large

cerebral blood vessel can cause ischemia in large areas of brain tissue depending on the location of the occlusion (proximal or distal). These large areas are called *territories*, and the territory name is based on the blood vessel that perfuses that particular area (Fig. 39.8). A territory may contain more than one lobe of the brain.

**Table 39.7 Clinical Manifestations of the Most Common Stroke Syndromes****Left Middle Cerebral Artery Syndrome**

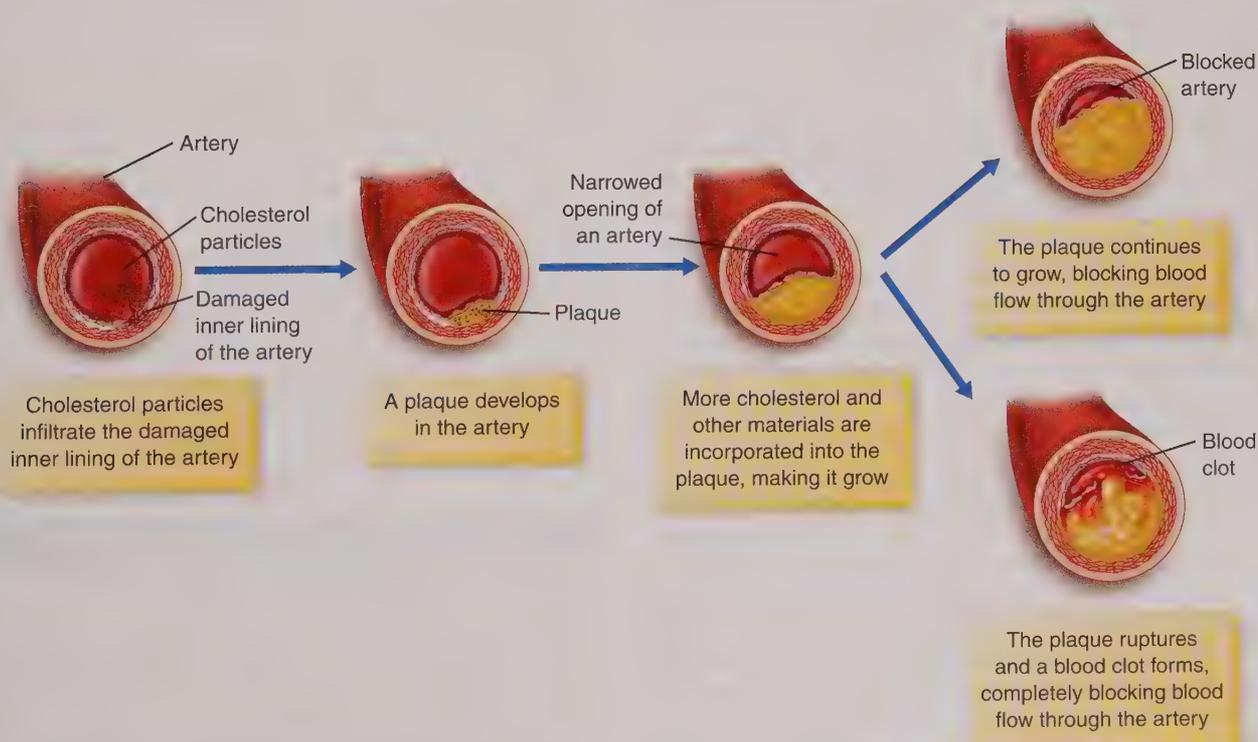

- Weakness of the right face, arm, and leg (arm weakness greater than leg weakness)
- Decrease in sensation on the right side of the body
- Right homonymous hemianopia (loss of vision in the right temporal field of vision and left nasal field of vision, requiring patients to scan an area in order to visualize objects on their right side)
- Dysphasia—in most patients, the language center of the brain is located in the left hemisphere. Language deficits may involve the motor speech area (*Broca's area*) and cause patients to have difficulty expressing thoughts and to make errors in speech that they are able to detect. Injury or ischemia to the sensory speech area (*Wernicke's area*) results in an inability to process speech input in the brain, causing patients to make errors in speech of which they are unaware.
- Inattention or neglect of the right side

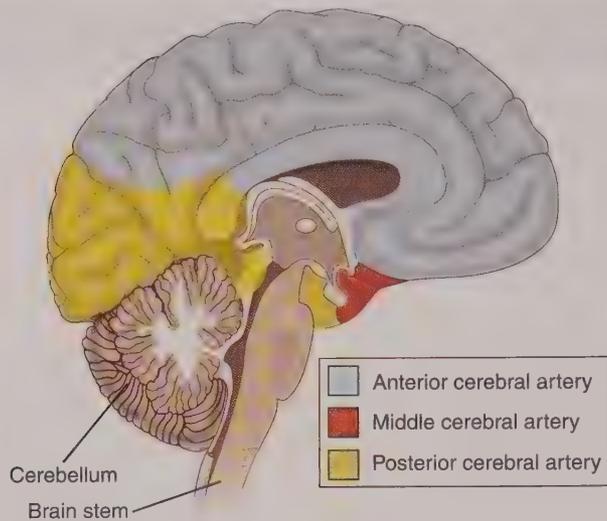

**Right Middle Cerebral Artery Syndrome**

- Weakness of the left face, arm, and leg (arm weakness greater than leg weakness)
- Decrease in sensation on the left side of the body
- Left homonymous hemianopia (loss of vision in the left temporal field of vision and right nasal field of vision, requiring patients to scan an area in order to visualize objects on their left side)
- Inattention or neglect of the left side

**Basilar Artery Syndrome**

- Dizziness
- Ataxia
- Tinnitus
- Nausea and vomiting
- Weakness on one side of the body that may be ipsilateral to the side of ischemia or injury or contralateral
- Decrease in sensation on one side of the body that may be ipsilateral to the side of ischemia or injury or contralateral
- Difficulty in the articulation of speech
- Difficulty with swallowing and managing oral secretions

**FIGURE 39.7** Development of atherosclerotic plaque that can lead to complete vessel obstruction or rupture.

**FIGURE 39.8** Territories of the brain. The territory name correlates to the blood vessel that perfuses the specific area.

The occlusion of small intracranial blood vessels supplying the peripheral regions of the brain and deep brain structures cause **lacunar stroke** syndromes, which vary in the severity of functional deficits. A lacunar stroke is a small infarction caused by an obstruction of a small blood vessel or group of small blood vessels. These small blood vessels are also called *perforating blood vessels* because they are the terminal branches of larger arteries. For example, the middle cerebral artery perfuses a large territory of brain tissue in the frontal, temporal, and parietal lobes, spanning the area from the cerebral cortex to the basal ganglia, and the arteries that supply the cortex and basal ganglia are small perforating vessels. Neurological deficits in lacunar stroke may fluctuate between improvement and worsening in the acute phase.

Embolization of blood clots from the heart (Box 39.3) can occur in patients with atrial fibrillation because blood stagnates in the poorly contracting atria, allowing blood clots to form that may be ejected from the left ventricle. Blood clots ejected from the left ventricle travel up the aorta and often flow easily into the left common carotid artery, where they may lodge in a large- or small-caliber blood vessel depending on the size of the blood clot. Smaller portions of a blood clot obstructing a blood vessel can also break off and travel forward into smaller blood vessels. Another structure involved in the pathogenesis of atrial fibrillation-associated cardiac emboli is the left atrial appendage, which is a muscular outpouching of the left atrium where blood clots form. Other conditions where embolization of blood clots occur include valvular infection or dysfunction, where blood clots develop on the irregular surface of valves, and cardiomyopathy, particularly with dilation of the left ventricle where blood collects, causing blood clot formation. Patients with a *patent foramen ovale*, a hole or communication between the right and left atria, are at risk of a clot traveling from the periphery into the heart from the right to the left

## Box 39.3 Common Areas and Causes of Embolic Stroke

### Left Atrium

- Atrial fibrillation or thrombus
- Atrial myxoma
- Atrial septal aneurysm

### Left Ventricle

- Recent myocardial infarction
- Ventricular aneurysm
- Cardiomyopathy

### Heart Valves

- Prosthetic valve complications
- Endocarditis
- Rheumatic heart disease
- Calcification
- Syphilis
- Valve prolapse

### Septal/Shunt Diseases and Disorders

- Patent foramen ovale
- Atrial septal defect
- Ventriculoseptal defect
- Congenital heart disease
- Pulmonary arteriovenous fistula

atrium and then out the left side of the heart through the aorta and ejected toward the brain.

Coagulation disorders causing hypercoagulability represent another significant but less frequent etiology of ischemic stroke that is considered carefully in young patients (aged <55 years) after a stroke. Patients with sickle cell disease may experience mechanical occlusion of a blood vessel because of red blood cell deformation. Disorders such as polycythemia vera (a disease process where the bone marrow produces an abnormally high number of red blood cells and in some cases white blood cells and platelets, which makes the blood more viscous), resulting in increased red blood cell volume, also place patients at higher risk of stroke. In a proportion of patients diagnosed with ischemic stroke, the cause cannot be determined after a comprehensive evaluation; this etiology is classified as *cryptogenic*, meaning that a discrete cause cannot be identified.

## CASE STUDY: EPISODE 4

Mr. Stewart possesses several modifiable risk factors for stroke, such as hypertension, high cholesterol, and smoking. His non-modifiable risk factors include his gender and age. This patient undergoes a series of tests, including ultrasonography of the carotid arteries to investigate whether a narrowing of one of the blood vessels leading to the brain may have been the cause

of the stroke. Cardioembolic stroke can be attributed to this type of defect. The diagnostic testing regimen after a patient has experienced a stroke is aimed at determining the cause of the stroke, which enables healthcare providers to tailor a secondary prevention program to prevent a recurrence of stroke for a given patient. Education and counseling on smoking cessation are also high priorities for Mr. Stewart...

## Management

### Medical Management

#### Diagnosis

Computed tomography (CT) scans and magnetic resonance imaging (MRI) are used, along with the clinical presentation, to guide the diagnostic evaluation of a patient with suspected stroke. Magnetic resonance imaging is more sensitive than CT in patients with strokes that are small or located in the brainstem, and an MRI may be ordered to investigate the caliber and existence of narrowing for the sections of blood vessels within the skull, which cannot be visualized with ultrasound. Carotid duplex scanning is indicated in patients when carotid stenosis or occlusion is the suspected cause of the stroke. Doppler ultrasound allows evaluation of the middle cerebral, intracranial carotid, and vertebrobasilar arteries. An echocardiogram may also be ordered to evaluate current cardiac function and determine whether a cardioembolic source is likely. An injection of agitated saline (agitation causes microbubbles to form) may be used to assist in determining whether the patient has a patent foramen ovale. Laboratory tests include CBC with differential, platelet count, serum electrolytes, BUN, creatinine, and cholesterol level.

#### Medications

Cerebral blood vessels may be opened or recanalized using IV recombinant tissue plasminogen activator (rt-PA), which allows a blood clot to be dissolved at the site and restores blood flow to ischemic neuronal tissue. Intravenous rt-PA for use in treating patients with acute ischemic stroke is currently the only treatment approved by the U.S. Food and Drug Administration (FDA) for ischemic stroke. In order to receive IV rt-PA, patients must present within 3 hours of stroke symptom onset. In some defined cases, IV rt-PA may be given up to 4.5 hours after stroke symptom onset. See Table 39.8 for inclusion and exclusion criteria used by stroke teams in determining patient eligibility to receive IV rt-PA. In order to mitigate injury to neurons due to ischemia, rt-PA must be given as soon as possible after ischemic stroke but not outside established therapeutic windows. The most significant risk associated with IV rt-PA administration is intracranial bleeding, which occurs in approximately 6.4% of patients receiving IV rt-PA. Administration of IV rt-PA benefits approximately 30% of treated

patients, as evidenced by a decrease in or absence of neurological deficits at 90 days after treatment. Adhering strictly to established inclusion and exclusion criteria is associated with a lesser incidence of symptomatic ICH after IV rt-PA.

Another therapy for acute ischemic stroke includes intra-arterial retrieval of the clot or thrombectomy (see Evidence-Based Practice: Treatment of Acute Ischemic Stroke). This intervention involves a cerebral angiogram to locate a vessel occlusion accompanied by the introduction of a stent to ensnare the clot and a suction system to reduce the likelihood of embolization of the clot as it is pulled out of the blood vessel with the stent (also called *endovascular technique*). Performed by an interventional neuroradiologist or other specialist trained in these techniques, this procedure includes the introduction of a catheter into the femoral artery that is then threaded up the aorta and across the aortic arch into the blocked artery (carotid arteries anteriorly and vertebral arteries posteriorly) for direct visualization of the patency or nonpatency of the blood vessel. Dye is injected into the blood vessels through the catheter, and images are obtained in quick succession using x-ray. These procedures require highly specialized teams of physicians and nurses trained in neurointerventional radiology and have the benefit of extending the time window after which a patient is ineligible for a therapy that could recanalize a blood vessel because these procedures may be performed up to 24 hours after the onset of stroke symptoms and identification of the occlusion of a large blood vessel on CT or magnetic resonance angiography. Potential complications of these procedures include damage or rupture of a blood vessel; breakage of the blood clot, which could travel forward and lodge in another blood vessel; and intracerebral hemorrhage. Research has demonstrated a significant recovery benefit when IV r-tPA is administered in combination with endovascular therapy for patients with occlusion of a large-caliber blood vessel (e.g., internal carotid arteries, basilar artery, and middle cerebral arteries). After patients are evaluated for eligibility to receive IV rt-PA and the infusion is initiated, they are then transported for advanced radiographic imaging (either CT angiogram or MR angiogram) to identify a large-vessel occlusion (thrombus). If an occlusion is identified, the patient is transported to the angiography area for thrombectomy while the IV rt-PA continues. Contraindications to these procedures follow the exclusion criteria for IV rt-PA. Traditionally, providers performing these interventions were radiologists with specialized training in cerebrovascular interventions; however, training programs for neurologists and neurosurgeons are emerging, with the intention of increasing patient access to this care, which has historically been available only in large academic medical centers. The Joint Commission, a regulatory body, now accredits primary and comprehensive stroke centers. Primary stroke centers offer access to IV rt-PA, and comprehensive stroke centers offer access to all stroke therapies, including endovascular therapy and neurosurgical services. Research has advanced significantly since 2015, expanding the therapeutic window for treating stroke,

**Table 39.8 Inclusion and Exclusion Criteria for the Administration of Tissue Plasminogen Activator (rt-PA)**

Inclusion Criteria	Exclusion Criteria 0- to 3-Hour Therapeutic Window	Exclusion Criteria 3- to 4.5-Hour Therapeutic Window
<ul style="list-style-type: none"> <li>● Measurable neurological deficit using NIHSS</li> <li>● No hemorrhage on head CT</li> <li>● Time since last time patient was seen to be normal is within 3 or 4.5 hours (if additional exclusions not present) before the IV rt-PA infusion was begun</li> <li>● Symptoms present for 30 minutes, not rapidly improving or attributable to another disease (e.g., seizures, migraine)</li> <li>● Imaging of head is consistent with an acute ischemic stroke, not hemorrhage or brain tumor</li> </ul>	<ul style="list-style-type: none"> <li>● Evidence of intracranial hemorrhage on pre-treatment CT scan</li> <li>● Minor or rapidly improving clinical manifestations</li> <li>● Clinical manifestations of subarachnoid hemorrhage even with normal head CT</li> <li>● Active internal bleeding: gastrointestinal or urinary bleeding within last 21 days or known bleeding risk, including but not limited to:               <ul style="list-style-type: none"> <li>● Platelet count less than 100,000/mm<sup>3</sup></li> <li>● Heparin during the preceding 48 hours associated with elevated aPTT</li> </ul> </li> <li>● Currently taking oral anticoagulants (e.g., warfarin sodium) or recent use with an elevated prothrombin time (PT) greater than 15 seconds or INR greater than 1.7</li> <li>● Major surgery or other serious trauma during preceding 14 days</li> <li>● Stroke, serious head trauma, or intracranial surgery during preceding 3 months</li> <li>● Recent arterial puncture at a noncompressible site</li> <li>● Recent lumbar puncture during preceding 7 days</li> <li>● Systolic BP greater than 185 mm Hg or diastolic BP greater than 110 mm Hg at the time of administration</li> <li>● rt-PA infusion and/or patient requires aggressive treatment to reduce blood pressure to within these limits</li> <li>● History of intracranial hemorrhage, neoplasm, arteriovenous malformation, or aneurysm</li> <li>● Recent acute myocardial infarction</li> </ul>	<ul style="list-style-type: none"> <li>● All exclusion criteria for the 0- to 3-hour therapeutic window apply, and additional criteria below are not present</li> <li>● Age greater than 80 years</li> <li>● Receiving anticoagulants, even if the INR is normal</li> <li>● Prior history of stroke and diabetes</li> </ul>

particularly occlusions in large blood vessels such as the internal carotid arteries, the basilar artery, and the middle cerebral arteries. Endovascular therapies are now available to patients who were last known to be well or without symptoms within 24 hours. Intravenous rt-PA can be used concomitantly with endovascular therapy in patients meeting the IV rt-PA therapeutic window (3 hours or 4.5 hours) demonstrating a large-vessel occlusion on radiographic imaging.

## Evidence-Based Practice

### Treatment of Acute Ischemic Stroke

A systematic literature review and a meta-analysis were conducted to evaluate the treatment effectiveness of

endovascular thrombectomy in comparison to best medical care treatment for acute ischemic stroke. Eight studies were identified, representing a total of 2,423 patients, and findings revealed better patient functional outcomes in patients who underwent thrombectomy. Additionally, these patients also demonstrated decreased mortality, with no increased incidence of intracerebral hemorrhage after endovascular thrombectomy.

Balami, J. S., Sutherland, B. A., Edmunds, L. D., Grunwald, I. Q., Newhaus, A. A., Hadley, G., ... Buchan, A. M. (2015). A systematic review and meta-analysis of randomized controlled trials of endovascular thrombectomy compared with best medical treatment for acute ischemic stroke. *International Journal of Stroke*, 10(6), 1–11.

The medical management of stroke also includes measures to prevent complications of stroke, including venous thromboembolism (VTE) prophylaxis, management of blood pressure, and control of risk factors for stroke to prevent stroke recurrence. Additionally, a diagnostic work-up aimed at finding the cause for the stroke (Table 39.9) is essential to guide focused treatment. Blood pressure management, particularly in patients who have not received thrombolytic agents, is controversial because of the complex physiology of cerebral blood flow and cerebral autoregulatory dysfunction

after stroke. Blood pressure treatment thresholds should be tailored by the provider to a patient's particular stroke type, location, and comorbidities, although blood pressure may be permitted to rise to a systolic goal of 180 to 220 mm Hg in some instances. Hypotension should be avoided in the acute period after stroke. Blood pressure control in acute stroke is based on the concept of **cerebral autoregulation**, which is the protective process by which cerebral blood vessels dilate when systemic blood pressure is reduced and constrict when systemic blood pressure is elevated to maintain

**Table 39.9 Diagnostic Testing in Stroke**

Diagnostic Test	Rationale
<b>Computed tomography (CT)</b>	<ul style="list-style-type: none"> <li>● CT scanning is performed in patients with clinical manifestations of stroke in order to determine whether hemorrhage is the cause of symptoms. Radiographical changes associated with ischemic stroke are typically not visualized within the first several hours following a stroke.</li> <li>● A CT scan can be performed with the aid of an IV contrast agent or without (non-contrast-enhanced scan). When initially evaluating a patient with suspected stroke, contrast is not used so that blood can be easily visualized. Intravenous contrast may be helpful in visualizing a mass lesion in the brain (e.g., tumor).</li> </ul>
<b>Magnetic resonance imaging (MRI)</b>	<ul style="list-style-type: none"> <li>● A stroke protocol is performed for patients receiving MRI for suspected stroke, which includes sequences that capture necrotic tissue and areas of the brain that are hypoperfused and directly visualizes the blood vessels to detect blood vessel obstruction or another abnormality such as an aneurysm.</li> </ul>
<b>Doppler ultrasound of the carotid arteries</b>	<ul style="list-style-type: none"> <li>● Doppler ultrasound of the carotid arteries is utilized to detect narrowing of the inner lumen of the carotid vessels by atherosclerotic plaque. Evaluation of the carotid arteries with ultrasound can detect narrowing in the carotid vessels before they enter the skull.</li> </ul>
<b>Cerebral angiography</b>	<ul style="list-style-type: none"> <li>● Four-vessel cerebral angiography is the “gold standard” for visualizing abnormalities such as aneurysms or occlusions in blood vessels as they pass into the skull and brain (intracranial vessels). The right and left carotid and vertebral arteries are entered separately in order to visualize the anterior (carotid arteries) portion of the circle of Willis and the posterior (vertebral arteries) portion of the circle of Willis, including the basilar artery. The femoral artery is typically cannulated for this procedure, although alternative sites such as the brachial artery may be used in specific instances.</li> <li>● Procedures such as angioplasty and stent deployment for narrowed blood-flow-limiting atherosclerotic deposits and coiling of aneurysms are performed using this radiographical modality.</li> </ul>
<b>Echocardiography</b>	<ul style="list-style-type: none"> <li>● Echocardiography is utilized to directly visualize myocardial wall movement and contraction of the chambers of the heart. In stroke, the TTE is utilized to evaluate overall cardiac function as well as the presence of blood clots within the heart that could embolize to the brain. Presence of a patent foramen ovale (PFO) may be revealed on TTE with the assistance of an IV agitated saline injection, where small bubbles may be seen traversing an abnormality in the atrial septum.</li> </ul>
<ul style="list-style-type: none"> <li>● Transthoracic (TTE)</li> <li>● Transesophageal (TEE)</li> </ul>	<ul style="list-style-type: none"> <li>● A TEE may reveal a PFO not found on TTE. A TEE allows better visualization of the left atrial appendage, which may be a source of blood clots, particularly in patients with atrial fibrillation.</li> </ul>
<b>Laboratory tests</b> to determine if hypercoagulability is the cause of stroke	<ul style="list-style-type: none"> <li>● A hypercoagulable state in the blood can cause stroke, particularly in young patients less than 55 years of age. Examples of laboratory tests that may be requested include lupus anticoagulant, anticardiolipin antibodies, protein C activity, protein S activity, and factor V Leiden mutation.</li> </ul>

constant blood flow. Cerebral autoregulation is dysfunctional after stroke, making it necessary to implement interventions to protect the brain from abnormally low systemic blood pressure in the absence of this protective mechanism.

Secondary stroke prevention strategies should be individualized for each patient according to specific stroke risk factors. According to stroke center accreditation guidelines, after a stroke, patients should be discharged with antiplatelet therapy, lipid-lowering therapy if indicated, anticoagulation if indicated for atrial fibrillation, and a blood pressure control strategy in patients with hypertension.

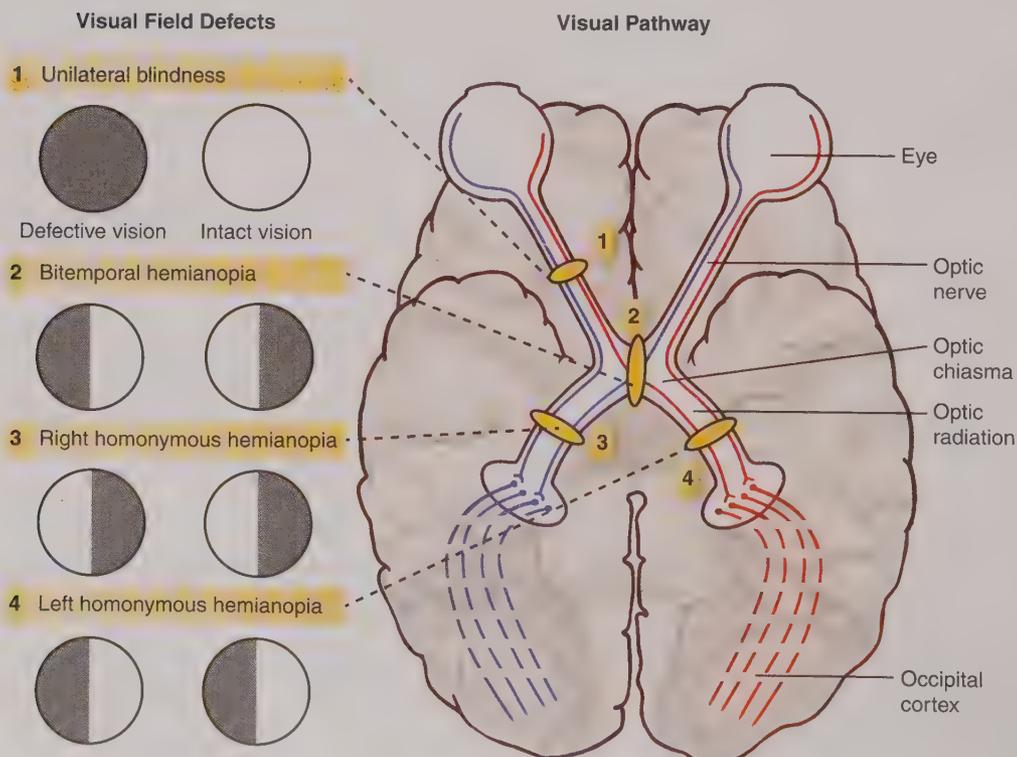

### Complications

Complications of ischemic stroke can be life threatening in the acute phase and life altering as time progresses. A life-threatening complication of acute ischemic stroke is hemorrhage into the area of infarcted (nonviable or dead) brain tissue, termed *hemorrhagic transformation*, which patients may experience in the absence of thrombolytic therapy or anticoagulation therapy. Hemorrhagic transformation is thought to occur as a result of blood vessel spasm around a blood vessel that has been occluded by a blood clot, which in time resolves, causing the blood clot to break apart and restoring blood flow to surrounding ischemic and infarcted brain tissue. During ischemia, tissues may become friable or fragile, and when normal blood flow or pressure is reestablished, this pressure may cause tissue damage or bleeding.

Cytotoxic edema may occur most often in a stroke occupying a large vascular territory in the brain. Cerebral edema in this situation is caused by the breakdown of intracellular

processes due to an inadequate oxygen supply, causing fluid to leak out of cells and into the interstitial space, resulting in edema. As ischemia persists and infarction occurs, cerebral edema may increase, causing increased ICP and placing a patient at risk for cerebral herniation syndrome. Aspiration of food, fluids, or secretions into the lungs is a common complication of stroke because of the decreased level of consciousness, as well as potential impairment of cranial nerves, facial muscles, and function of the palate. Measures to screen for swallowing dysfunction after stroke, early intervention by speech-language pathologists (SLPs), and general aspiration precautions are necessary in preventing this complication.

Chronic complications of stroke may include weakness or paralysis of the extremities and associated risk of muscle contracture. Splinting, passive range of motion, and physical and occupational therapies assist in preserving function and increasing the probability of the return of function to the extremities. Neglect or inattention (also termed **agnosia**) to one side of the body can occur in strokes in the right or left hemisphere; however, this deficit is most characteristic of stroke syndromes in the right hemisphere of the brain. Neglect or inattention of one side of the body occurs on the opposite side of the body from the area of brain injury and causes a patient not to recognize or acknowledge the affected side of the body. Integration of both sides of the body is a major goal in the rehabilitation of patients after stroke. Visual field deficits, such as **homonymous hemianopia** (vision loss on the same side of the visual field in both eyes), commonly occur in stroke and affect an entire side of vision (both nasal and temporal fields; Fig. 39.9).

**FIGURE 39.9** Visual field defects due to stroke. Visual field deficits, such as homonymous hemianopia, commonly occur in stroke and affect an entire side of vision (both nasal and temporal fields).

Patients with this type of visual field deficit must learn scanning techniques in order to ensure that they are able to visualize an entire visual target. For example, in order to ensure that patients are able to eat their entire meal on a tray or place setting, they must scan the entire space to compensate for the darkened or absent visual fields.

Disorders of speech due to facial muscle or cranial nerve weakness and language are common residual deficits of stroke that often require intensive speech and cognitive therapies. The interprofessional team, including physicians, nurses, and speech therapists, is integral in incorporating strategies into the patient's routine, with the goal of reinforcing learned strategies and adding contextual meaning to the strategies.

Disturbances in the planning of motor activities, or **apraxia**, often occur in strokes that involve the frontal and temporal lobes of the brain. When patients demonstrate a type of apraxia called *ideational apraxia*, they may be able to correctly identify an object such as a comb but proceed to brush their teeth with the comb. Occupational therapists (OTs) work with patients, families, and the healthcare team to develop strategies for recoupling common meanings with objects or activities.

The complication of depression after stroke is important to consider when working with these patients because it can significantly impact recovery and rehabilitation. Depression occurs with an increased incidence in patients with a stroke in the right hemisphere of the brain. Patients should be evaluated at different time points during their recovery phase for depression, which initially could be related to the new situation and residual deficits or body changes that the patient may be experiencing but could potentially become a chronic issue that must be addressed by the interprofessional team.

## Hemorrhagic Stroke

### *Pathophysiology and Clinical Manifestations*

Hemorrhagic stroke is separated into three main subtypes: nontraumatic subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), and intraventricular hemorrhage (IVH). **Subarachnoid hemorrhage** is typically caused by a ruptured **aneurysm** (weak, dilated vessel) and less commonly by an **arteriovenous malformation (AVM)**, which is a mass of arteries and veins that is not connected by a capillary network. Cerebral aneurysms occur in 3% to 5% of the general population, and aneurysmal rupture with subsequent SAH makes up approximately 5% of all strokes. Approximately 10% to 15% of patients with aneurysmal SAH die prior to reaching medical care, and mortality for patients treated in the hospital is approximately 50%. Despite intensive treatment, an estimated 50% of SAH survivors have significant, permanent neurological deficits. Risk factors for SAH include hypertension, smoking, heavy alcohol use, use of sympathetic nervous system stimulants such as cocaine, female gender, history of cerebrovascular disease, and postmenopausal state.

A cerebral aneurysm is thought to occur as a result of an inherent weakness or gradually acquired weakness of the medial layer in a segment of a blood vessel. The medial layer in a blood vessel is the muscular layer that adds shape and tone to the vessel; a weakness in a segment of this layer causes an outpouching of the blood vessel through the outermost adventitial layer. Cerebral aneurysms are most often located at bifurcations of blood vessels, and 85% are located in the anterior portion of the circle of Willis (i.e., internal carotid artery, middle cerebral artery, anterior cerebral artery, and anterior communicating artery). The remaining 15% of aneurysms occur in the posterior portion of the circle of Willis (e.g., posterior communicating arteries, posterior cerebral arteries, vertebrobasilar system). Some patients have multiple aneurysms, sometimes making it difficult to discern the source of the rupture. An aneurysm typically ruptures in the thinnest-walled portion of the aneurysm, also called the *dome*. The degree of neurological impairment at onset is quantified using the Hunt and Hess or World Federation of Neurological Surgeons scoring system (Box 39.4). Patients may or may not lose consciousness at the time of aneurysm rupture, which may be related to the size, location, and magnitude of the rupture in the aneurysm. Subarachnoid hemorrhage is characterized by a sudden severe headache, often termed a “thunderclap” headache because of the intensity of the pain experienced at the onset. Subsequent neck stiffness and pain ensue because of the irritation of the meninges, particularly at the base of the skull, where pooling of blood occurs. Photosensitivity may also be associated with meningeal irritation or inflammation.

Nontraumatic intracranial hemorrhage has several causes, the most common of which is hypertension, typically occurring in the deep structures of the brain such as the basal

### Box 39.4 Grading Scales for Subarachnoid Hemorrhage

#### Hunt and Hess Grading Scale

- Grade I: Asymptomatic or slight headache and neck stiffness
- Grade II: Headache and neck stiffness, cranial nerve deficit
- Grade III: Headache, neck stiffness, focal motor deficit, lethargy
- Grade IV: Stuporous, dense hemiparesis or posturing
- Grade V: Comatose, posturing, moribund

#### Fisher Grading Scale, Determined by Amount of Blood Visualized on Computed Tomography (CT) Scan

- Grade 1: No blood on CT scan
- Grade 2: Blood layering less than 1-mm thickness
- Grade 3: Blood layering greater than 1-mm thickness
- Grade 4: Intraparenchymal or intraventricular blood

ganglia and thalamus. Another common cause of intracerebral hemorrhage is oral anticoagulation use (e.g., warfarin [Coumadin] and dabigatran [Pradaxa], apixaban [Eliquis], rivaroxaban [Xarelto]). Intracerebral hemorrhage can also be caused by tumors and AVMs, as well as other disease processes such as Moyamoya disease and amyloid angiopathy (Table 39.10). Intracerebral hemorrhage may be accompanied by extension of the hemorrhage into the ventricular system, leading to IVH. Intraventricular hemorrhage may also occur as a primary site of hemorrhage. Intracerebral hemorrhage is typically managed using medical therapies to manage blood pressure and prevent expansion of the hematoma as well as therapies to reverse coagulopathy and treat increased intracranial pressure (e.g., osmotic therapy, hyperventilation, drainage of CSF).

### Medical and Surgical Management

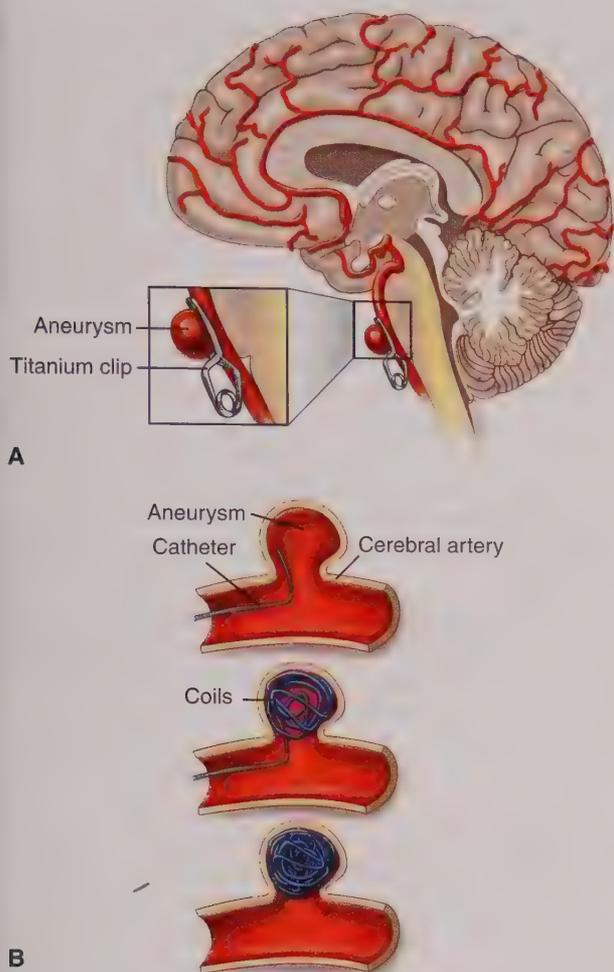

Medical and surgical management of subarachnoid hemorrhage (SAH) aims to prevent and mitigate complications such as aneurysm rebleeding and cerebral vasospasm. **Cerebral vasospasm** occurs in approximately 30% of patients with SAH and causes narrowing of blood vessel segments (refer to the Complications section for a more detailed discussion). Aneurysms are secured either by applying a titanium clip to the neck of the aneurysm during surgery using a microscope or by deploying platinum coils into the aneurysm during angiography, both with the goal of reducing blood flow into the aneurysm (Fig. 39.10). In cases where neither clipping nor coiling the aneurysm is feasible, reinforcement of the aneurysmal wall by wrapping the outside of the aneurysm with synthetic material or muscle during the surgery may be accomplished. Wrapping of cerebral aneurysms is not considered a definitive treatment of the aneurysm because it remains at risk for rupture because blood continues to flow

through the weakened aneurysmal vessel wall. The decision to secure an aneurysm by microsurgical technique using clips or by endovascular technique using coils is determined collaboratively by neurosurgeons and neurointerventional radiologists. Factors considered in determining the best treatment for an aneurysm include a patient's overall medical condition and hemodynamic stability and the cerebrovascular anatomy surrounding the aneurysm, such as whether the opening or neck of the aneurysm is wide or narrow or the degree of tortuosity of feeding vessels. Patients with high-grade Hunt and Hess scores (grade 4 or 5), as well as patients with multiple comorbid conditions and with hemodynamic instability at baseline, may be better candidates for aneurysm coiling. Aneurysms with a wide neck and tortuous vascular anatomy may be better candidates for aneurysm clipping. Treatment of other early complications, such as hydrocephalus occurring as blood occludes arachnoid villi, can be accomplished through external ventricular drainage. Management of blood pressure is important in the early period after subarachnoid hemorrhage in order to prevent rebleeding of an aneurysm. Evidence for a precise blood pressure range does not yet exist. The guidelines for the management of SAH recommend management of blood pressure while considering the risk of either hypoperfusion or rebleeding in the period prior to securing the aneurysm.

Surgical management of intracranial hemorrhage above the tentorium cerebelli (supratentorial) has not been shown to improve outcomes unless a hematoma is superficial in location. Surgical evacuation of a hematoma below the tentorium, infratentorial, is generally recommended and supported by recent guidelines because of the risk of brainstem compression and irreversible brain injury. Intraventricular hemorrhage is typically managed with cerebrospinal drainage. Research focusing on the application of thrombolytic therapy

**Table 39.10 Causes of Intracerebral Hemorrhage**

<b>Brain tumor</b>	Brain tumors may involve blood vessels and may have a hemorrhagic component. It is often difficult to determine if a mass is underlying an intracranial hemorrhage; therefore, follow-up imaging (e.g., CT, MRI, or angiography) in 1 to several weeks after hemorrhage may be necessary.
<b>Arteriovenous malformation (AVM)</b>	An AVM is a mass of arteries and veins that is not connected by a capillary network. One of the roles of a capillary network is to provide a transition between high- and low-pressure systems. In an AVM, a high-pressure system is connected directly to a low-pressure system, which predisposes the malformation to bleeding. An AVM may not be apparent on initial imaging in the setting of ICH, so follow-up imaging and angiography are required to rule out AVM as a cause for ICH.
<b>Moyamoya disease</b>	Moyamoya disease involves constriction or narrowing of the end of the internal carotid arteries and narrowing of the smaller branches of the arteries in the anterior circulation (e.g., middle cerebral artery, anterior cerebral artery). An arterial network (collateral circulation) develops in response to the narrowing of arteries over time in order to augment blood supply to the affected areas of the brain.
<b>Cerebral amyloid angiopathy</b>	Cerebral amyloid angiopathy (CAA) involves the deposition of beta-amyloid into the walls of blood vessels, rendering them fragile and at risk for damage, resulting in intracerebral hemorrhage. Beta-amyloid is one of the substances thought to play a role in Alzheimer's disease, and in this case, the substance is deposited into blood vessels. Cerebral amyloid angiopathy occurs mainly in older adults.

**FIGURE 39.10** Methods of securing cerebral aneurysms. *A*, Aneurysm clipping. *B*, Aneurysm coiling. *A*, Aneurysms may be secured by applying a titanium clip to the neck of the aneurysm during surgery using a microscope to reduce blood flow into the aneurysm. *B*, Aneurysms may be secured by deploying platinum coils into the aneurysm during angiography to reduce blood flow into the aneurysm.

to maintain ventricular catheter patency and achieve earlier dissolution of an intraventricular blood clot to improve functional outcome is ongoing.

### Complications

Subarachnoid hemorrhage causes neurological and systemic complications such as ischemic stroke, cerebral edema, pulmonary edema, and myocardial ischemia. The morbidity and mortality of patients with SAH are influenced by the management of systemic medical complications, which can cause or exacerbate brain injury. For example, myocardial injury can cause left ventricular failure, resulting in pulmonary edema and hypoxemia that may exacerbate **cerebral ischemia** (insufficient blood flow to the brain to meet metabolic demand).

Cerebral vasospasm causing delayed ischemic neurological deficit is a major complication of SAH, affecting 30% of patients and occurring between days 4 and 14 after the SAH. The peak risk period for cerebral vasospasm occurs from days 5 to 9 after the SAH and is a narrowing of a

segment of a cerebral artery that leads to local cerebral ischemia. Although the precise etiology of cerebral vasospasm is unknown, several postulated causes include an influx of calcium into damaged cells of local tissue and the involved blood vessel, potentially causing local spasm; release and activation of inflammatory mediators in response to endothelial damage, causing vasoconstriction; and adhesion and infiltration of white blood cells across the arterial wall, amplifying the inflammatory response that produces vasospasm.

The clinical manifestations of vasospasm can include confusion, changes in level of consciousness, or new **focal** (localized area) motor weakness, often in a waxing and waning pattern. A new focal motor weakness should be evaluated and treated urgently in a similar manner to an acute ischemic stroke because vasospasm can lead to cerebral infarction. Treatment of vasospasm has historically been centered on hypertension, hypervolemia, and hemodilution, widely known as **triple-H therapy**, with the goal of maintaining arterial patency and preventing cerebral infarction. Hypertension may be accomplished by withholding antihypertensive medications in patients with a history of hypertension or elevating the blood pressure with vasoactive medications. Hypervolemia may be achieved by administering crystalloid or colloidal solutions such as albumin, targeting a hemodynamic parameter that measures or approximates intravascular volume (e.g., central venous pressure, pulmonary artery occlusion pressure [PAOP], global end-diastolic volume). Cardiac output may also be chosen as an endpoint for therapy. The intent of hemodilution is to decrease the viscosity of the blood in order to facilitate flow through often narrowed arteries. Hemodilution may be achieved as hypervolemia is employed, although minimum thresholds for hemoglobin are typically maintained at approximately 30 g/dL with the intent of ensuring adequate oxygen delivery to the brain tissue.

Administration of nimodipine, a calcium-channel blocker, improves outcomes in patients experiencing vasospasm; however, this medication is associated with hypotension, which may necessitate alteration in dosing by increasing the frequency of dosing and decreasing the dose or discontinuing the therapy in some instances. Hypotension in the setting of vasospasm may worsen ischemia caused by the narrowing of the blood vessel. Cerebral angioplasty may be indicated to reestablish blood flow through narrowed arteries in patients who develop focal neurological deficits despite medical therapies to maintain blood flow. In some cases, arterial vasodilators are utilized during cerebral angiography in an attempt to dilate a focal arterial narrowing.

Hyponatremia is a common complication in patients with SAH, which may be caused by syndrome of inappropriate antidiuretic hormone (SIADH) or by cerebral salt-wasting syndrome, also known as renal salt-wasting syndrome. The etiology of sodium and water imbalance in these patients is often difficult to determine because large amounts of fluid, and in some cases large amounts of sodium, are administered, interfering with the results of the serum and urine assays traditionally used in evaluating sodium and water

imbalances. Furthermore, SIADH has many potential causes, including medications and mechanical ventilation. The usual treatment of SIADH, focused on fluid restriction, may be problematic in patients with SAH undergoing treatment for cerebral vasospasm with hypervolemic therapy because of the need to maintain adequate blood pressure and intravascular volume. Cerebral salt-wasting syndrome is thought to be a common etiology of hyponatremia in patients with SAH and is characterized by a decrease in sodium accompanied by increased urinary output. The precise physiological mechanism for cerebral salt-wasting syndrome is unknown; however, a postulated mechanism involves the release of atrial natriuretic peptide (ANP) from myocardial cells in response to increased stretch of the myocardium, which occurs with fluid shifts. Treatment of cerebral salt-wasting syndrome includes replacement of fluid losses, sodium replenishment, and administration of fludrocortisone (a synthetic glucocorticoid) to regulate sodium and water reabsorption at the level of the kidney.

Other systemic complications such as myocardial ischemia and infarction, acute left ventricular failure, and acute respiratory distress syndrome (ARDS) may occur secondary to subarachnoid hemorrhage. Patients with SAH require intensive interprofessional, neurological, and general intensive care monitoring in order to optimize functional outcomes.

### Connection Check 39.4

A patient is admitted to a unit with a diagnosis of left middle cerebral artery acute ischemic stroke and is not eligible for thrombolytic therapy. The nurse recognizes that this patient is at high risk for which complication?

- A. Delirium
- B. Aspiration
- C. Bronchospasm
- D. Palpitations

### Connection Check 39.5

The nurse receives a report on a patient in the ICU with an SAH and clarifies that the date of the patient's initial bleed was 4 days before. The nurse needs this information to gauge the patient's risk of which complication of SAH?

- A. Hydrocephalus
- B. Aspiration
- C. Vasospasm
- D. Myocardial ischemia

## Nursing Management

### Assessment and Analysis

Neurological assessment of patients with acute ischemic or hemorrhagic stroke is integral in detecting potentially treatable neurological deterioration rapidly, which allows for the

best chance to preserve or restore function. A clear understanding of a patient's baseline neurological status serves as the basis for future assessments and enables the nurse to quickly identify and analyze changes. In patients after hemorrhagic stroke, close monitoring of vital signs, particularly blood pressure, is necessary to prevent rebleeding or expansion of a hematoma. If blood pressure is higher than the prescribed targets, there is the risk of increased ICP and rebleeding, and if the blood pressure is below prescribed targets, there is the risk of cerebral hypoperfusion. Identification of rhythm disturbances, such as atrial fibrillation, ST segment, or T-wave changes associated with myocardial ischemia, is essential in determining potential causes of stroke and intervening in complications of stroke. Close monitoring of serum electrolytes, particularly sodium, is necessary to identify disorders of salt and water imbalance resulting in hyponatremia, which places patients who have suffered a stroke at high risk for cerebral edema and neurological deterioration. Regular assessment of systems enables the nurse to identify potential complications early, track progress, and make appropriate referrals to the interprofessional team, ensuring the best possible outcome for the patient.

### Safety Blood Pressure Monitoring

#### Alert

It is important for the nurse caring for a patient with ischemic or hemorrhagic stroke to closely monitor the patient's blood pressure and ensure that it remains within prescribed limits. When the blood pressure falls below prescribed levels, a reduction in cerebral blood flow may occur, exacerbating ischemia and resulting in a worsening of stroke symptoms. The injured brain is not able to effectively regulate blood flow independently of systemic blood pressure (this usual protective mechanism is called **autoregulation**); therefore, it is important for the nurse to monitor for changes in blood pressure that may require further medical management. Blood pressure values that exceed ordered limits may result in hemorrhage into a region of ischemic or infarcted tissue or place a patient at risk for increased ICP because of an inability of the brain to automatically constrict blood vessels, reducing intracranial blood volume.

### Nursing Diagnoses

- **Impaired swallowing** related to lower cranial nerve dysfunction or decreased level of consciousness
- **High risk for impaired gas exchange** related to aspiration
- **Sensory perceptual alterations** related to damage to sensory input areas in the brain and/or integration of sensory inputs
- **Impaired physical mobility** related to hemiparesis

- **Impaired verbal communication** related to decreased perfusion to the speech centers in the brain (Broca's [motor speech] and Wernicke's [sensory speech])
- **Impaired family coping** related to catastrophic illness and uncertain outcome

## Nursing Interventions

### ■ Assessments

- Serial neurological assessments every 1 to 2 hours  
*Changes in level of consciousness are early indicators of increased ICP. Neurological deterioration must be identified quickly in order to mitigate further brain injury. Neurological deterioration during or after IV rt-PA can signal intracranial hemorrhage. When IV rt-PA is administered, neurological assessments, including level of consciousness, motor strength, and pupillary reflexes, are performed every 15 minutes × 6 hours, every 30 minutes × 2 hours, and every 1 hour × 16 hours.*
- Vital signs every 1 to 2 hours or more often when administering medications that alter BP. When IV rt-PA is given, the frequency of vital signs is as follows: BP, HR, and RR every 15 minutes × 6 hours, every 30 minutes × 2 hours, and every 1 hour × 16 hours.  
*A protective mechanism of the brain, cerebral autoregulation, is dysfunctional after stroke, rendering the brain vulnerable to hypotension because the cerebral blood vessels are not able to automatically dilate, ensuring adequate oxygen delivery to brain tissue. Conversely, high BP can also have negative effects, such as increasing blood volume in the head, resulting in increased ICP. Uncontrolled hypertension after IV rt-PA infusion places a patient at a higher risk for intracranial hemorrhage because of the decrease in fibrinogen caused by rt-PA.*
- Neurovascular assessment of the extremity (pulse checks of the dorsalis pedis or posterior tibial artery) used during endovascular therapy must be performed frequently during the first 4 hours after of the procedure.  
*Implemented in order to detect arterial clotting due to accessing the artery during the arteriogram*
- Puncture site used during the arteriogram is also monitored frequently during the first 4 hours after arterial sheath removal to detect signs of bleeding from the accessed blood vessel.  
*The site is assessed for oozing of blood from the puncture site and the presence of a hematoma when palpating the site.*
- Electrocardiogram (ECG) and cardiac enzymes  
*A possible etiology of ischemic stroke is atrial fibrillation, and continuous electrocardiogram (ECG) monitoring assists in identifying cardiac dysrhythmias. Patients with hemorrhagic stroke, particularly after SAH, may experience myocardial stunning or injury. Trending of 12-lead ECGs and cardiac enzymes allows identification of potential myocardial infarction and/or reversible myocardial stunning.*
- Serum electrolytes, particularly sodium  
*Hyponatremia is a common complication of ICH, due potentially to SIADH and cerebral salt-wasting syndrome,*

*which increases the risk for cerebral edema and neurological deterioration.*

- Intake and output, cumulative fluid balance  
*Accurate accounting of fluid balance is important in evaluating potential sodium and water imbalances as well as approximating volume status, especially in patients with SAH receiving triple-H therapy.*

### ■ Actions

- Administer rt-PA as ordered.  
*Recombinant tissue plasminogen activator (rt-PA) allows a blood clot to be dissolved at the site and restores blood flow to ischemic neuronal tissue. It is administered intravenously for treating acute ischemic stroke and is currently the only treatment approved by the FDA for ischemic stroke. In order to receive IV rt-PA, patients must present within 3 hours of stroke symptom onset. In some defined cases, IV rt-PA may be given up to 4.5 hours after stroke symptom onset.*
- Perform bedside swallow screening.  
*After a stroke, many patients experience swallowing dysfunction, which places them at risk for aspiration and subsequent pneumonia. The process of swallowing is complex and involves structures in the brainstem, thalamus, and cerebral cortex as well as tongue and facial movements, many of which can be compromised after stroke. Cranial nerves IX, X, XI, and XII, which exit from the medulla in the brainstem, contribute to swallowing and innervate the palate and pharynx, assisting in airway protection. When these cranial nerves have been damaged, aspiration of food or fluid into the lungs can occur.*
- Elevate the head of the bed greater than or equal to 30 degrees.  
*If a patient is at risk for or is exhibiting clinical manifestations of increased ICP, the head of the bed is elevated to an angle greater than or equal to 30 degrees, and efforts are made to keep the patient's neck in a midline position in order to ensure unobstructed drainage of venous blood from the head, which may decrease ICP.*
- Position the head of the bed for patients who have undergone endovascular therapy beginning at 0 to 15 degrees, depending on provider order, and incrementally progressing to 90 degrees before the patient is able to stand.  
*Positioning of the head of the bed is important to reduce the incidence of bleeding at the arteriogram access site. The patient is also instructed not to move the affected extremity, typically the leg, for the first 4 to 6 hours after the procedure.*
- Place a nasogastric or postpyloric feeding tube for nutrition and medication administration.  
*A nasogastric tube or postpyloric feeding tube may be placed to facilitate enteral feeding to allow time for swallowing function to improve or for more formal swallowing evaluation to be completed. A videographical swallowing assessment performed by an SLP is common and enables the practitioner to visualize all phases of the swallowing process to determine the type and extent of swallowing dysfunction that is present. If swallowing dysfunction is thought to be a long-term problem or permanent, a percutaneous endoscopically*

placed gastrostomy tube may be placed by a surgeon or gastroenterologist.

- **Implement aspiration precautions.**

*Specific methods used to prevent aspiration include providing supervision of the patient while eating to observe for clinical manifestations of aspiration or choking, maintaining the head of the bed at least 45 degrees or greater while eating or drinking, reducing distractions to assist a patient in concentrating on eating and drinking, and advocating for evaluation of the patient by an SLP. Some patients require additional measures to prevent aspiration, which are often recommended by an SLP and include tucking the chin when swallowing and thickening liquids with fiber additives.*

*Ensure that patients receive the prescribed therapeutic food preparation, such as a soft or pureed diet. Other members of the healthcare team may be involved in the feeding of patients; therefore, it is critical for the nurse to communicate the appropriate precautions and diet to these team members in order to ensure safety around meals. Patients with dysphagia are typically evaluated by an SLP and may be able to take food and fluid by mouth with a customized plan to prevent aspiration of liquids or solids into the lungs.*

- **Bleeding precautions are necessary for patients who have received thrombolytics or anticoagulants.** Specific precautions include utilizing an electric razor instead of a razor blade for shaving, utilizing a soft toothbrush for oral hygiene, alternating a BP cuff from the left to the right arm to prevent bruising during serial BP measurement, avoiding rectal temperature measurement, and observing strict fall precautions because these patients are at a greater risk for injury related to a fall.

*Patients who have received thrombolytics for acute stroke typically are considered to be at risk for bleeding up to 24 hours after thrombolytic administration because of the inhibition of normal clotting mechanisms (decrease in fibrinogen) caused by rt-PA. Patients receiving anticoagulants are at risk for minor and major bleeding events throughout their course of treatment.*

- **Provide frequent repositioning, elevate paralyzed or weak limbs to minimize dependent edema, and advocate for evaluation of the patient by OTs and physical therapists (PTs) early.**

*Patients with hemiparesis or hemiplegia are at greater risk for the development of pressure injuries because of decreased mobility. Frequent repositioning allows off-loading of pressure from bony prominences (e.g., ankles, heels, ischium, and occiput). Occupational therapists and PTs recommend passive or active range-of-motion regimens and functional splinting, which prevent musculoskeletal and functional complications that can hinder a patient's rehabilitation.*

## ■ Teaching

- **Stroke diagnosis**

*Patients and their families should receive information regarding the specific type of stroke and usual course to enable them to become involved in their own care or the care*

*of their family member. Having specific knowledge of the type of stroke (e.g., hemorrhagic, ischemic) and the causes allows the patient or family to make informed decisions about care and affords them the opportunity to ask further questions.*

- **Activation of EMS**

*Patients and their families should receive information regarding the specific type of stroke and usual course to enable them to become involved in their own care or the care of their family member. Knowledge imparted to patients and families is used as an intervention to increase autonomy and decrease anxiety and stress to the extent that this is possible in this acute circumstance.*

- **Warning signs and symptoms of stroke**

*Knowing the signs and symptoms of stroke may assist a patient or family member in recognizing stroke in his or her own family or in other settings, which improves public health and safety.*

- **Patient-specific and family risk factors for stroke**

*Patients and their families should be aware of the specific risk factors they possess that place them at risk for stroke recurrence. Reviewing family risk factors with other members of the patient's family may help to prevent a first stroke in others. Many risk factors for stroke may be controlled, such as smoking, hypertension, and hypercholesterolemia. Knowledge of the role that these factors play in recurrent stroke may be empowering to patients who must be encouraged to take control of their health in order to prevent recurrent stroke or other conditions such as heart disease.*

- **Smoking cessation**

*Exposure to nicotine due to cigarette smoking causes a decrease in oxygen levels in the blood, which may contribute to blood clot formation and vasoconstriction with each inhalation of smoke. Additionally, nicotine may cause more rapid deposition and accumulation of atherosclerotic plaque. Patients may be more willing to consider smoking cessation after an illness such as stroke.*

- **Medications for secondary prevention of stroke**

*Adherence to medication regimens to reduce BP and hypercholesterolemia and prevent blood clotting is important in instructing patients about their care (Box 39.5). In order to increase adherence to medication regimens, factors such as medication cost and financial resources as well as side-effect profiles should be considered.*

## Evaluating Care Outcomes

Patients with ischemic and hemorrhagic stroke are highly vulnerable to complications of the disease process, which can be prevented or mitigated by aggressive specialty care targeting the preservation of neurological function. Functional outcomes may not be able to be ascertained in the acute care setting, and preparation of patients for rehabilitation or continued care is necessary to optimize conditions for recovery of function (motor, sensory, and cognitive functions). Implementation, teaching, and reinforcement of secondary stroke prevention measures such as taking

## Box 39.5 Medications Prescribed for Secondary Stroke Prevention

### Antihypertensives

Used to reduce blood pressure to prevent long-term damage from excessive shear stress and reduce the chance for complications of hypertension, such as intracerebral hemorrhage

#### Beta blockers

Metoprolol (Lopressor), labetalol (Trandate)

#### Calcium-channel blockers

Diltiazem (Cardizem)

Amlodipine (Norvasc)

Verapamil (Calan)

#### Diuretics

Hydrochlorothiazide (HCTZ or Aquazide-H)

### Lipid-Lowering Medications

Used to reduce the production of cholesterol or the reabsorption of cholesterol, which leads to deposition in blood vessels and eventual blood vessel occlusion

#### Statins

Simvastatin (Zocor)

Pravastatin (Pravachol)

Atorvastatin (Lipitor)

Rosuvastatin (Crestor)

#### Niacin

Bile acid sequestrants

Ezetimibe (Zetia)

### Platelet Inhibitors

Used to prevent platelet aggregation, reducing the risk of blood clot formation, which could cause cerebral blood vessel occlusion

#### Cyclooxygenase inhibitors

Acetylsalicylic acid (aspirin)

#### Adenosine diphosphate (ADP) receptor inhibitors

Clopidogrel (Plavix)

Prasugrel (Effient)

#### Combination medications

Dipyridamole (Persantine) and aspirin combined into one pill (Aggrenox)

### Anticoagulants

Used to prevent clotting in patients with disorders such as atrial fibrillation

Unfractionated heparin (used as an infusion in the hospitalized patient for short-term anticoagulation)

Warfarin (Coumadin)

Dabigatran (Pradaxa)

Apixaban (Eliquis)

Rivaroxaban (Xarelto)

antiplatelet therapy and lipid-lowering and antihypertensive medications and follow-up cerebrovascular care after discharge are critical to promoting wellness and preventing stroke recurrence. In addition to rehabilitation services, it is important to consider the psychosocial aspects of the

illness affecting patients' position in the family (e.g., main wage earner), their employment, and their need for caregiver support. Evaluation and resources provided by a social worker and case manager are helpful to patients and their families as they transition out of the acute care setting. Nurses caring for patients play a central role in patient outcome along the continuum of stroke care from initial presentation through rehabilitation and discharge to the community.

## TRAUMATIC BRAIN INJURY

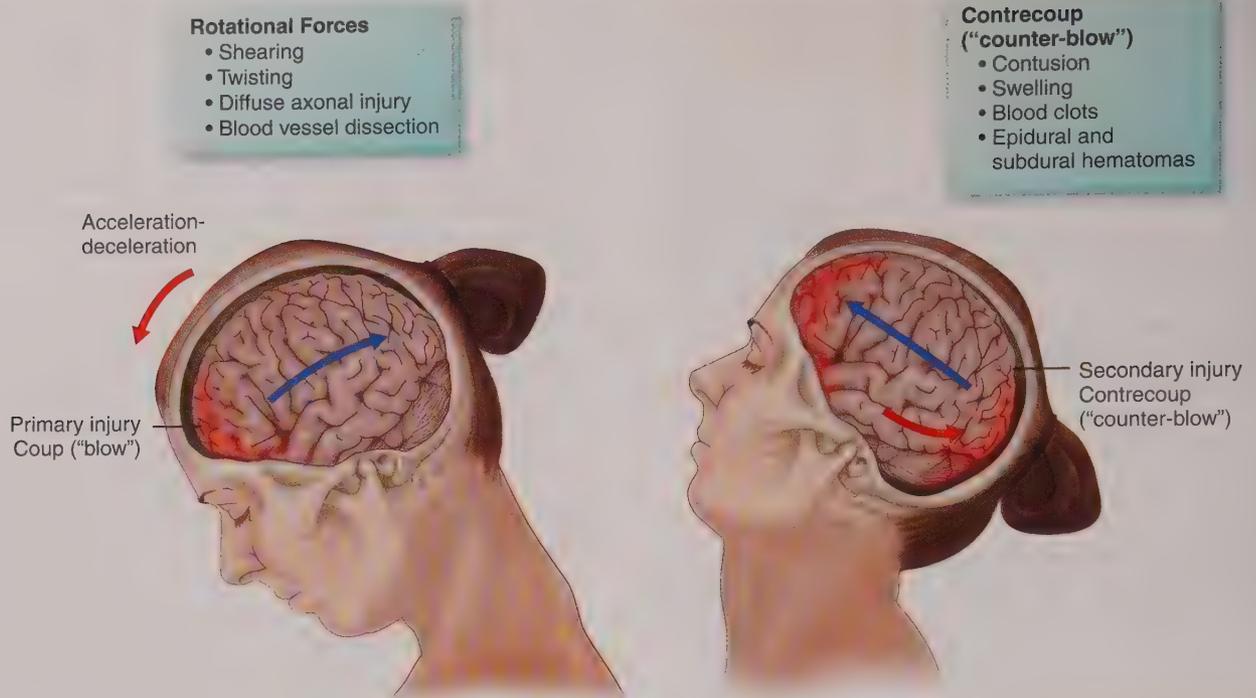

### Epidemiology

Approximately 1.7 million people per year sustain a traumatic brain injury (TBI), with about 52,000 dying from their injury. The human and financial costs of TBI are immense. Many who sustain even a mild head injury suffer long-term effects, such as memory loss and personality changes, that compromise their quality of life. Costs related to TBI are financial and human; many patients are unable to return to previous roles within the family and in their personal and professional lives. The care of a patient with TBI occurs best in environments where seamless continuity and progression of care can occur, from EMS to the ED to the operating room, the critical care unit, acute care unit, rehabilitation unit or facility, and outpatient services. TBI often occurs in conjunction with other systemic injuries that require coordinated, expert management in order to optimize patient outcome. Nurses in acute care, emergency departments, and critical care units play an integral role in anticipatory monitoring of patients and coordinating care for patients with TBI and their families.

### Pathophysiology

#### Types of Head Injury

Traumatic brain injury is classified by the Glasgow Coma Scale (GCS) score into three different categories: mild (GCS 13–15), moderate (GCS 9–12), and severe ( $\leq$ GCS 8). This disease process is marked by heterogeneity in that there are several possible **mechanisms of injury** (Fig. 39.11), which can cause different injury patterns and damage in the same patient. Concurrent systemic injuries inherent in traumatic events complicate and may exacerbate brain injury. Types of TBI may involve the scalp, skull, meningeal layers, cerebral blood vessels, brain tissue, and neurons (Table 39.11). Often, more than one cranial or cerebral structure is involved in a traumatic injury; for example, a patient may have sustained a frontal contusion as well as a temporal **epidural hematoma**. Traumatic brain injury is further classified into two phases: primary and secondary brain injury. Primary injury occurs with the initial mechanical insult, and secondary injury encompasses all processes that occur subsequent to the initial injury. The role of healthcare providers, from initial encounters with EMS personnel to the ED and critical care units, is to prevent or attenuate the effects of secondary brain injury.

**FIGURE 39.11** Mechanisms of injury in head trauma. Primary injury occurs with the initial mechanical insult, and secondary injury encompasses all processes that occur subsequent to the initial injury.

**Table 39.11** Types of Head Injury

Type of Head Injury	Explanation
<b>Skull fracture</b>	A skull fracture can be linear or displaced. The skull fragments in a displaced fracture can remain in the same plane or can become depressed into the dura or brain tissue. In certain circumstances, these fractures require a surgical procedure to elevate and stabilize the bone (titanium plates and screws may be used). Direct visualization of the dura and underlying structures (e.g., arteries, dural sinuses, brain tissue) is possible in the operating room and is important in identifying additional injury. Fractures occurring at the base of the skull may involve a breach of the dura and subsequent cerebrospinal leak and can damage or impinge cranial nerves and blood vessels that traverse the foramina in the skull base. For example, it is important to evaluate extraocular movements because cranial nerves IV and VI could be damaged if a fracture occurs near the foramen through which they travel.
<b>Penetrating injury</b>	Penetrating injuries occur often as a result of a projectile such as a bullet and can also be caused by a knife or other projectile such as a bomb fragment. Penetrating injuries can cause catastrophic brain injury depending on the location of the injury. In addition to direct tissue damage caused by a bullet or bomb fragment, percussion injury (shock-wave-type force) also causes shearing and stretching injury to neurons, resulting in neuronal injury and death.
<b>Concussion</b>	A concussion is caused by blunt force to the head causing the brain to strike the inside of the skull. Although structural injury does not appear on conventional imaging such as a CT scan, damage has occurred at the cellular level causing an increase in cellular metabolism, resulting in an imbalance between supply of oxygen and glucose and demand because of a decrease in cerebral blood flow. Concussion was once thought to be a relatively benign disorder but has gained recent attention, particularly in athletics, related to the fact that multiple concussions can result in permanent brain injury.
<b>Contusion</b>	A contusion is superficial bleeding that occurs on the surface of the brain (cortex), often at the point of initial impact or “coup” location. Contusions may expand into hematomas and are often associated with cerebral edema. Patients with contusions are often monitored in a setting where they can receive frequent neuro assessments to capture a neurological decline from development of cerebral edema or an expanding hematoma.

**Table 39.11 Types of Head Injury—cont'd**

Type of Head Injury	Explanation
<b>Epidural hematoma</b>	An epidural hematoma is often caused by damage to an artery traveling in grooves on the inside of the skull when the skull is impacted or fractured. This blood collects in the space between the inside of the skull and the dura, pushing the dura farther away from the skull. Because the dura is tethered to the inside of the skull at the suture lines, the collection of blood is confined in width and expands inward toward the brain, displacing structures laterally and having a convex appearance. When an epidural hematoma is caused by an artery, the speed and force of the blood collection has a rapid effect on ICP and can cause neurological deterioration and coma very quickly. This type of injury typically requires emergency neurosurgery to evacuate the hematoma and decompress the brain structures displaced by the epidural hematoma.
<b>Subdural hematoma</b>	A subdural hematoma is typically caused by damage to a vein or network of veins called <i>bridging veins</i> . When the brain moves within the dural covering, small bridging veins that span the inside of the dura to the surface of the brain can be stretched or disrupted, causing bleeding. Blood collects between the inside of the dura and the cortex of the brain and is not confined, so the blood is able to collect in a larger space around the brain. The speed with which the blood collects and the amount are related to the vascular structure that was injured. For example, if a small area of bridging veins is disrupted, blood will begin to collect around the brain but may take some time to cause neurological clinical manifestations. If a larger area of bridging veins or a large venous sinus or an artery is damaged, blood may accumulate more quickly and may cause signs of increased ICP more quickly. There are three types of subdural hematomas: acute subdural hematoma where symptoms occur within minutes to 24 hours after injury; subacute subdural hematoma where symptoms occur within 2 weeks of injury, and chronic subdural where symptoms occur from 2 weeks to months or years after injury. Subacute subdural hematomas are more common in older adults and in patients with a history of alcohol abuse because of cerebral atrophy placing gradual stretch forces on the bridging veins coupled with a high risk of falling. Surgical intervention for subdural hematomas is primarily dependent on the patient's initial neurological status. If neurological status is poor (severe focal neurological deficits or coma), surgery may be performed emergently; however, patients with a mild neurological deficit or absence of neurological deficits may be monitored for neurological worsening and undergo surgery later if necessary.
<b>Intraparenchymal hematoma</b>	An intraparenchymal hematoma is a focal area of bleeding in the brain tissue usually below the cortex. Surgical intervention is typically not performed for this injury because the procedure could cause additional injury, and the blood typically breaks down and is reabsorbed over time. These hematomas are associated with cerebral edema.
<b>Subarachnoid hemorrhage</b>	
<b>Diffuse axonal injury</b>	Diffuse axonal injury (DAI) is caused by rotational and acceleration-deceleration forces and results in direct injury to the axon. Swelling and microscopic hemorrhages can occur. Often, this type of injury occurs deep within the white matter in the area of the reticular activating system, which controls wakefulness. In severe DAI, where many neurons have been injured, patients may not regain consciousness. Treatment for this type of injury does not currently exist. A DAI caused by neuronal injury can be visualized on MRI but may not be visible before 24 hours after injury.

CT, Computed tomography; ICP, intracranial pressure; MRI, magnetic resonance imaging.

Treatment paradigms, algorithms, and protocols are aimed at preventing or aggressively managing hypotension and hypoxemia in the immediate period after injury because these factors are implicated in increased mortality of patients with severe TBI. The global reduction in cerebral blood flow in the immediate period after TBI associated with cerebral autoregulatory dysfunction places the injured brain at great risk for ischemic injury, as well as injury from biochemical processes accelerated by inflammation.

Injuries to the scalp are of varying severity involving one or more layers of skin and, in some cases, underlying blood vessels. The scalp is a vascular structure, and injuries are typically associated with significant bleeding. Injuries to the scalp warrant careful inspection and palpation for

irregularities signifying skull fractures and consideration of concomitant brain injury.

### Skull Fractures

The natural function of the skull is to absorb and disperse blunt forces. Skull fractures are separated into two categories, open and closed. An open skull fracture is associated with a disruption of the scalp such that the skull is exposed to the atmosphere. A closed skull fracture may be palpated through the scalp or visualized on x-ray or other radiographical imaging. Skull fractures are further classified as nondisplaced, displaced, or comminuted. Nondisplaced skull fractures must be visualized using radiographical imaging and rarely involve disruption of the meninges because

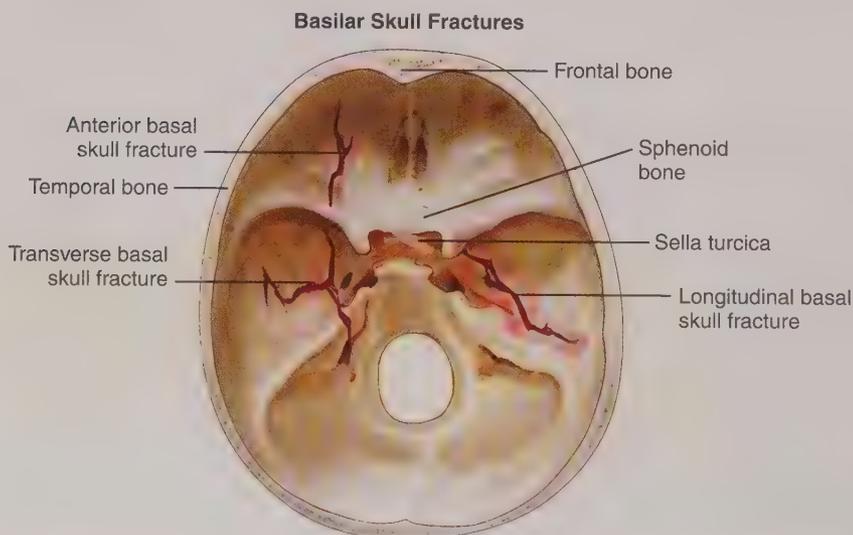

the edges of the fracture are approximated and have not moved from their original position. If a skull fracture is displaced, the edges of the fractured bone are no longer approximated and can be displaced or depressed downward toward the brain; fragments from a comminuted fracture may also be present. The edges of fractured bone or individual bone fragments are often sharp and irregular and can tear the dura mater covering the brain, underlying blood vessels, and venous sinuses, and in some circumstances, these sharp edges can violate the meninges, directly injuring brain tissue. If the dura is damaged, CSF begins to leak, placing a patient at risk for infection and herniation syndrome as intracranial contents shift with the loss of CSF. If a CSF leak is persistent, a catheter may be inserted into the lumbar spine similar to the lumbar puncture procedure; however, the catheter is introduced through the dura and left in place to drain CSF. This catheter is attached to an external CSF drain and is referred to as a lumbar drain. If vascular structures, such as jugular veins and carotid arteries, which traverse the base of the skull through openings called *foramina* and occupy bony ridges on the inside of the skull (middle meningeal artery), are damaged, life-threatening hemorrhage can result (see the following text for descriptions of hematomas).

Fractures of the base of the skull are called **basilar skull fractures** and involve the bony structures at the level of the midface. The major bones in this area are the sphenoid bone, sella turcica (protects the pituitary gland), and inferior portions of the frontal and temporal bones. The hallmark sign of a basilar skull fracture (Fig. 39.12), when the dura has been breached, is the visualization of fluid from the ear (fracture in the middle fossa) or nose (fracture in the anterior fossa). A late sign of a basilar fracture is bruising around the eyes (racoon's eyes) or the ears (**Battle's sign**; Fig. 39.13). Many blood vessels and cranial nerves traverse the bony structures of the skull base and are vulnerable to injury depending on the location and size of a basilar skull fracture. For instance, the carotid arteries travel through

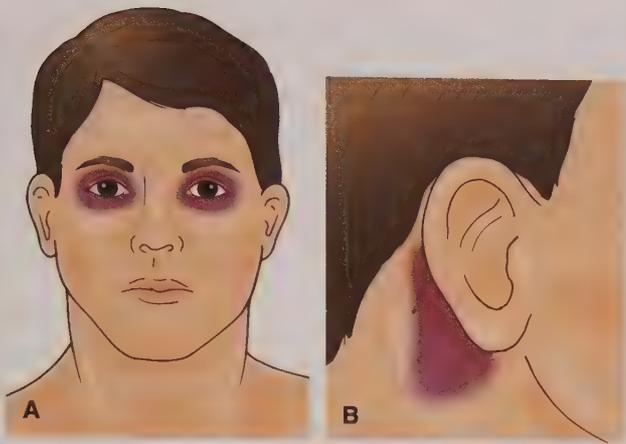

foramina in the sphenoid bone and may be injured, causing clinical manifestations of stroke if a fracture has occurred in that area of the skull base and the carotid artery has been disrupted. Cranial nerves that control the movement of the eyes may also become entrapped or damaged.

### Hematomas

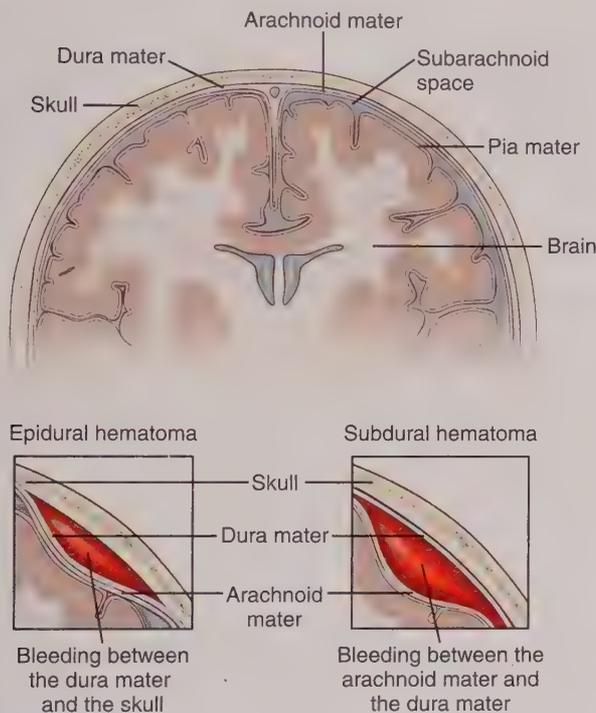

An **epidural hematoma** occurs when blood collects in the potential space between the skull and the dura mater (Fig. 39.14). The dura is the tough covering of the brain that covers the brain and spinal cord and is connected to the inside surface of the skull in the suture lines, forming potential compartments or spaces. Potential spaces are collapsed until filled with matter (i.e., fluid or air). When an epidural hematoma occurs, blood fills a particular epidural space or compartment and begins to compress or displace brain tissue inward, causing a concave appearance on radiographical imaging. One of the more common etiologies of an epidural hematoma is an arterial bleed caused by a temporal bone fracture, resulting in disruption of the middle meningeal artery. An epidural hemorrhage is most often caused by an arterial bleed but may also be caused by a venous injury. When an artery is damaged, the flow of blood is very rapid and is under pressure; therefore, the speed with which blood collects and the potential amount can cause a rapid increase in ICP and herniation of brain tissue laterally and then downward if this bleeding is not stopped. An epidural hematoma is a neurosurgical emergency requiring prompt evacuation of the blood clot and repair to the damaged blood vessels. The clinical presentation of an epidural hematoma varies from a comatose state on initial presentation to a lucid (aware of surroundings) state, depending on the size and location of the hematoma as well as the rate and volume of blood collection in the epidural space. Patients with epidural hematomas may initially lose consciousness, regain consciousness and appear lucid, and then very rapidly deteriorate to unresponsiveness with signs of cerebral herniation syndrome. This phased

**FIGURE 39.12** Basilar skull fractures.

**FIGURE 39.13** Late signs of a basilar fracture. A, Raccoon's eyes. B, Battle's sign.

**FIGURE 39.14** Hematomas. In an epidural hematoma, blood collects between the skull and dura mater. In a subdural hematoma, blood collects between the arachnoid mater and dura mater.

presentation occurring in a proportion of patients with an epidural hematoma is referred to as the “talk and die phenomenon.” Because of the typically rapid accumulation of blood in the epidural space and the tendency for the fluid collection to expand inwardly, compressing brain tissue, this injury is a neurological emergency for which immediate surgical evacuation of the hematoma is the only option.

A **subdural hematoma** refers to a collection of blood beneath the dura and above the arachnoid layer, which is most often caused by venous bleeding but can involve arterial disruption (see Fig. 39.14). The brain is connected to the inner surface of the dura by a network of veins called *bridging veins*. When the head is impacted by a blunt force,

the brain moves within the skull and dural covering. When the brain moves within the dural covering, tension is placed on the bridging veins, causing stretching and tearing and releasing a steady flow of blood around the brain in the subdural space, increasing ICP. Neurosurgical intervention for a subdural hematoma often depends on the clinical stability of the patient and the state of the neurological examination. For instance, if the patient is easily arousable, alert and oriented, and without focal motor deficits, surgical intervention may be deferred while the patient's neurological status is closely monitored.

### Contusion

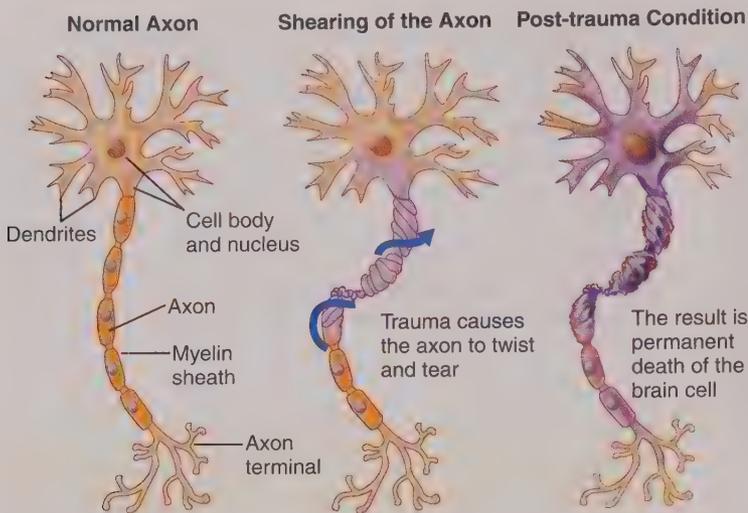

A **cerebral contusion** is a bruise on the surface of the brain that has the potential to transform into a hematoma and is associated with the development of significant cerebral edema. Patients with a cerebral contusion require serial neurological assessments with a high degree of suspicion for neurological deterioration. Neurological assessment is the best means by which to identify increased ICP due to bleeding of the hematoma or cerebral edema and facilitates rapid evaluation and medical intervention, which may be lifesaving.

### Neuronal Injury

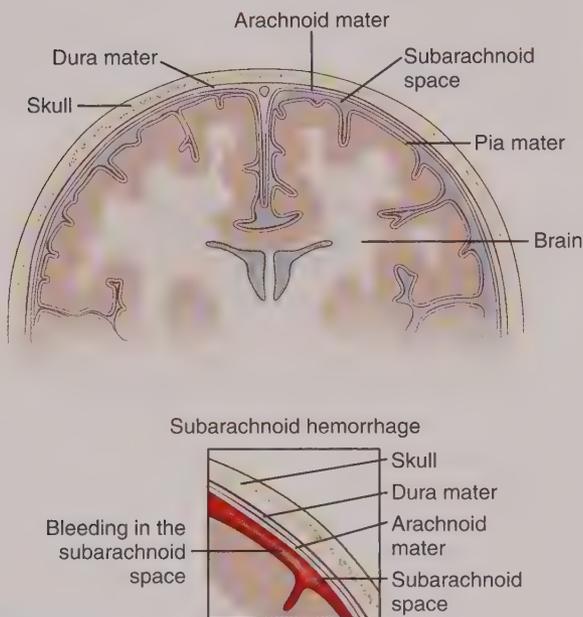

An increasing body of knowledge exists surrounding neuronal injury during head trauma, which is not easily visualized with the usual radiographical tests such as CT or MRI because the problem is at the cellular level and involves a hypermetabolic state where energy is rapidly consumed and an energy crisis is created, causing cellular injury and death. Magnetic resonance imaging spectroscopy and positron emission tomography (PET) are helping researchers characterize the neuronal responses to head injury across the spectrum of severity from mild to severe. During acceleration, deceleration, or rotational forces, the brain moves within the skull and meninges. **Diffuse axonal injury (DAI)** describes direct injury to neurons due to shearing and rotational forces (Fig. 39.15). The severity of the DAI depends on the location and extent of neuronal injury. For example, if networks of neurons in the area of the reticular activating system are injured, a patient may not have the ability to awaken. Diffuse axonal injury may also be associated with sympathetic dysregulation, also termed **sympathetic storming**, which presents with episodic tachycardia, tachypnea, and hyperthermia and may be accompanied by spontaneous motor posturing (flexor or extensor).

### Vascular Injury

Traumatic subarachnoid hemorrhage (SAH) is the most common cause of SAH and is associated with a poor prognosis in patients with TBI. Traumatic SAH is typically focal in location as opposed to aneurysmal SAH, which is more often characterized by diffuse layering of blood in the arachnoid layer (Fig. 39.16). This type of injury occurs as a result of disruption to veins and arteries traversing the arachnoid layer. Local vasospasm may occur as a result of this type of injury, although the local nature of the bleeding

**FIGURE 39.15** Diffuse axonal injury. Diffuse axonal injury (DAI) is direct injury to neurons due to shearing and rotational forces.

**FIGURE 39.16** Traumatic subarachnoid hemorrhage (SAH). Traumatic SAH is typically focal in location and occurs as a result of disruption to veins and arteries traversing the arachnoid layer.

separates it from the typical course experienced by patients with aneurysmal SAH.

Arterial dissection may occur during head or neck trauma. The extracranial portions of the carotid and vertebral arteries located in the neck are vulnerable to mechanical injury. Arterial dissection is characterized by a disruption or tear to one or more of the blood vessel layers. Disruption of the intima, the innermost layer, can result in clot formation that can occlude the inner lumen of the blood vessel. An intimal tear can also produce a flap of tissue that can occlude an artery, causing an ischemic stroke. Arterial dissection may present with sudden focal neurological changes corresponding to the vascular territory of the involved vessel. Neck pain and the presence of **Horner's sign** are also associated

with this injury. Horner's sign refers to the following triad of symptoms ipsilateral (on the same side) to the injury: miosis (pupillary constriction), ptosis (eyelid droop), and anhidrosis (decrease in sweating).

## Management

### Medical Management

The management of traumatic head injury focuses on minimizing the damage caused by direct trauma to underlying brain tissue and structures, managing intracranial pressure, and promoting cerebral perfusion. With traumatic head injuries, ICP-monitoring measures (discussed earlier in this chapter) are often implemented. The choice of type of ICP monitoring is typically related to the type of injury as well as whether there is disruption of the skull. Because of the potential for airway, breathing, and circulatory complications associated with traumatic head injuries, emergent management of these patients includes ensuring an effective airway, breathing pattern, and hemodynamic stability.

### Diagnosis

Computed tomography of the head is an initial diagnostic test performed in patients with traumatic head injury. Transcranial Doppler studies may also be used to indirectly measure cerebral blood flow and are often used to determine cerebral blood cessation in severe head injuries. Laboratory analysis includes baseline serum electrolytes, complete blood cell count, and coagulation studies. The serum sodium and osmolality are particularly important in the event that hyperosmolar agents are used to decrease ICP.

### Treatment

Specific interventions to manage increased ICP include proper positioning as well as the administration of hyperosmolar agents to decrease fluid in the brain (see Increased ICP section earlier in this chapter). Uncontrolled increased ICP ultimately leads to herniation syndrome (see Table 39.1).

Treatment of herniation syndrome is often referred to as a “brain code” due to the rapid nature of resuscitation and the resources required for resuscitation that mirror those of cardiac arrest. Herniation syndrome is treated with the same interventions as increased ICP acutely to decrease ICP and relieve the pressure causing displacement of brain tissue within the skull or through the foramen magnum at the bottom of the cranium.

### Surgical Management

Depending on the type of traumatic head injury, various surgical procedures are indicated. With skull fractures, there is a need to debride and clean the wound area as well as to remove any bone fragments that may be at the area of impact. Patients with skull fractures are at risk for infections of the central nervous system, including meningitis and encephalitis (discussed in Chapter 36).

A craniotomy may be indicated in patients with hemorrhagic injuries and typically involves opening of the skull and removal of blood accumulations. Both epidural and subdural hematomas are surgically evacuated to decrease ICP. Surgery is not indicated in patients with diffuse axonal injuries because there is no specific area of blood removal. After surgery, the patients are managed in the ICU, with management of ICP as the priority.

### Complications

Patients with TBI may develop complications such as increased ICP, herniation syndromes (discussed earlier in this chapter), meningitis (discussed in Chapter 36) especially with open fractures and dural tears, seizure activity, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH). When swelling in the brain places pressure directly on the posterior portion of the pituitary gland or on blood vessels supplying this area, disorders of sodium and water balance can occur. Antidiuretic hormone (ADH) is secreted from the posterior portion of the pituitary gland. Diabetes insipidus occurs in the absence of ADH where urinary output increases rapidly, causing a loss of free water and severe dehydration manifesting as hypernatremia and low urine specific gravity (<1.005). Diabetes insipidus is treated by replacing fluid losses and ADH with an exogenous form, either intravenously, subcutaneously, or intranasally.

SIADH occurs when an excessive amount of ADH is secreted from the posterior pituitary. Traumatic brain injury is associated with disruption of the hypothalamic–pituitary axis, and one possible consequence of this disruption can be SIADH. In contrast to DI, SIADH results in the retention of free water, causing hyponatremia (dilutional) and a normal to low urinary output. The mainstay of treatment for SIADH is restricting the intake of free water; typical restrictions are 1,000 to 2,000 mL per day. Reducing the intake of free water allows urinary output to exceed the amount of free water retained, and serum sodium returns to the normal range. (Both DI and SIADH are discussed in more detail in Chapter 41.)

## Nursing Management

### Assessment and Analysis

Monitoring for clinical manifestations of increased ICP as well as ensuring effective cerebral perfusion are the priority assessments in the patient after traumatic head injury. It is imperative that the nurse be vigilant to subtle changes in level of consciousness, which may be complicated with the use of medications to induce a barbiturate coma to decrease cerebral metabolism. Vital sign assessments are also important because an effective blood pressure is necessary to facilitate cerebral perfusion in the patient with increased ICP. Serial neurological examinations, including the Glasgow Coma Scale, are aspects of these patients’ plans of care. When repeated neurological assessments are performed, a neurological change, such as a change in level of consciousness, subtle motor weakness, or cranial nerve deficit, may be identified early enough to intervene, preventing further damage to the brain.

### Nursing Diagnoses

- **Ineffective airway clearance** related to decreased level of consciousness and inability to protect the airway
- **Ineffective cerebral tissue perfusion** related to increased ICP, cerebral edema, hemorrhage, impaired autoregulation, and hyperventilation
- **Risk for impaired thermoregulation** related to damaged temperature-regulating mechanisms in the brain
- **Risk for impaired skin integrity** related to bedrest, hemiparesis, hemiplegia, immobility, decreased level of consciousness, or restlessness
- **Impaired family coping** related to sudden life-threatening illness and uncertain outcome

### Nursing Interventions

#### ■ Assessments

- Serial neurological assessments every 1 to 2 hours in the acute phase of injury  
*It is necessary to continually assess the patient with a TBI against an established baseline for signs of increased ICP as well as to monitor for cerebral edema, expansion of a hematoma, or conversion of a contusion to a hematoma.*
- ECG and cardiac biomarkers  
*Patients with severe TBI may demonstrate ECG findings suspicious for myocardial ischemia and injury due to an initial surge of catecholamines during the sympathetic nervous system response upon initial injury. The release of catecholamines during the initial injury usually results in reversible injury to the myocardium, also referred to as myocardial stunning.*
- Vital signs  
*Although changes in vital signs are a late sign of increased ICP, it is necessary to trend BP, HR, RR, and temperature as additional pieces of data in analyzing a patient’s overall condition. An effective BP is particularly important with increased ICP in order to maintain a therapeutic CPP.*

*A temperature elevation may be seen with infection (meningitis) or secondary to the area of the brain that controls thermoregulation.*

- Seizure activity  
*Patients with TBI above the tentorium (supratentorial) and closer to the cerebral cortex are at risk for seizure activity because cellular dysfunction and tissue injury from ischemia may cause a disruption in electrical impulse conduction in the brain, causing disorganized electrical activity, which is a seizure. (Care of patients with seizures is discussed in Chapter 36.)*

### ■ Actions

- Positioning head of bed greater than 30 degrees with the patient's head in midline, and avoiding sharp hip flexion  
*Patients are positioned in the midline with the head of the bed elevated to facilitate drainage of venous blood from the head, decreasing ICP.*
- Management of CSF leak: If clear fluid is draining from the ear or nose, it should not be stopped; it should be collected using loosely applied gauze.  
*It is important to identify a leakage of CSF because this indicates a breach in the dura and places patients at risk for infection (meningitis or encephalitis). A lumbar drain is placed when a CSF leak is persistent in order to facilitate healing of the dural tear because it reduces pressure on the injured tissue. Drainage may also be tested for glucose in some instances.*
- Avoid nasogastric tube placement in patients with a known basilar skull fracture or in patients where the base of the skull has not been visualized on radiographical injury.  
*In patients with a basilar skull fracture, placement of a nasogastric tube may cause further disruption of a fracture and places the patient at risk for the tube to invade the cranium. Orogastric tube placement is an alternative.*
- Initiate enteral nutrition.  
*Current guidelines suggest starting enteral nutrition within the first 72 hours of injury in order to reach an adequate goal rate by 7 days. Patients with severe TBI demonstrate a hypercatabolic state where the body utilizes substrates at a rapid pace, causing utilization and depletion of fat and protein stores. Bedside indirect calorimetry may be helpful in establishing a patient's resting metabolic rate and true caloric needs to optimize his or her nutritional regimen. Indirect calorimetry is performed at the bedside by a respiratory therapist or other credentialed clinician.*
- Maintain normothermic temperature (antipyretics and cooling devices as ordered).  
*Normal temperature should be achieved and maintained in order to prevent an increase in cerebral oxygen and energy demands, which can worsen metabolic dysfunction in neurons.*
- Implement seizure precautions.  
*Precautions for seizure activity, particularly generalized tonic-clonic seizure activity, include having suction readily*

*available to clear the airway after a seizure. Common medications to be given during a seizure are benzodiazepines (lorazepam [Ativan]) to stop the seizure activity; antiepileptic medications such as fosphenytoin (Cerebyx), levetiracetam (Keppra), or phenytoin (Dilantin) are administered to prevent further seizures.*

- Ensure venous thromboembolism (VTE) prophylaxis with sequential compression devices, graduated compression stockings, and subcutaneous injections of an anticoagulant as prescribed.  
*Patients with severe TBI are at an increased risk for VTE and subsequent pulmonary embolus because of tissue or endothelial damage occurring with the traumatic event, immobility, and hypercoagulability caused by the systemic inflammatory response that is activated after a traumatic event (these three factors are known as Virchow's triad).*

### ■ Teaching

- Specific teaching regarding the patient's injury, coma, and increased ICP  
*Families of patients with severe TBI benefit from succinct information regarding the patient's specific type of brain injury and anticipated course. Specific information about a patient's specific type of head injury may empower patients or family members to ask further questions or to take a greater part in their own or their family member's healthcare.*
- Orientation to the patient's ICU room and monitoring equipment  
*Families should be aware of the purpose of different pieces of monitoring equipment, such as ICP monitors, cardiac monitors, and the ventilator, in order to decrease anxiety and attempt to make them comfortable in the room so that they can accomplish their caregiving role for the patient to the greatest extent possible.*

### Connection Check 39.6

The family of a patient who sustained a left temporoparietal subdural hematoma and bilateral frontal contusions is visiting the patient for the first time and is asking repeatedly when the patient will awaken. What is the best method for the nurse to use for beginning education with this family?

- Providing a detailed diagram of the brain and pointing out the functions of each lobe in order to create a foundation from which the family can understand the patient's injury
- Providing a handout printed from the Internet on severe TBI
- Assessing the family's level of knowledge and information about the patient's brain injury and providing general information regarding the uncertainty of the outcome in the first several days after TBI
- Deferring any sharing of information until a formal family conference is held with the medical care team

## Evaluating Care Outcomes

Patients with severe TBI have varied responses to brain injury, and treatment depends on the location and severity of the brain injury, comorbid factors, and preexisting health status, as well as the onset of complications. In order to mitigate secondary brain injury and preserve neurological function, the nurse provides anticipatory monitoring of the neurological status and vigilant assessment for potential complications. Educating, supporting, and linking the patient's family with available resources is an essential role of the nurse in promoting family coping.

## NEUROGENIC SHOCK

### Pathophysiology and Clinical Manifestations

Neurogenic shock, a type of distributive shock causing vasodilation and relative hypovolemia, threatens underlying acute conditions due to hypoperfusion if it is not recognized and treated rapidly. A disruption in sympathetic nervous system stimulation causes an inability of vascular smooth muscle to constrict, resulting in decreased blood return to the heart and decreased cardiac output. Sympathetic nervous system interruption, with unopposed parasympathetic nervous system action, may result in transient, profound bradycardia in some patients. Neurogenic shock occurs as a result of conditions such as spinal cord injury (above the T6 level), stroke in the brainstem, high doses of barbiturates, and anesthesia techniques, both general and regional. In spinal cord injury, neurogenic shock is caused by a disruption of cardiac sympathetic fibers (vasomotor fibers) that exit the spinal cord at the T1 to T6 levels. Disruption of these fibers causes hypotension, bradycardia, and peripheral vasodilation below the level of injury. Additionally, these vasomotor fibers typically oppose the parasympathetic nervous system, preventing sustained bradycardia; however, in this case, the parasympathetic nervous system is unopposed, producing profound bradycardia. When neurogenic shock is caused by general anesthesia or stroke in the brainstem, symptoms of neurogenic shock (hypotension, bradycardia, and peripheral vasodilation) arise from the vasomotor center in the brainstem.

In the absence of pathology causing dysfunction in the sympathetic nervous system, vascular smooth muscle is able to readily constrict, altering the caliber of systemic blood vessels in response to position or systemic volume changes. Vascular tone in neurogenic shock is significantly decreased without the ability to constrict, rendering a patient vulnerable to systemic hypoperfusion. Patients with neurogenic shock typically have warm and dry skin due to systemic vasodilation. Hypovolemia in neurogenic shock is characterized as relative because of the fact that the size of the systemic vasculature has rapidly expanded without a concurrent increase in volume to fill that expanded space. The effects of hypoperfusion in distributive shock are anaerobic metabolism and resultant lactate accumulation, resulting in

acidosis, myocardial ischemia, and cerebral hypoperfusion. The clinical presentation includes profound bradycardia, hypotension, changes in level of consciousness, and metabolic acidosis.

## Management

### Medical Management

The management of neurogenic shock is focused on correcting the primary etiology when possible and treating cardiovascular effects such as hypotension and bradycardia. Intensive cardiovascular support, including fluid resuscitation (boluses of crystalloid to increase stretch of the myocardial fibers in the atria, resulting in an increase in the strength of ventricular contraction and increased cardiac output), vasoactive infusions (e.g., norepinephrine [Levophed], epinephrine [adrenaline], phenylephrine [Neo-Synephrine]), atropine to block vagal (parasympathetic) stimulation, and transcutaneous or transvenous pacing capabilities to treat sustained symptomatic bradycardia, is necessary to prevent systemic complications of shock. If the primary condition cannot be improved, continued cardiovascular support is necessary to maintain adequate systemic perfusion.

Loss of vascular tone is treated with vasoactive agents that have an effect on alpha receptors, such as phenylephrine, norepinephrine, epinephrine, and dopamine (at doses >10 mcg/kg/min). Concurrent fluid resuscitation is undertaken to restore vascular volume and improve systemic perfusion. Episodic bradycardia is treated with parasympatholytic medications such as atropine. Transcutaneous and then transvenous pacing may be utilized to treat repeated episodes of profound bradycardia. Serum lactate levels and arterial blood gases may be utilized to monitor acidosis and judge the effectiveness of resuscitation strategies.

Ongoing treatment of decreased vascular tone may include oral sympathomimetics such as midodrine (Amatine, ProAmine), which affects the alpha-1 receptors (alpha-1 receptors control vasoconstriction of vascular smooth muscle), causing constriction of the peripheral vasculature. After administration of midodrine, the nurse should see a rise in blood pressure because this medication affects only alpha-1 receptors, and effects on heart rate should not be seen. Vigilant nursing monitoring and care coupled with medical interventions are necessary to prevent multisystem organ failure in neurogenic shock.

### Complications

The complication of neurogenic shock is continued systemic hypoperfusion leading to multisystem organ failure. Hypoperfusion in patients with neurogenic shock occurs as a result of massive systemic vasodilation causing a reduction in cardiac output and blood pressure. Bradycardia may also occur, further compromising blood flow to vital tissues and organs because of the disruption of sympathetic outflow, which also contributes to decreased cardiac output and blood pressure.

## Nursing Management

### Assessment and Analysis

Patients with neurogenic shock require intensive cardiovascular monitoring in order to detect bradycardia, dysrhythmias, and hypotension that result from a disruption in sympathetic innervations. Rapid medical interventions, including administration of atropine, transcutaneous or transvenous pacing, fluid resuscitation, and administration of vasoactive medications, may be employed in the care of a patient with neurogenic shock. Ongoing assessments for patients in neurogenic shock may include monitoring cardiac output, intravascular volume, and other hemodynamic parameters. Mechanical ventilation may also be required in patients with neurogenic shock depending on the underlying cause. Management of common complications such as deep venous thrombosis, pulmonary embolus, and skin breakdown is essential in optimizing outcomes in this patient population.

### Nursing Diagnoses

- **Impaired tissue perfusion** related to hypotension, bradycardia, and peripheral vasodilation
- **Risk for fluid volume deficit** due to relative hypovolemia that occurs with loss of vasomotor tone and maldistribution of volume in the vascular space
- **Anticipatory grieving** related to sudden loss of function and accompanying critical illness

### Nursing Interventions

#### ■ Assessments

- Vital signs every 1 to 2 hours or more frequently if vasoactive infusions (e.g., norepinephrine [Levophed], phenylephrine [Neo-Synephrine]) are being administered  
*Frequent monitoring of vital signs allows for rapid identification of cardiovascular deterioration, such as hypotension or an episode of bradycardia, that may require further intervention, such as titration of vasoactive medications, use of a pacemaker, or administration of atropine (to increase HR).*
- Hemodynamic parameters such as central venous pressure (CVP), pulmonary artery occlusion pressure (PAOP), cardiac output/cardiac index (CO/CI), stroke volume (SV), and systemic vascular resistance (SVR) may be measured every 2 to 4 hours or after treatments such as a bolus of IV fluid to evaluate patient response. *Hemodynamic parameters are measured in order to evaluate a patient's response to medical therapies. For example, the CVP or PAOP is evaluated in order to determine whether an adequate vascular volume or preload has been reestablished. The cardiac output (CO) or cardiac index (CI), which is cardiac output divided by body surface area, is evaluated to determine the overall condition of the vascular system, and systemic vascular resistance is used to quantify the degree of vasoconstriction or vasodilation in the vascular system (see Chapter 32 for further discussion of hemodynamic monitoring).*

- Intake and output every 1 to 2 hours.  
*Accurate measurement of input and output plays a role in determining whether fluid balance is in excess or if a patient requires additional fluid.*
- Physical assessment at least every 4 hours  
*Comprehensive physical assessment is integral in detecting multisystem complications that may arise in patients with neurogenic shock, such as ARDS, pneumonia, paralytic ileus, and skin breakdown.*

#### ■ Actions

- Raise the head of bed slowly (10–15 degrees per hour) in a systematic manner.  
*Because of loss of systemic vasomotor tone, raising the head of the patient's bed may cause orthostatic hypotension because of an inability of the peripheral blood vessels to constrict upon position change. Orthostatic hypotension in this circumstance may cause hemodynamic instability (e.g., lowered BP and cardiac output).*
- Assist with the insertion of an arterial line for continuous BP monitoring.  
*An arterial line enables continuous monitoring of BP and the ability to set alarm parameters so that hypotension is identified immediately. Frequent blood sampling for ABGs and other laboratory tests is facilitated by the presence of an arterial line.*
- Assist with the insertion of a pulmonary artery catheter in situations where cardiovascular dysfunction is severe. *A pulmonary artery catheter allows for frequent monitoring of preload (measured as CVP and PAOP), afterload (measured as SVR), and contractility (to some extent with cardiac output and stroke volume and right and left stroke work indices) in order to optimize medical therapies on the basis of patient response.*
- Administer IV fluids and IV sympathomimetic agents (e.g., phenylephrine [Neo-Synephrine], norepinephrine [Levophed]).  
*Fluid resuscitation is undertaken in order to increase vascular volume, which is inadequate compared to the increase in the size of the vascular space due to vasodilation. Administration of sympathomimetics aids in increasing vasomotor tone, which is reflected as an increase in systemic vascular resistance. These strategies used in combination ideally raise cardiac output and restore adequate tissue perfusion.*
- Administer atropine.  
*Medications such as atropine inhibit the action of the vagal nerve, causing the HR to increase, and treat symptomatic bradycardia.*
- Prepare for transcutaneous pacing if a patient does not have transvenous pacing wires in place.  
*A temporary pacemaker may be required to manage bradycardia in patients with neurogenic shock because of sympathetic nervous system dysfunction. In some cases where dysfunction of the sympathetic nervous system is irreversible, a permanent pacemaker may be required.*
- Implement VTE prophylaxis.  
*Patients in neurogenic shock are at high risk for VTE, particularly in cases where the etiology of neurogenic shock*

is spinal cord injury. Pharmacological methods or mechanical devices (e.g., sequential compression devices, pneumatic foot pumps) may be used alone or in combination depending on patient-specific factors.

### Teaching

- Explain the specific cause of neurogenic shock and anticipated impact on the patient's immediate and future hospital course.  
*There are several causes of neurogenic shock with specific associated implications and factors that impact a patient's overall condition. For instance, in spinal cord injury, neurogenic shock may last for weeks to months or longer, requiring long-term medication management and, in some cases, an implanted pacemaker, whereas a patient in neurogenic shock due to general anesthesia has resolution of clinical manifestations when anesthetics are metabolized.*
- Explain the reason for medication therapy.  
*Explaining therapeutic measures such as medications that are administered may provide a patient and his or her family a greater sense of control over a traumatic circumstance, where most control is perceived to be exercised by the healthcare team.*
- Explain supportive therapies.  
*Understanding the rationale behind other supportive therapies may give patients and their families needed information to make necessary decisions regarding care as well as a sense of control in decision making.*

### Evaluating Care Outcomes

Intensive monitoring of a patient's response to interventions is necessary to establish and maintain adequate tissue perfusion, initially compromised because of systemic hypoperfusion in neurogenic shock. Continuous evaluation of BP, HR, RR, and hemodynamic parameters measuring preload, such as CVP and PAOP, provides valuable information on the effectiveness of interventions. In addition to these physiological parameters, evaluation of mentation can be a sensitive indicator of the adequacy of resuscitation. In patients with a spinal cord injury, an often-irreversible cause of neurogenic shock, decreased vascular tone may be managed with a long-term regimen of oral sympathomimetics and vigilant surveillance of hemodynamic response to different activities, such as transitioning from a lying to a sitting position and transferring from bed to wheelchair. Symptomatic bradycardia may be managed with an implanted pacemaker. See Chapter 37 for a full discussion of spinal cord injury.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Stewart is diagnosed with a right middle cerebral artery stroke and carotid stenosis of the right carotid artery (approximately 85% occluded) due to atherosclerosis. Mr. Stewart makes steady

progress after evaluations by physical and occupational therapies as well as speech-language pathology. As a strategy to prevent him from experiencing another stroke, he is scheduled for a carotid endarterectomy, a surgical procedure that removes atherosclerotic plaque that has caused extreme narrowing of a blood vessel and stroke. After the carotid endarterectomy, Mr. Stewart is discharged to an acute inpatient rehabilitation facility, where he makes steady progress in regaining the use of his left leg and continues to progress in regaining some function of his left arm.

### Case Study Questions

1. The nurse recognizes which findings in Mr. Stewart as modifiable risk factors for stroke? (Select all that apply.)
  - A. 58 years old
  - B. History of hypertension
  - C. History of high cholesterol
  - D. Male
  - E. Tobacco use
2. Which diagnostic study is indicated in Mr. Stewart to evaluate cardiac function and assess for a cardioembolic source of his stroke?
  - A. CT scan
  - B. ECG
  - C. MRI
  - D. Ultrasound
3. What is a contraindication to the administration of rt-PA in a patient with suspected ischemic stroke?
  - A. Patient who awakens from 6 hours of sleep with symptoms of stroke
  - B. Neurological impairment based on the NIHSS
  - C. Platelet count of 200,000 mm<sup>3</sup>
  - D. Onset of symptoms 2½ hours before presenting to ED
4. The nurse is monitoring Mr. Stewart after he receives rt-PA. Which clinical manifestation indicates an adverse effect of rt-PA?
  - A. Decreasing level of consciousness
  - B. Hyperglycemia
  - C. Gastroparesis
  - D. Productive cough
5. The nurse includes which information in the teaching plan for Mr. Stewart and his family about the management of acute ischemic stroke? (Select all that apply.)
  - A. Stroke risk factors
  - B. Need for annual CT scan
  - C. Prevention of aspiration
  - D. Prevention of deep vein thrombosis
  - E. Importance of BP control

## CHAPTER SUMMARY

Care of the critically ill patient with neurological illness focuses on preventing deterioration and, in cases where it cannot be prevented, mitigating the effects of neurological deterioration through rapid identification of complications and aggressive medical interventions. Increased ICP is a common complication of neurological illness such as ischemic and hemorrhagic stroke, central nervous system infection, brain tumors, and intracranial surgery. Decreased level of consciousness is the most sensitive and early indicator of increased intracranial pressure (ICP). When a patient is monitored for increased ICP, the reason for a change in the patient's neurological assessment may not be obvious, but initial treatment and evaluation strategies for increased ICP are the same regardless of the cause. Initial measures such as ensuring a patent airway with adequate oxygenation and ventilation, elevating the head of the bed, administration of osmotic diuretics (if indicated), and preparing the patient for radiographical imaging should be accomplished in rapid sequence.

Patients with ischemic and hemorrhagic stroke require close surveillance of vital signs, particularly BP, to prevent worsening of ischemia or further bleeding depending on the patient's specific stroke diagnosis. Patients who experience a stroke are vulnerable to complications such as aspiration because their ability to swallow after any type of stroke is often impaired. Systematic screening for swallowing dysfunction, appropriate referral to a speech-language pathologist, and implementation of a patient-specific plan for avoiding aspiration help to decrease this morbidity in patients after a stroke. A major complication of subarachnoid hemorrhage is cerebral vasospasm, which occurs most often between days 4 and 14 after the initial hemorrhage, with the peak risk period at 5 to 9 days after initial bleeding. Anticipatory monitoring for clinical manifestations of vasospasm enables timely implementation of a plan of care aimed at preventing cerebral infarction.

Developing and implementing a teaching plan specific to a patient's type of stroke, cerebrovascular risk factors, medications, access to emergency care, and need for continued follow-up care is essential in caring for this population of patients. It is important to take into consideration the patient's or family's learning needs and reported preferences for this important teaching. When teaching specific

psychomotor skills for self-administration of medication or other treatments, it is important to include demonstration and return-demonstration activities so that the nurse can be sure that a patient or family member is able to translate verbal or written information into performance of the required activity. During initial encounters with patients and family members, it is important to consider their apparent emotional state as well as their need for information about the event or condition. Assessing the level of knowledge about the situation serves as a foundation to choose specific topics and methods for providing information and education to patients and families.

Traumatic brain injury (TBI) is classified by the Glasgow Coma Scale (GCS) as mild (GCS 13–15), moderate (GCS 9–12), or severe ( $\leq$ GCS 8). Traumatic injuries to the brain include skull fractures, epidural hematomas, subdural hematomas, contusions, traumatic subarachnoid hemorrhage, and diffuse axonal injuries. Management of these injuries focuses on the management of increased intracranial pressure, maintaining optimal hemodynamic status through the administration of IV fluids and vasoactive medications, and minimizing complications. Recovery from TBI is often a long process, requiring close surveillance of patients and support and teaching for both the patient and families.

Neurogenic shock is caused by several different etiologies, the most well-known of which is spinal cord injury, and is caused when sympathetic innervation is disrupted, resulting in loss of vasomotor tone and possibly bradycardia. Nursing care of the patient with neurogenic shock involves monitoring of the patient's responses to therapies and anticipation of complications that require further intervention to restore hemodynamic stability and maintain patient safety. The nurse should be able to anticipate general medical interventions that may be ordered in the case of deterioration, such as fluid therapy, medications (atropine for bradycardia and vasoactive medications for decreased BP or cardiac output), and cardiac pacing.

Vigilant, skilled, anticipatory monitoring by the nurse caring for critically ill patients with a neurological injury makes a significant impact in preventing complications and restoring or preserving neurological function. These patients allow the nurse to utilize a broad range of nursing skills, such as assessment, teaching, interpersonal, psychomotor, and emergency skills.

## Promoting Health in Patients With Endocrine Disorders

### Chapter 40

## Assessment of Endocrine Function

*Janice Hoffman*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the location and function of endocrine glands
2. Discussing the actions of hormones excreted by endocrine glands
3. Explaining the procedure for completing a history and physical assessment of the endocrine system
4. Correlating diagnostic examinations to endocrine function
5. Explaining nursing considerations for diagnostic studies relevant to the endocrine system
6. Discussing changes in endocrine function associated with aging

#### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Metabolism

#### ESSENTIAL TERMS

Aldosterone  
Calcitonin  
Catecholamines  
Corticosteroid  
Cortisol

Thyroxine  
Triiodothyronine  
Tropic hormones

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Greta Johnson is a 27-year-old female who has been experiencing insomnia, restlessness, and irritability the past several months. Because these symptoms are interfering with her ability to complete her work as a graduate research assistant at a local community college, she presents today to her nurse practitioner for a complete physical. During the initial interview, Greta describes that sometimes she feels as if her “heart is racing” and has noticed palpitations. She has also noted an 8-pound weight loss over the last month despite an increased appetite and food intake ...

## INTRODUCTION

The endocrine system includes glands found in various locations in the body and works in conjunction with the nervous system in coordinating many life-sustaining functions associated with metabolism, growth and development, blood glucose control, and sexual functioning.

Endocrine glands include the hypothalamus, pituitary gland, adrenal glands, thyroid glands, parathyroid glands, gonads, and select cells of the pancreas (islet cells) (Fig. 40.1). These glands secrete **hormones** that are chemical messengers that act on specific **target tissues**, resulting in physiological functions. Underproduction and overproduction of selected hormones are the leading causes of endocrine dysfunction. Table 40.1 lists the major endocrine glands and their associated hormones.

Hormones from the endocrine glands are secreted directly into the blood system, compared with hormones secreted from **exocrine** glands that are released through ducts. Exocrine glands include lacrimal, salivary, and sweat glands and the part of the pancreas that secretes pancreatic juices that are released in the small intestine. The function of the endocrine system is directly associated with secretion and levels of circulating hormones, and disorders are classified as primary, secondary, tertiary, and quaternary. Primary disorders involve actual dysfunction of the endocrine gland, secondary disorders refer to dysfunction of the anterior pituitary gland, tertiary disorders refer to dysfunction of the hypothalamus, and quaternary disorders refer to the inability of the target tissue to respond to the hormone.

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

The function of the endocrine system is closely linked to the nervous system and is commonly referred to as

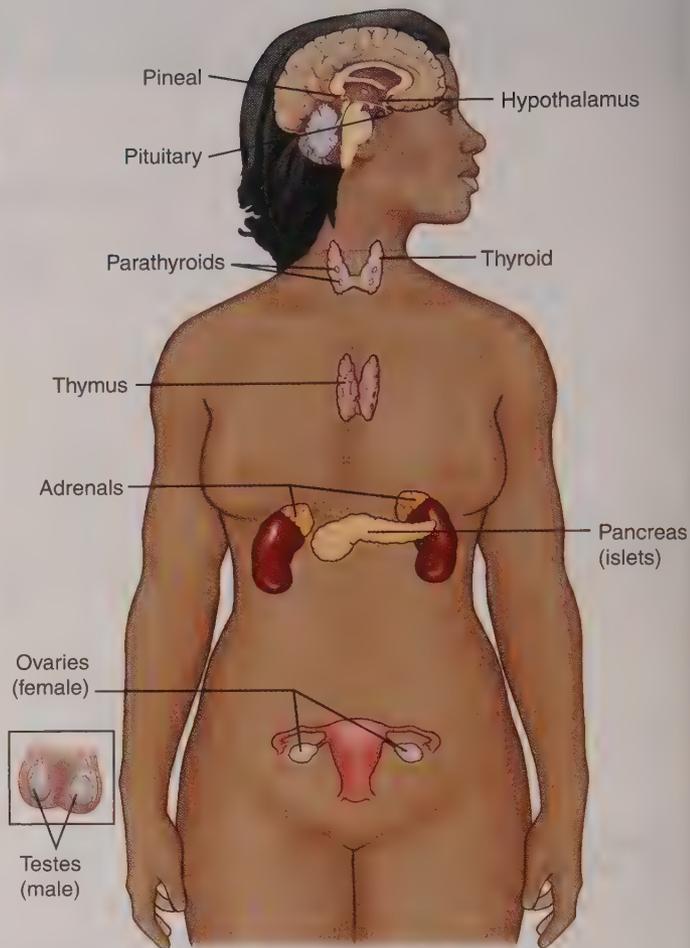

FIGURE 40.1 Major glands of the endocrine system.

*neuroendocrine regulation.* Both the hypothalamus and pituitary gland play an active role in endocrine function. The secretion of hormones is regulated via signals from the nervous system, levels of hormones in the blood, and other chemical changes in the blood such as glucose, sodium, and potassium levels. Hormonal release is controlled by a **negative feedback system** that increases hormone secretion when circulating levels are decreased. For example, the hypothalamus releases thyrotropin-releasing hormone (TRH) when there are decreased levels of the thyroid hormones; **triiodothyronine** (T3) and **thyroxine** (T4)—circulating in the bloodstream. In turn, the TRH acts on its target gland, the anterior pituitary gland, and thyroid-stimulating hormone (TSH) is released. The target gland for TSH is the thyroid gland, which releases the T3 and T4. While levels of circulating T3 and T4 increase, the feedback to the hypothalamus is to decrease secretion of TRH. Most disorders of the endocrine glands develop secondary to changes in hormone secretion associated with primary disorders (changes in an endocrine gland), secondary disorders (changes in the anterior pituitary gland), or tertiary disorders (changes in the hypothalamus). For example, patients who develop pituitary tumors or sustain injury

**Table 40.1 Glands of the Endocrine System**

Gland	Hormone	Target	Action
<b>Hypothalamus</b>	Corticotropin-releasing hormone	Anterior pituitary gland	Increases release of adrenocorticotropic hormone
	Gonadotropin-releasing hormone (GnRH)	Anterior pituitary gland	Increases release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
	Growth hormone-releasing hormone (GHRH)	Anterior pituitary gland	Stimulates release of growth hormone (GH)
	Growth hormone-inhibiting hormone (somatostatin; GHIH)	Anterior pituitary gland	Inhibits release of GH
	Thyrotropin-releasing hormone (TRH)	Anterior pituitary gland	Stimulates release of thyroid-stimulating hormone (TSH)
	Prolactin-inhibiting hormone	Anterior pituitary gland	Inhibits release of prolactin
<b>Anterior pituitary</b>	Adrenocorticotropic hormone (ACTH)	Adrenal glands	Increases secretion of glucocorticoids and mineralocorticoids
	Follicle-stimulating hormone (FSH)	Ovaries in females	Stimulates maturation of ovarian follicles, ovulation, and estrogen secretion
		Testes in males	Stimulates sperm production
	LH	Ovaries in females	Stimulates secretion of estrogen and progesterone and ovulation
		Testes in males	Stimulates testosterone production
	GH	Tissues and bones	Facilitates growth of bones and tissues through protein synthesis, fat metabolism, and insulin antagonism
	TSH	Thyroid glands	Increases secretion of thyroid hormones (triiodothyronine [T3] and thyroxine [T4])
Prolactin	Mammary glands	Stimulates production of breast milk	
Melanocyte-stimulating hormone	Melanocytes (melanin-producing cells in the skin and hair)	Increases pigmentation (skin and hair color)	
<b>Posterior pituitary</b>	Vasopressin (antidiuretic hormone; ADH)	Distal tubules and collecting ducts in the kidney	Increases water reabsorption
	Oxytocin	Uterus and mammary glands	Stimulates uterine contractions in labor and milk ejection
<b>Adrenal cortex</b>	Glucocorticoids (cortisol)	Liver	Promotes gluconeogenesis (increasing blood glucose)
		Cells of the body	Decreases glucose use Promotes protein catabolism Promotes fat synthesis
		Bone marrow	Suppresses inflammatory processes
	Mineralocorticoids (aldosterone)	Distal tubules and collecting ducts in the kidney	Promotes sodium reabsorption and potassium excretion by the kidney
<b>Adrenal medulla</b>	Catecholamines (epinephrine and norepinephrine)	Cells of the body	Mimics actions of the sympathetic system

Continued

**Table 40.1 Glands of the Endocrine System—cont'd**

Gland	Hormone	Target	Action
<b>Thyroid gland</b>	Triiodothyronine (T3)	Cells of the body	Increases metabolic rate
	Thyroxine (T4)		Increases response to catecholamines
	Thyroid calcitonin (calcitonin)	Bones	Decreases osteoclastic (breakdown of bone) activity
		Kidneys	Decreases reabsorption of calcium in the renal tubules
		Intestines	Decreases reabsorption of calcium in the intestines
<b>Parathyroid gland</b>	Parathyroid hormone (PTH)	Bones	Increases osteoclastic (bone breakdown) activity
		Kidney	Increases renal tubule reabsorption of calcium
		Intestines	Increases gastrointestinal reabsorption of calcium (vitamin D required)
<b>Ovaries</b>	Estrogen	Female reproductive organs (primarily controlled by FSH)	Stimulates development of female sex organs and secondary sex characteristics (pubic hair, axillary hair, etc.). In pregnancy, it enhances enlargement of uterus and breasts.
	Progesterone	Female reproductive organs (primarily controlled by LH)	Promotes growth of uterine wall, maintains pregnancy with fertilization, and influences menstruation with no fertilization.
			Stimulates growth of mammary glands.
<b>Testes</b>	Testosterone	Male reproductive organs	Promotes maturation of male sex organs, sperm production, and development of secondary sex characteristics (beard growth, deep voice)
<b>Pancreas</b>	Insulin	Cells of the body	Lowers blood glucose levels by moving glucose into cells
	Glucagon	Liver	Promotes glycogenolysis (increased blood glucose levels by conversion of glycogen to glucose)
		Muscles	Promotes gluconeogenesis (increased blood glucose levels by conversion of amino acids to glucose)

to the pituitary gland secondary to trauma may develop alterations in endocrine function.

### Connection Check 40.1

The nurse correlates an increase in the secretion of which hormone with the release of thyrotropin-releasing hormone?

- Triiodothyronine (T3)
- Thyroxine
- Thyroid stimulating hormone (TSH)
- Thyroid calcitonin

In addition to levels of circulating hormones, the release of hormones is also influenced by intrinsic factors. For example, as part of the stress response, **cortisol** secretion is increased to assist the body in dealing with stresses such as trauma, infection, and disease. Additionally, when patients are prescribed certain medications, such as **corticosteroids** for inflammation, these exogenous agents impact the function of the negative feedback system. Because there are increased circulating levels of corticosteroid, the hypothalamus decreases secretion of corticotropin-releasing hormone. This in turn leads to decreased secretion of adrenocorticotropic hormone

(ACTH) from the anterior pituitary gland, which results in decreased secretion of cortisol from the adrenal cortex. These coordinated activities between the nervous system and endocrine glands assist in maintaining homeostasis.

**Safety Alert** Patients who are prescribed corticosteroids for more than 10 to 14 days require “tapering” of the medication. Because of the effects of the exogenous corticosteroid on the hypothalamus, anterior pituitary, and adrenal cortex, the normal hormonal feedback system is interrupted. Abrupt withdrawal of the exogenous drug may lead to adrenal insufficiency (presented in Chapter 42), which is a medical emergency characterized by decreased blood pressure and hypoglycemia.

## Hypothalamus and Pituitary Gland

The hypothalamus and pituitary gland play key roles in the feedback system that regulates homeostasis, and this regulation is commonly referred to as the *hypothalamic-pituitary system* or *complex*. The hypothalamus is a small structure located beneath the thalamus (Fig. 40.2). It is shaped like a flattened funnel and forms the walls and floor of the third ventricle. Hormones produced and secreted by the hypothalamus act directly on other endocrine glands (including the pituitary gland) and are described in Table 40.1. The hypothalamus is connected to the pituitary gland by the **infundibulum**.

## Connection Check 40.2

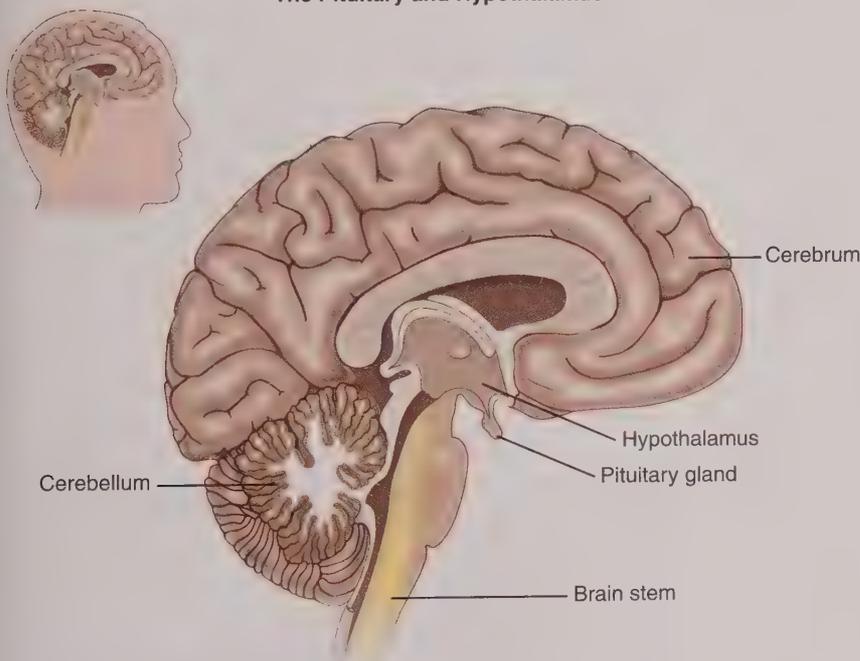

Which hormones are released from the posterior pituitary gland? (*Select all that apply*).

- A. Aldosterone
- B. Antidiuretic hormone
- C. Follicle-stimulating hormone
- D. Luteinizing hormone
- E. Oxytocin

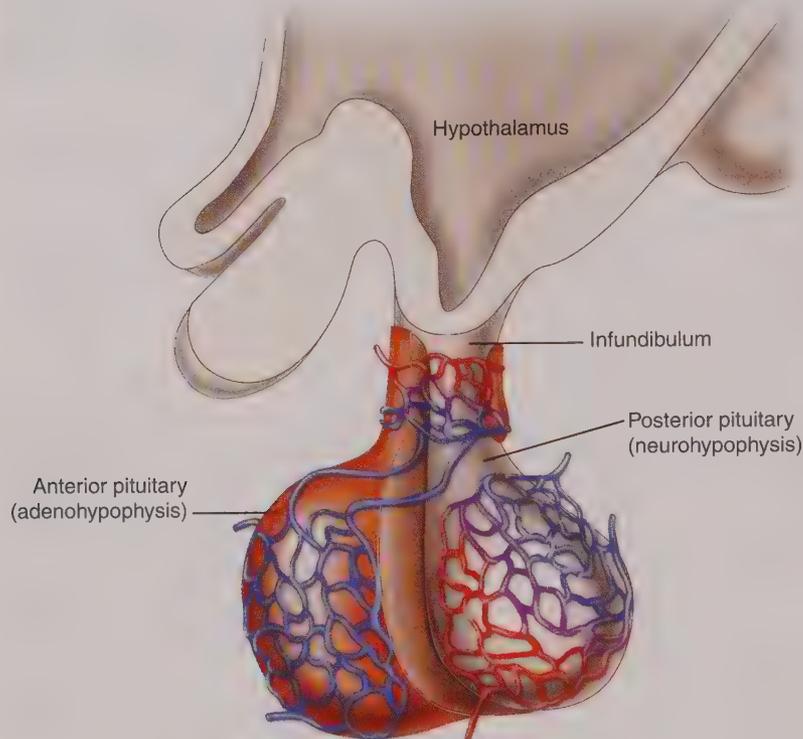

The pituitary gland is located at the base of the brain in the sella turcica, which is a depression of the sphenoid bone. Approximately the size of a lima bean, the pituitary gland is approximately 1–3 cm wide and communicates directly with the hypothalamus. The pituitary gland is composed of two lobes, the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis), which have distinct functions (Fig. 40.3). The hypothalamus regulates anterior pituitary gland function through the secretion of hormones whose target tissue is the anterior pituitary gland (see Table 40.1).

The anterior pituitary gland secretes two gonadotropins (hormones that stimulate the gonads), follicle-stimulating hormone (FSH) and luteinizing hormone (LH) that have major roles in female and male reproductive functions. Thyroid-stimulating hormone works directly on the thyroid glands located in the anterior neck and is also released from the anterior pituitary gland and stimulates release of thyroid hormones. Adrenal cortical function is also regulated by the release of adrenocorticotropic hormone (ACTH) that stimulates release of **glucocorticoids** and

The Pituitary and Hypothalamus

**FIGURE 40.2** Location of the pituitary gland and hypothalamus.

**FIGURE 40.3** Anterior and posterior lobes of the pituitary gland.

**mineralocorticoids** from the adrenal cortex. Prolactin, growth hormone (GH), and **melanocyte-stimulating hormone** are also secreted from the anterior pituitary gland. Prolactin is responsible for milk formation. Growth hormone, also called **somatotropin**, is necessary for maintaining bone density and cartilage growth as well as facilitating protein synthesis. It also increases the use of fatty acids and affects blood glucose levels by decreasing the use of glucose for energy. Growth hormone has an insulin-resistance effect in the peripheral tissue that inhibits the uptake of glucose by muscle and adipose tissue. Melanocyte-stimulating hormone affects skin and hair color. **Melanocytes** are cells of the epidermis that give color to skin through the synthesis of melanin (pigment granules that influence skin color).

The posterior pituitary gland is composed of nerve tissue that arises in the hypothalamus. These nerve fibers are responsible for neuroendocrine reflexes that result in hormone secretion in response to signals from the nervous system. Hormones secreted from the posterior pituitary gland (antidiuretic hormone [ADH] and oxytocin) are actually synthesized in the hypothalamus but are stored and released from the posterior pituitary gland. Antidiuretic hormone is secreted in response to decreased blood pressure, dehydration, and increased serum osmolality and works by increasing water reabsorption in the kidneys. The target tissues of oxytocin are the uterus (causing contractions in labor) and the mammary glands (causing milk release in the lactating woman).

### Adrenal Glands

The adrenal glands are located on top of each kidney, and each measures approximately 5-cm long, 1-cm thick, and

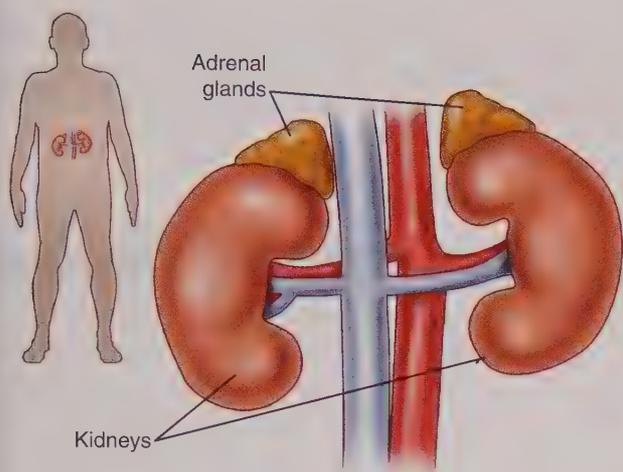

3-cm wide (Fig. 40.4). Each adrenal gland has an inner core, the medulla, and a thick outer covering, the cortex, both with distinct endocrine functions (Fig. 40.5).

#### Adrenal Cortex

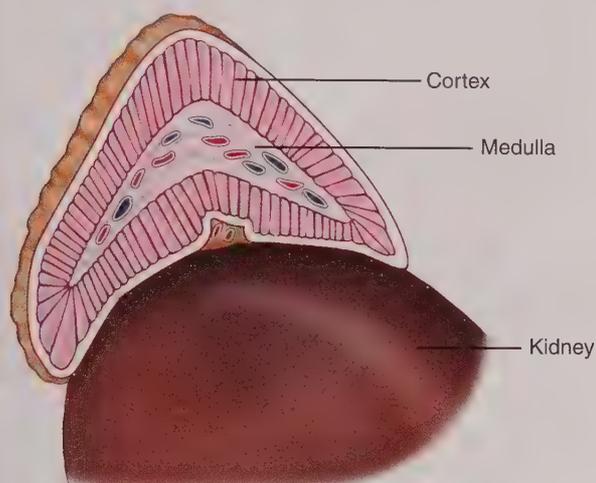

The adrenal cortex comprises approximately 90% of the adrenal gland and secretes three types of hormones. The **mineralocorticoids** control fluid balance through their effects on the kidney. The target cells of the mineralocorticoids are the collecting ducts in the kidney, and stimulation leads to reabsorption of sodium and water and excretion of potassium. **Aldosterone** is the primary mineralocorticoid. The adrenal cortex also secretes **glucocorticoids**, which are hormones whose effects are essential for life. These hormones have an effect on carbohydrate, protein, and fat metabolism and suppress inflammatory and immune functions. Similar to the mineralocorticoids, glucocorticoids also cause reabsorption of sodium and excretion of potassium in the kidneys. **Cortisol** is the primary glucocorticoid.

#### Adrenal Medulla

The adrenal medulla is under the control of the sympathetic nervous system (SNS). **Catecholamines** (epinephrine and norepinephrine) are secreted from the adrenal medulla when stimulated by the SNS, and their actions vary according to the receptor sites. There are two major types of receptors, alpha (further divided into alpha<sub>1</sub> and alpha<sub>2</sub>) and beta (further divided into beta<sub>1</sub>, beta<sub>2</sub>, and beta<sub>3</sub>). Alpha<sub>1</sub> receptors primarily affect responses in the vascular smooth muscle, whereas alpha<sub>2</sub> receptors can decrease release of norepinephrine and influence blood pressure. Beta<sub>1</sub> receptors are located primarily in the heart, and

**FIGURE 40.4** Location of the adrenal glands.

**FIGURE 40.5** Adrenal medulla and cortex.

beta<sub>2</sub> receptors are located in the bronchioles and other sites such as the kidneys. Beta<sub>3</sub> receptors are found primarily in adipose tissue and, when stimulated, enhance **thermogenesis** (heat production). Target tissues for the catecholamines include various types of cells and specific organs of the body; the effects of these hormones are described in Table 40.2. Because epinephrine and norepinephrine are also produced by the SNS, the adrenal medulla and its secretion of these hormones are not essential to life. However, hypersecreting tumors of the adrenal medulla (**pheochromocytomas**), are life threatening and are discussed further in Chapter 42.

### Connection Check 40.3

Increased secretion of ADH results in which action?

- Decreased urine output
- Increased urine output
- Decreased serum potassium
- Increased serum potassium

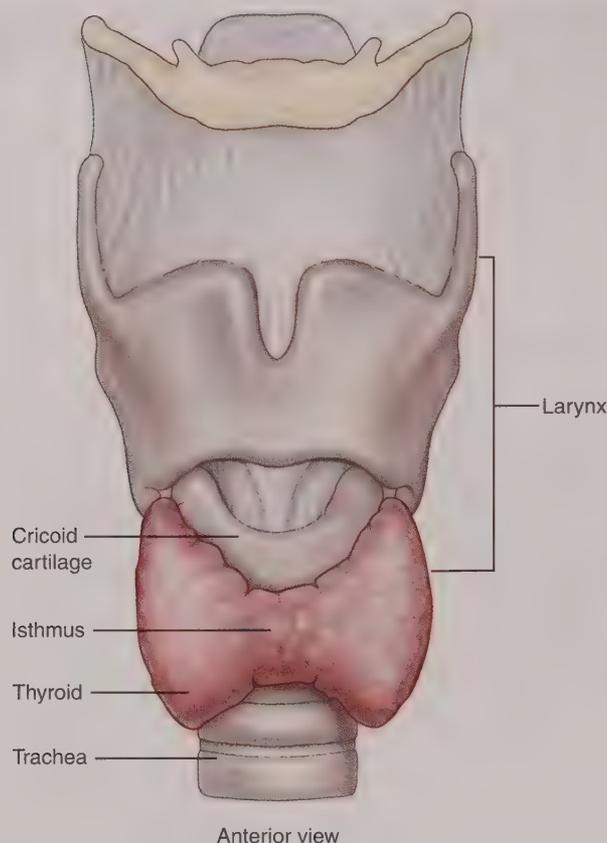

**Table 40.2** Catecholamine Effects on Target Tissues

Target Tissue	Receptor	Effects
<b>Lungs</b>	Beta <sub>2</sub>	Dilates bronchioles
<b>Heart</b>	Beta <sub>1</sub>	Affects chronotropic (rate) activity Affects inotropic (contractility) activity
<b>Blood vessels</b>	Alpha	Promotes vasoconstriction
	Beta <sub>2</sub>	Promotes vasodilation
<b>Kidneys</b>	Beta <sub>2</sub>	Increases renin release
<b>Gastrointestinal (GI) tract</b>	Alpha	Increases sphincter tone
	Beta	Decreases GI motility
<b>Bladder</b>	Alpha	Promotes sphincter contraction
	Beta <sub>2</sub>	Relaxes detrusor muscles
<b>Skin</b>	Alpha	Increases sweating
<b>Liver</b>	Alpha	Increases gluconeogenesis and glycogenolysis
<b>Pancreas</b>	Alpha	Decreases release of glucagon and insulin Increases release of glucagon and insulin
<b>Eyes</b>	Alpha	Promotes pupil dilation

### Thyroid Gland

Located in the anterior neck, the thyroid gland lies directly below the cricoid cartilage (Fig. 40.6). Composed of two lobes, it is connected by a strip of tissue called the *isthmus*. The thyroid gland produces three thyroid hormones, triiodothyronine (T<sub>3</sub>), thyroxine (T<sub>4</sub>), and **thyrocalcitonin** (**calcitonin**). Production of these hormones requires adequate dietary intake of protein and iodine. Release of T<sub>3</sub> and T<sub>4</sub> is controlled by the hypothalamic-pituitary system and is based on the circulating levels of these thyroid hormones. When T<sub>3</sub> and T<sub>4</sub> levels are low, the hypothalamus secretes TRH that stimulates the release of TSH from the anterior pituitary gland. In turn, TSH acts on the thyroid gland, leading to secretion of T<sub>3</sub> and T<sub>4</sub>. While the circulating levels of T<sub>3</sub> and T<sub>4</sub> increase, the feedback system causes the hypothalamus to decrease release of TRH. Other conditions that increase secretion of TRH, independent of circulating T<sub>3</sub> and T<sub>4</sub>, are cold and stress. The end result is an increase in metabolic activity with both conditions.

Although both T<sub>3</sub> and T<sub>4</sub> share the same functions, they differ in structure and potency. Most of the circulating T<sub>3</sub> and T<sub>4</sub> is plasma protein bound. However, it is the free unbound thyroid hormone that is active. For this reason, it is important to assess plasma protein levels (albumin) when assessing

**FIGURE 40.6** Location of the thyroid gland.

thyroid function, because an increase in free thyroid hormone may occur in the patient with hypoalbuminemia.

Regulation of metabolic activity is controlled by T3 and T4, and secretion of both hormones increases metabolism. Specific actions of T3 and T4 include:

- Increased rate and contractility of the heart
- Increased rate and depth of respirations
- Increased oxygen use
- Increased glucose intake by cells
- Increased glycolysis and enhanced gluconeogenesis
- Increased protein synthesis and catabolism
- Increased mobilization of fatty acids
- Increased oxidation of free fatty acids
- Decreased cholesterol and phospholipids

This overall increase in metabolic activity results in increased heat production in all tissues. The clinical manifestations of thyroid disorder are directly associated with these physiological changes.

Thyrocaltitonin (calcitonin) has a role in the regulation of calcium, along with parathyroid hormone (PTH; **parathormone**) secreted from the PTH glands. Serum calcium and phosphorus levels are lowered by the actions of calcitonin on the bones. Bone **resorption** is a process involving breakdown of bone through **osteoclastic** activity that involves secretion of enzymes and acid that dissolve microscopic bits of bone matrix. Because osteoclastic activity is decreased by calcitonin, there is less calcium released

from the bone into the circulation. The release of calcitonin is actually regulated by serum calcium levels. When serum calcium levels are low, calcitonin secretion is inhibited; and conversely, when calcium levels are high, secretion of calcitonin is increased (Fig. 40.7).

### CASE STUDY: EPISODE 2

The nurse practitioner completes a detailed history and physical examination of Greta Johnson. Because of her symptoms of restlessness, irritability, and anxiety along with tachycardia and palpitations, an evaluation of thyroid function is started. The nurse assesses Greta's vital signs and finds her heart rate to be 134 bpm and her blood pressure 130/80 mm Hg. The nurse practitioner arranges for blood to be drawn for T3, T4, and TSH...

### Parathyroid Glands

The PTH glands are usually found partially embedded in the thyroid gland; however, they may also be found above the hyoid bone or near the aortic arch (Fig. 40.8). Measuring approximately 3 to 8 mm in length and 2 to 5 mm in width, they secrete parathyroid hormone (PTH). Secreted in response to low serum calcium levels, the target tissues of PTH include the bones, kidneys, and small intestine.

Parathyroid hormone increases serum calcium through the following actions:

- Increases bone resorption through osteoclastic activity
- Stimulates renal reabsorption of calcium
- Stimulates activation of vitamin D, which increases intestinal reabsorption of calcium.

The action of PTH is opposite to that of calcitonin, secreted by the thyroid gland, because calcitonin decreases serum calcium levels.

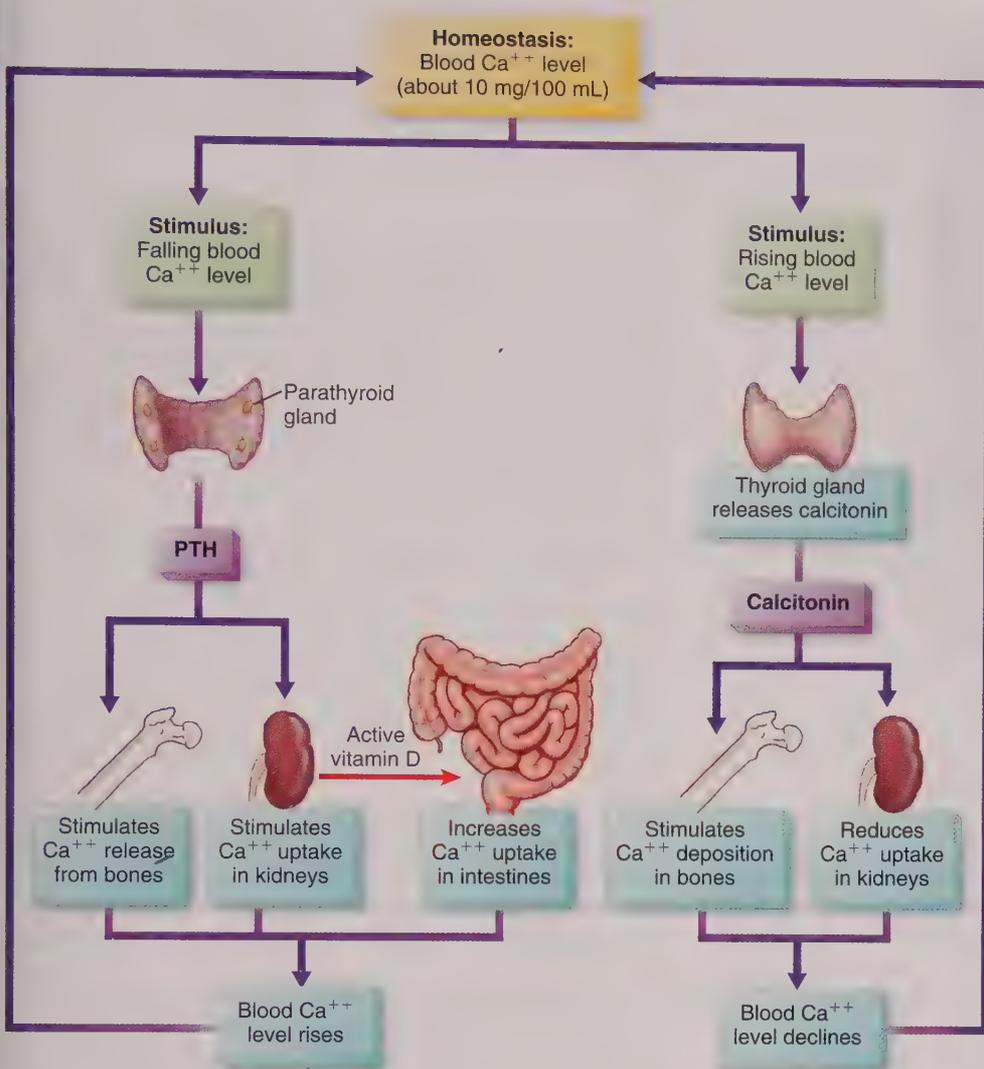

Parathyroid hormone also affects phosphorus levels through the following actions:

- Reduces the reabsorption of phosphate from the proximal tubes in the kidneys, leading to a decrease in serum phosphorus levels
- Increases bone resorption, leading to an increase in phosphorus release from the bone
- Increases small intestine absorption of phosphate

The net result of these actions is to lower serum phosphate levels, particularly due to phosphorus loss through the kidneys.

### Gonads

Sexual development and function are controlled by hormones secreted from the ovaries and testes. Both the ovaries

**FIGURE 40.7** Overview of calcium regulation.

and testes are controlled by **tropic hormones** released from the anterior pituitary gland based upon secretion of gonadotropin releasing hormone from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) both stimulate maturation of male and female reproductive organs. In the male, FSH and LH stimulate production of **testosterone**, and in the female, these same hormones stimulate production of **estrogen** and **progesterone** that influence development of secondary sexual characteristics, ovarian maturation, and ovulation. These hormones are also required for maintaining normal pregnancy through effects on the cervix, uterine, and breasts. Testosterone in the male is responsible for male sexual characteristics, as well as the production of sperm (see Table 40.1) (these hormones are described in more detail in Unit XV).

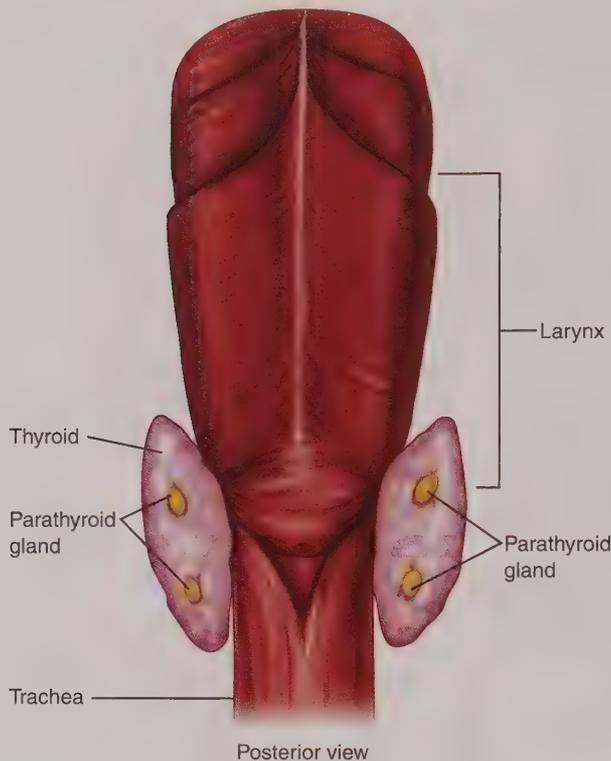

## Pancreas

The pancreas, located in the upper left quadrant of the abdominal cavity, has both exocrine and endocrine functions (Fig. 40.9). The exocrine function of the pancreas involves the secretion of pancreatic juices into the small intestine

that aid in digestion. Blood glucose control by the islet cells of the pancreas is the endocrine function. Two hormones released by the pancreas play a central role: **insulin**, released from the beta cells of the pancreas, and **glucagon**, released from the alpha cells of the pancreas. To understand diabetes, it is important to understand how blood glucose levels are normally controlled in a healthy person. Glucose arrives in the bloodstream from one of three sources:

- Carbohydrates converted to glucose via digestion, and absorbed through the gastrointestinal tract
- Glucose released from stored **glycogen** in muscles and liver cells
- Glucose newly created (**gluconeogenesis**) in the liver

Once in the bloodstream, the glucose is transported to the target cells. There, insulin facilitates transport of glucose across the cell membrane to the cell's interior. Inside the cell, glucose is metabolized as fuel, releasing energy necessary for normal cellular functioning. Without the effective action of insulin, very little glucose would be able to reach the inside of the cell. Instead, glucose would remain in the bloodstream, and blood glucose levels would rise.

**FIGURE 40.8** Location of the parathyroid glands.

A continuous, dynamic balance is maintained between the glucose level in the blood, levels of insulin and glucagon, and cellular uptake of glucose. If blood glucose levels are high, more insulin is secreted by the pancreas. Blood glucose is then driven into the cells and metabolized and as a result glucose levels in the blood fall. On the other hand, if blood glucose levels fall too low, insulin release is suppressed; glucose remains in the bloodstream instead of being driven into the cells. In addition, in response to low blood glucose levels, the hormone glucagon is released from

the pancreatic alpha cells. Glucagon stimulates production and release of glucose from glycogen stores in the liver leading to increased blood glucose levels.

## ASSESSMENT

### History

In assessing the patient for an endocrine disorder, it is essential that the nurse complete a comprehensive history. Because the endocrine system affects homeostasis and metabolic activity, the nurse must assess changes in nutritional status, physical appearance, weight, sleep pattern, energy, elimination pattern, and reproductive function. Evaluating family history for endocrine disorders is also important because some diseases are genetic.

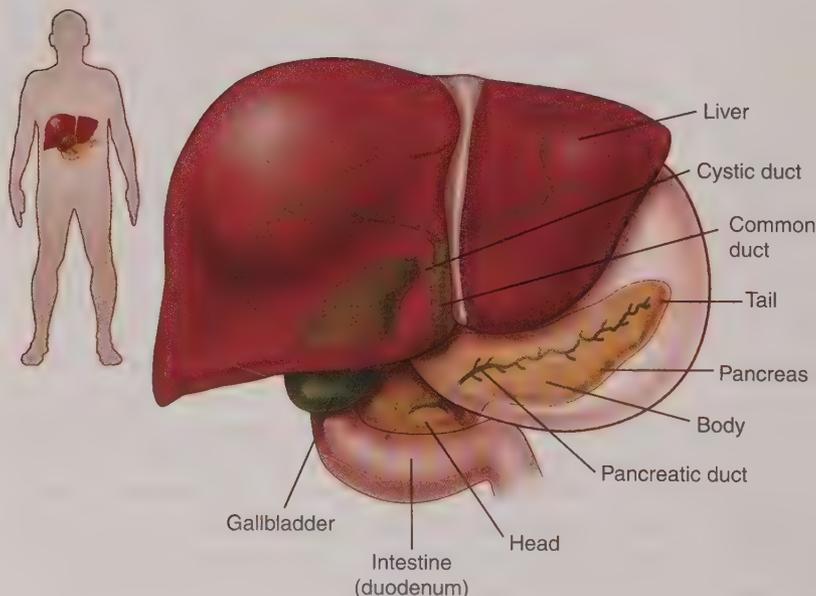

### Physical Assessment

#### Inspection

The nurse completes a head-to-toe assessment when evaluating a patient for an endocrine disorder, because changes in physical appearance may be apparent. For example, in the patient with elevated levels of growth hormone (GH), a broadening of the forehead or jaw may be noted. Similarly, in patients with elevated levels of cortisol, the nurse may note puffiness of the face. (Specific clinical manifestations associated with specific diseases are further described in the endocrine disorder chapters.)

#### Auscultation

During the assessment, the nurse auscultates the chest to assess cardiac rate and rhythm because some endocrine disorders affect cardiovascular function. In patients with hyperthyroidism, tachydysrhythmias may occur and may be auscultated. Additionally, because of the increased vascularity associated with hyperthyroidism, the nurse also

**FIGURE 40.9** Location of the pancreas.

listens over the carotid arteries for carotid bruits. Direct auscultation over the thyroid gland may also reveal a thyroid bruit in the patient with hyperthyroidism because of the increased thyroid vascularity associated with this disorder.

### Palpation

The nurse uses palpation to assess the testes and the thyroid glands; both are evaluated for size, symmetry, shape, and any nodules or changes in texture. The thyroid gland may be best palpated by standing behind the patient (Fig. 40.10A). The thumbs of both hands are placed on the back of the neck, and the fingers are curved to the front of the neck on either side of the trachea. The patient is asked to swallow, and the nurse locates the isthmus by feeling it rise when the patient swallows. The nurse assesses both the right and left lobes of the thyroid gland. The right lobe is palpated while the patient's head is turned to the right, and the nurse assesses for any irregularities or nodules. The left lobe is similarly evaluated by having the patient turn the head to the left. The thyroid gland may also be assessed from the front. With this approach, the nurse faces the patient and uses the thumbs or fingers to palpate each lobe of the thyroid gland (Figure 40.10B).

### Connection Check 40.4

To better locate the isthmus of the thyroid gland in preparation for palpation, the nurse asks the patient to perform which action?

- "Say 'ah.'"
- "Touch your chin to your chest."
- "Look at the ceiling."
- "Swallow a sip of water."

**FIGURE 40.10** Palpation of the thyroid gland. A, Posterior approach. The thyroid gland may be best palpated by standing behind the patient. The thumbs of both hands are placed on the back of the neck, and the fingers are curved to the front of the neck on either side of the trachea. The patient is asked to swallow, and the nurse locates the isthmus by feeling it rise when the patient swallows. B, Anterior approach. The thyroid gland may also be assessed from the front. With this approach, the nurse faces the patient and uses the thumbs or fingers to palpate each lobe of the thyroid gland.

## DIAGNOSTIC STUDIES

Diagnostic evaluation of the patient with a suspected endocrine disorder includes laboratory assessment of urine and blood samples as well as imaging studies. The specific laboratory tests conducted are associated with the disorder under investigation (Table 40.3). For example, in the patient with suspected diabetes mellitus, blood and urine levels of glucose are measured. In the patient with suspected dysfunction of the adrenal cortex, serum potassium levels are evaluated.

Measurements of circulating hormone levels are also evaluated. In patients with suspected thyroid disease, T<sub>3</sub>, T<sub>4</sub>, and TSH levels are assessed (laboratory assessments for specific disorders are presented in Chapters 41 through 44.)

Stimulation and suppression tests are also ordered for patients with suspected endocrine disease. With stimulation testing, a selected hormone is administered to stimulate the target tissue to produce its hormone. Failure of the target to secrete sufficient hormone indicates hypofunction of that gland. Conversely, suppression tests are indicated when there are excess levels of circulating hormone. When levels of circulating hormone do not decrease with suppression testing, hyperfunction of the gland is confirmed.

### Imaging Studies

Diagnostic imaging studies are indicated to assess for changes in the size or presence of tumor formation in the glands of the endocrine system. Disorders of the posterior pituitary gland may occur as a result of a pituitary tumor. A pheochromocytoma, a tumor of the adrenal medulla, may be confirmed with imaging studies of the retroperitoneal area. Computed tomography (CT) and magnetic resonance imaging, as well as x-rays are used to confirm abnormalities of the endocrine glands.

### Connection Check 40.5

A patient is undergoing a stimulation test to assess adrenal function. After the administration of cortisol, which laboratory result indicates normal function?

- Decreased blood glucose
- Decreased serum sodium
- Decreased serum potassium
- Decreased serum calcium

## AGE-RELATED CHANGES

Changes in endocrine function are associated with aging, and early detection and treatment can minimize long-term consequences. Menopause is an age-related change, but it is also a "normal state" of ovarian hormone deficiency that affects all women as they age. Physiological changes caused by menopause are usually diminished with the use

**Table 40.3 Laboratory Tests for Endocrine Disorders**

Test	Normal Range for Adults	Significance
<b>Calcium</b>	8.2–10.2 mg/dL	Decreased in hypoparathyroidism Increased in hyperparathyroidism Decreased by thyrocalcitonin from thyroid gland
<b>Ionized calcium</b>	4.6–5.3 mg/dL	Decreased in hypoparathyroidism Increased in hyperparathyroidism
<b>Cortisol</b>	5–25 mcg/dL (morning) 3–16 mcg/dL (afternoon)	Decreased in hypocortisolism (Addison's) Elevated in hypercortisolism (Cushing's)
<b>Glucose</b>	65–99 mg/dL	Increased in diabetes mellitus Increased in hypercortisolism
<b>Magnesium</b>	1.6–2.6 mg/dL	Decreased in hypoparathyroidism
<b>Phosphorus</b>	2.5–4.5 mg/dL	Increased in hypoparathyroidism Decreased in hyperparathyroidism
<b>Potassium</b>	3.5–5.0 mEq/L	Increased in hypocortisolism (Addison's) Decreased in hypercortisolism (Cushing's)
<b>Sodium</b>	135–145 mEq/L  (Actual sodium levels may be normal as fluid is retained or lost as the sodium is retained or excreted, respectively.)	Increased in diabetes insipidus (DI) Decreased in syndrome of inappropriate antidiuretic hormone (SIADH) Decreased in hypocortisolism Increased in hypercortisolism Decreased in hypoaldosteronism Increased in hyperaldosteronism
<b>Free T3 (triiodothyronine)</b>	2.6–4.8 pg/mL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Total T3 (triiodothyronine)</b>	70–204 ng/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Free T4 (thyroxine)</b>	0.8–1.5 ng/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Total T4 (thyroxine)</b>	4.6–12 mcg/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Thyroid-stimulating hormone (TSH)</b>	0.5–8.9 microinternational units (mIU)/mL	Increased in primary hypothyroidism Decreased in secondary or tertiary hypothyroidism Decreased in primary hyperthyroidism Increased in secondary and tertiary hyperthyroidism
<b>Urine specific gravity</b>	1.005–1.030	Decreased with DI Increased in SIADH
<b>Vitamin D</b>	20–100 ng/dL	Decreased in hypoparathyroidism Variable in hyperparathyroidism

of hormone replacement therapy; however, there are growing concerns associated with these exogenous hormone replacements.

Some of the endocrine changes associated with age are secondary to hypoactive function of endocrine glands secondary to **downregulation** (decreased number of receptors on the surface of the target tissue). Other age-related changes may be associated with an increased incidence of chronic disease. Hormone production, secretion rates, and tissue responsiveness may all decrease with age. Changes may also be associated with compensatory responses to changes in hormone levels; for instance, glucose levels rise with age-related insulin resistance.

Decreased metabolism is associated with decreased appetite, susceptibility to cold intolerance, changes in the quality of sleep, and decreased resting pulse rate and blood pressure. Changes in release of reproductive hormones may lead to problems with sexual functioning, including erectile dysfunction and decreased libido. Patients with decreased glucose tolerance may present with elevated blood glucose levels and weight gain. Decreased synthesis of ADH in the older adult is associated with increased urine frequency and dilute urine, leading to an increased risk of dehydration. Bone density decreases, thinning and drying of the skin, and perineal and vaginal dryness are all associated with advancing age. Although many of these are often associated with aging, it is imperative that a comprehensive evaluation is completed to rule out other causes with these physiological changes.

### Connection Check 40.6

The nurse correlates which findings with age-related changes of the endocrine system in a 55-year-old female?

(Select all that apply.)

- A. Breast enlargement
- B. Decreased libido
- C. Increased sweating
- D. Vaginal dryness
- E. Insomnia

### Making Connections

#### CASE STUDY: WRAP-UP

The nurse practitioner begins a work-up for thyroid dysfunction for Greta Johnson. On the basis of her clinical presentation, hyperthyroidism is suspected. The laboratory results reveal increased levels of T3 and T4 with decreased levels of TSH. A tentative diagnosis of primary hyperthyroidism is made, and Greta is referred for further evaluation and treatment.

### Case Study Questions

- In assessing a patient with an alteration in thyroid function, the nurse must understand that TRH release is from which structure?
  - Hypothalamus
  - Anterior pituitary gland
  - Posterior pituitary gland
  - Thyroid gland
- Which clinical manifestation observed in Ms. Johnson does the nurse correlate with elevated levels of thyroid hormone?
  - Lethargy
  - Insomnia
  - Dry skin
  - Constipation
- Which thyroid hormone value does the nurse correlate with primary hyperthyroidism?
  - Elevated TRH
  - Elevated TSH
  - Elevated T3
  - Elevated thyrocalcitonin
- The nurse recognizes that the negative feedback system causes which change secondary to increased T3 and T4?
  - Increased TRH
  - Decreased TSH
  - Increased parathormone
  - Decreased thyrocalcitonin
- In a patient with a secondary disorder of the thyroid gland, the nurse assesses for changes in function in which structure?
  - Thyroid gland
  - Hypothalamus
  - Posterior pituitary gland
  - Anterior pituitary gland

### CHAPTER SUMMARY

The endocrine system consists of glands located throughout the body that are essential to many vital functions. The hypothalamus plays a major role in endocrine function because of its control of the anterior and pituitary glands. Hormones from the anterior pituitary gland control the function of the adrenal glands, thyroid glands, and reproductive organs. Additionally, GH is controlled by the anterior pituitary gland. The posterior pituitary secretes antidiuretic hormone (ADH) that maintains fluid volume balance by promoting water reabsorption in the kidneys, and sexual hormones.

The adrenal glands are composed of the cortex and medulla, which have independent functions. The adrenal cortex, under the control of hormones from the anterior pituitary gland (ACTH), secretes mineralocorticoids and glucocorticoids. Aldosterone, the primary mineralocorticoid, promotes sodium reabsorption in the kidneys as well as the excretion of potassium. Cortisol, the primary glucocorticoid, has many functions including promoting gluconeogenesis and glycogenolysis that lead to an increase in blood glucose levels. Glucocorticoids have a major role in growth and development as well as anti-inflammatory actions. The adrenal medulla releases catecholamines (epinephrine and norepinephrine) that influence the functions of most body systems.

The thyroid gland secretes hormones that greatly influence metabolic activity (triiodothyronine and thyroxine) and thyrocalcitonin that lowers serum calcium levels. Parathyroid hormone (PTH), secreted by the parathyroid glands, plays a major role in calcium regulation. An increase

in PTH increases serum calcium levels, whereas a decrease in PTH lowers serum calcium levels.

Reproductive function is also controlled by the endocrine system. Maturation of both female and male reproductive organs is facilitated by hormones produced from the anterior pituitary glands (follicle-stimulating hormone and luteinizing hormone). Estrogen and progesterone are key to normal female functioning, including controlling the menstrual cycle, facilitating and maintaining pregnancy, and development of secondary sexual characteristics. Testosterone is required for sperm production and development of secondary male sexual characteristics.

The pancreas controls regulation of blood glucose levels and carbohydrate, fat, and protein metabolism through the release of insulin and glucagon. Glucagon increases blood glucose levels through gluconeogenesis and glycogenolysis. Insulin lowers blood glucose levels by facilitating the movement of glucose into cells.

# Chapter 41

## Coordinating Care for Patients With Pituitary Disorders

*Janice Hoffman*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of pituitary disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Hypopituitarism
  - b. Hyperpituitarism
  - c. Diabetes insipidus (DI)
  - d. Syndrome of inappropriate antidiuretic hormone (SIADH)
3. Describing the diagnostic results used to confirm the diagnosis of pituitary disorders
4. Discussing the medical management of:
  - a. Hypopituitarism
  - b. Hyperpituitarism
  - c. Diabetes insipidus (DI)
  - d. Syndrome of inappropriate antidiuretic hormone (SIADH)
5. Developing a comprehensive plan of nursing care for patients with pituitary disorders
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with pituitary disorders
7. Coordinating the interprofessional plan of care for the patient undergoing treatment for pituitary disorders

### CONCEPTS

- Assessment
- Collaboration
- Comfort
- Fluid and Electrolyte Balance
- Medication
- Metabolism
- Nursing Roles
- Perioperative

### ESSENTIAL TERMS

Acromegaly  
Adenohypophysis  
Antidiuretic hormone (ADH)  
Desmopressin (DDAVP)  
Diabetes insipidus (DI)  
Dwarfism  
Gigantism  
Hypophysectomy  
Neurohypophysis  
Oxytocin  
Panhypopituitarism  
Pitressin  
Rhinorrhea  
Sella turcica  
Somatotropin  
Stereotactic radiosurgery  
Syndrome of inappropriate antidiuretic hormone (SIADH)  
Vasopressin

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Carol Andrews makes an appointment with her primary health-care provider because of a persistent headache, changes in vision, and occasional episodes of nausea. She also complains of enlargement of her hands and feet, requiring her to remove her rings and purchase larger shoes. Her primary health-care provider orders a series of laboratory studies including serum chemistries and hematology studies. Magnetic resonance imaging (MRI) of the head is also ordered...

## INTRODUCTION

The hypothalamus and pituitary glands, described as the hypothalamus-pituitary complex, work together to control many endocrine functions. The pituitary gland, located in

the **sella turcica** (a depression of the sphenoid bone), controls many body functions including growth, fluid balance, metabolism, sexual development, and pigmentation. The pituitary gland is composed of two lobes, the anterior lobe (**adenohypophysis**) and the posterior lobe (**neurohypophysis**) that have distinct functions. Hormones secreted by the anterior pituitary gland are controlled by hormones secreted by the hypothalamus (Table 41.1). The hormones released from the posterior pituitary are synthesized in the hypothalamus but stored and released from the posterior pituitary gland.

The anterior lobe of the pituitary gland secretes several major hormones related to metabolic functioning:

- **Adrenocorticotropic hormone (ACTH)** is involved in the synthesis of corticosteroids.
- **Growth hormone (GH)**, also known as **somatotropin**, stimulates growth through carbohydrate, protein and fat metabolism.
- **Follicle-stimulating hormone (FSH)** assists in the maturation of the ovaries in females and in spermatogenesis in males.
- **Luteinizing hormone (LH)** is involved in ovulation in females and the production of testosterone in males.

**Table 41.1 Hypothalamus and Pituitary Hormones and Actions**

Hypothalamus	Anterior Pituitary Gland	Target	Effects
<b>Corticotropin-releasing hormone (CRH)</b> Stimulates release of ACTH	Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Increases secretion of glucocorticoids and mineralocorticoids
<b>Gonadotropin-releasing hormone</b> Stimulates release of FSH and LH	Follicle-stimulating hormone (FSH) Luteinizing hormone (LH)	Ovaries in females Testes in males	Stimulates maturation of ovarian follicles, ovulation, and estrogen secretion Stimulates sperm production
<b>Growth hormone-releasing hormone (GHRH)</b> Stimulates release of GH	Growth hormone (GH)	Tissues and bones	Facilitates growth of bones and tissues through protein synthesis, fat metabolism, and insulin antagonism
<b>Growth hormone inhibiting hormone (GHIH)</b> Inhibits release of GH	Growth hormone (GH)	Tissues and bones	Opposes the effects of GHRH thus decreasing the metabolic effects of growth hormone
<b>Thyrotropin-releasing hormone (TRH)</b> Stimulates release of TSH	Thyroid-stimulating hormone (TSH)	Thyroid gland	Increases secretion of thyroid hormones (triiodothyronine and thyroxine), increasing metabolism
<b>Posterior Pituitary</b>			
	Vasopressin (antidiuretic hormone; ADH)	Distal tubules and collecting ducts in the kidney	Increases water reabsorption
	Oxytocin	Uterus and mammary glands	Stimulates uterine contractions in labor and milk ejection

- *Prolactin* stimulates the mammary glands for milk production.
- *Thyroid-stimulating hormone* (TSH) controls the secretion of thyroxine (T4) and triiodothyronine (T3) thyroid hormones.

The posterior lobe of the pituitary gland secretes hormones responsible for the following actions:

- **Antidiuretic hormone (ADH)** controls water retention by the kidneys and moderates vasoconstriction and the release of ACTH in the anterior lobe of the pituitary.
- **Oxytocin** plays a major role in circadian homeostasis, the release of breast milk, and cervical changes and uterine contractions during labor and delivery.

Because of the essential role of these hormones, patients with pituitary adenomas are usually followed and treated by a healthcare provider who specializes in managing patients with endocrine disorders both preoperatively and postoperatively.

## DISORDERS OF THE ANTERIOR PITUITARY GLAND

Disorders related to the function of the anterior pituitary gland may be caused by an increase or decrease in the secretion of hormones from the hypothalamus or the anterior pituitary gland itself. Primary disorders are related to alterations in function of endocrine glands (for example, the adrenal cortex or thyroid glands), secondary disorders are related to alterations in hormone secretion from the anterior pituitary gland, and tertiary disorders are related to alterations in hormone secretion from the hypothalamus. Patients may present with disorders related to one specific hormone, or in very rare cases, they may present with **panhypopituitarism**. This disorder involves hyposecretion of all hormones from the hypothalamus and has dramatic effects on normal function.

### Hypopituitarism

Hypopituitarism is hyposecretion of hormones from the anterior pituitary gland. Because hormones released from the anterior pituitary gland regulate hormone release from the adrenal cortex, thyroid gland, and gonads, alterations in hormonal release affect many body functions. The hyposecretion of growth hormone is also seen with hypopituitarism.

### Epidemiology

Hypopituitarism is a rare disorder according to the National Institutes of Health (NIH), affecting fewer than 200,000 individuals in the United States. The etiology of anterior pituitary dysfunction is often secondary to a pituitary tumor or damage to the hypothalamus. Increased intracranial pressure secondary to head trauma, central nervous system (CNS) infections such as meningitis, or brain tumors may also affect perfusion of the hypothalamus and result in

damage. Postpartum hemorrhage, resulting in large blood loss and corresponding hypotension, may lead to severe hypoperfusion and infarction of the anterior pituitary. The onset of clinical manifestations of hypopituitarism is gradual and occurs after a majority (70%–90%) of the anterior pituitary is nonfunctional or destroyed.

### Pathophysiology

A deficiency of one of the anterior pituitary hormones results in changes in metabolic or sexual function, dependent on which hormone level is decreased. The effects of a decrease in one or more of the anterior pituitary hormones determine the pathophysiology of hypopituitarism. A decrease in adrenocorticotropic hormone (ACTH) leads to a decrease in release of the mineralocorticoids (aldosterone) and glucocorticoids (cortisol) from the adrenal cortex. Likewise, there is a decrease in thyroid hormones secondary to the decreased secretion of thyroid-stimulating hormone (TSH) from the anterior pituitary gland. Alterations in sexual and reproductive functioning are caused by decreased secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). There is also a decrease in growth hormone that presents differently according to the age of the patient. In children before the closure of the epiphyses, **dwarfism** (small stature) develops. A lack of growth hormone in adults does not affect bone length but does affect bone density, and osteoporosis (reduction in bone density) may develop.

### Clinical Manifestations

The clinical presentation of hypopituitarism is directly related to the hormone involved. Table 41.2 provides an overview of the clinical manifestations.

## Connection Check 41.1

The nurse correlates which clinical manifestation to the pathophysiology of decreased ACTH production from the anterior pituitary gland?

- Hypotension
- Polyuria
- Diarrhea
- Pruritus

## Management

### Medical Management

#### Diagnosis

Diagnostic evaluation of hypopituitarism focuses on the particular hormone and target cells/glands affected by the lack of tropic hormone. Hormonal studies conducted to assess for hypopituitarism include the ACTH (Cortrosyn) stimulation test and measurements of TSH, FSH, LH, prolactin, and growth hormone provocative tests. If a tumor of the brain or pituitary is suspected, a head computed tomography (CT) or MRI may be completed. A battery of serum

**Table 41.2 Clinical Manifestations Associated With Hypopituitarism**

Hormone	Clinical Manifestations
<b>Adrenocorticotropic hormone (ACTH)</b>	<p>Decreased glucocorticoids</p> <ul style="list-style-type: none"> <li>● Hypoglycemia</li> <li>● Decreased cortisol levels</li> <li>● Decreased ability to handle stress</li> </ul> <p>Decreased mineralocorticoids</p> <ul style="list-style-type: none"> <li>● Hyponatremia</li> <li>● Hypotension</li> <li>● Hyperkalemia</li> </ul>
<b>Growth hormone</b>	<p>Decreased bone density</p> <p>Decreased muscle strength</p> <p>Increased risk of bone fractures</p>
<b>Luteinizing hormone</b>	<p>Females</p> <ul style="list-style-type: none"> <li>● Irregular menses or amenorrhea</li> <li>● Decreased ovulation</li> </ul> <p>Males</p> <ul style="list-style-type: none"> <li>● Decreased testosterone</li> </ul>
<b>Follicle-stimulating hormone</b>	<p>Females</p> <ul style="list-style-type: none"> <li>● Decreased estrogen production</li> <li>● Decreased ovulation</li> </ul> <p>Males</p> <ul style="list-style-type: none"> <li>● Decreased sperm production</li> </ul>
<b>Thyroid-stimulating hormone (TSH)</b>	<p>Decreased levels of T3 and T4</p> <ul style="list-style-type: none"> <li>● Decreased metabolic rate</li> <li>● Weight gain</li> <li>● Thinning of hair</li> <li>● Decreased libido</li> </ul>

studies related to effects on target glands or cells is also performed to assist in a definitive diagnosis based on physical presentation. With suspected abnormalities in growth hormone, manifested by complaints of weakness or pathologic bone fractures, diagnostic evaluation often focuses on “ruling-out” other causes. Direct measurement of growth hormone is difficult because the levels change throughout the course of a day.

### Medications

The goals of medical management of hypopituitarism are aimed at restoring target hormone levels to normal levels. Hormone replacement is guided by the specific hormone deficiency. In addition to hormone replacement, supportive

therapies such as fluid and electrolyte replacement are the key to managing the patient with hypopituitarism. Hormone replacement may include cortisol, thyroid hormone, testosterone, or estrogen. Management of a decrease in growth hormone is usually focused on the pathophysiological processes associated with decreased bone density and osteoporosis and includes ensuring adequate intake or supplementation with vitamin D and calcium.

### Complications

Patients with hypopituitarism may develop life-threatening emergencies, particularly with panhypopituitarism. Lack of ACTH with a resultant decrease in glucocorticoids and mineralocorticoids is a life-threatening emergency because the patient is unable to maintain adequate fluid volume status, which may lead to circulatory collapse (discussed in more detail in Chapter 42). Additionally, a lack of TSH, leading to a decrease in thyroid hormone secretion, may result in a severe decrease in metabolism that affects all body functions and is particularly dangerous in relation to metabolism of medications.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations observed in the patient with hypopituitarism are directly related to the specific hormone deficiency. Common findings may include:

- Hypoglycemia related to decreased secretion of ACTH, resulting in decreased secretion of cortisol
- Decreased ability to cope with stress secondary to decreased secretion of cortisol
- Hyponatremia and hypotension secondary to decreased aldosterone secretion
- Hyperkalemia secondary to decreased aldosterone secretion
- Decreased bone density secondary to decreased growth hormone secretion

#### Nursing Diagnoses

- **Fluid volume deficit** related to decreased glucocorticoid and mineralocorticoid secondary to decreased secretion of ACTH from the anterior pituitary gland
- **Risk for injury: Falls** related to osteoporosis and weakened bone density associated with decreased growth hormone
- **Impaired mobility** related to increased risk of pathological fractures secondary to decreased bone density

#### Nursing Interventions

##### Assessments

- Vital signs  
*Hypotension and tachycardia develop secondary to decreased secretion of ACTH, leading to decreased secretion of glucocorticoid and mineralocorticoid, resulting in sodium and water loss.*
- Changes in fertility  
*Decreased testosterone may lead to sterility in males. Decreased LH or FSH may lead to amenorrhea and infertility in females.*

- Signs of decreased bone density  
*A lack of growth hormone in adults affects bone density, and the patient is at risk for osteoporosis.*

### ■ Actions

- Implement safety measures  
*Risk of injury related to falls and pathologic fractures increases secondary to decreased secretion of growth hormone.*
- Increase vitamin D and calcium intake  
*Treats osteoporosis secondary to decreased growth hormone, vitamin D promotes absorption of calcium in the gastrointestinal tract.*
- Hormone replacement  
*Supplementation of sex hormones may be administered to treat hypofunction of the gonads.*
- Collaborate with physical therapy to maximize mobility  
*Osteoporosis increases the risk for falls, and the physical therapist can provide input into safe transfers from bed to chair and measures to decrease the incidence of falls.*

### ■ Teaching

- Signs and symptoms of acute adrenal insufficiency  
*Infection, injury, and stress lead to an increased need for ACTH. Because of underlying hypopituitarism, the patient may require exogenous glucocorticoids in the event of stress (physiological or psychological).*
- Importance of taking hormone supplements in the morning  
*Taking hormone supplements in the morning mimics the normal release of these hormones.*

### Evaluating Care Outcomes

Patients with hypopituitarism can achieve relatively normal function by complying with prescribed therapy. Replacement hormone therapy based on the specific hormone is combined with supportive treatment to address end gland/target cell effects. Vital signs within normal limits, improved mobility, stable weight, and normal fluid volume status are indicative of stable anterior pituitary function. With appropriate hormone replacement, fertility and conception may be achieved. During periods of stress, such as invasive procedures, the patient needs to be aware of the signs of adrenal insufficiency and the clinical manifestations they should report to their healthcare provider.

## Hyperpituitarism

Hyperpituitarism is a disorder related to hypersecretion of hormones from the anterior pituitary gland. As with hypopituitarism, the pathophysiology and clinical presentation are directly related to which hormone levels are elevated secondary to hypersecretion. Hypersecreting tumors of the anterior pituitary gland are often the etiology of hyperpituitarism.

### Epidemiology

Hyperpituitarism is usually related to a hypersecreting tumor. The incidence of these types of tumors is higher in females, but there are no differences based on race or

ethnicity. These types of tumors may present in children or adults, and there is a genetic association with the tumor development. The patient presentation is consistent with clinical manifestations associated with the oversecreted hormone, and the tumor itself may lead to headaches or visual changes secondary to compression of the optic nerve (CN II) and other structures in the central nervous system.

### Pathophysiology

Hyperpituitarism secondary to hypersecretion of hormones leads to specific dysfunction related to the hormone involved. An excess of one of the anterior pituitary hormones results in changes in metabolic or sexual function that are dependent on which hormone level is elevated. The effects of an increase in one or more of the anterior pituitary hormones determine the pathophysiology of hyperpituitarism. An increase in ACTH leads to an increase in release of the mineralocorticoids and glucocorticoids from the adrenal cortex. Likewise, there is an increase in thyroid hormone released secondary to the increased secretion of TSH from the anterior pituitary gland. Alterations in sexual and reproductive functioning are caused by increased secretion of the gonadotropins (LH and FSH). There is also an increase in growth hormone that presents differently according to the age of the patient. In children before the closure of the epiphyses, **gigantism** (large stature) develops. An excess of growth hormone in adults does not affect bone length because of closure of the epiphyses but does affect bone density, and **acromegaly** (thickening of bones, particularly of the hands, feet, and facial bones) may develop (Fig. 41.1).

### Clinical Manifestations

The clinical presentation of hyperpituitarism is directly related to the excessive secretion of ACTH, growth hormone, and TSH. Table 41.3 provides an overview of the clinical manifestations. Excessive secretions of LH and FSH are not associated with physiological changes.

### Management

#### Medical Management

##### Diagnosis

Diagnostic evaluation of hyperpituitarism focuses on the particular hormone and target cells/glands affected by the excess of tropic hormone. Hormonal studies conducted to assess for hyperpituitarism include the ACTH (Cortrosyn) stimulation test and measurements of TSH, FSH, LH, prolactin, and growth hormone provocative tests. If a hypersecreting tumor of the brain or pituitary is suspected, a head CT or MRI may be completed. A battery of serum studies associated with effects on target glands or cells is also performed to assist in a definitive diagnosis based on physical presentation. With suspected increases in growth hormone, the patient presents with increases in the size of the hands and feet and broadening of the facial bones.

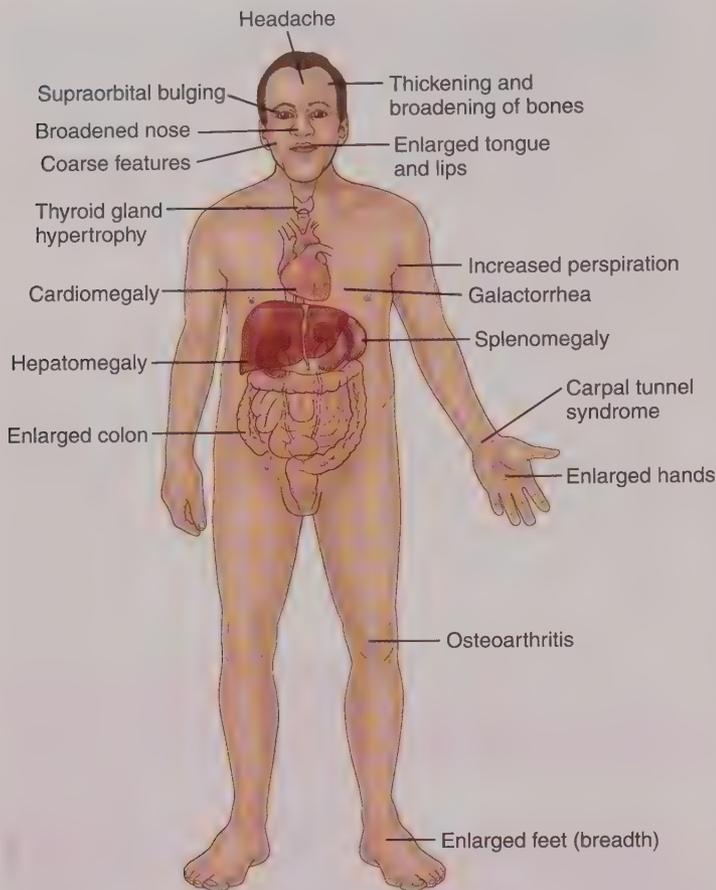

FIGURE 41.1 Characteristics of acromegaly.

**Table 41.3 Clinical Manifestations Associated With Hyperpituitarism**

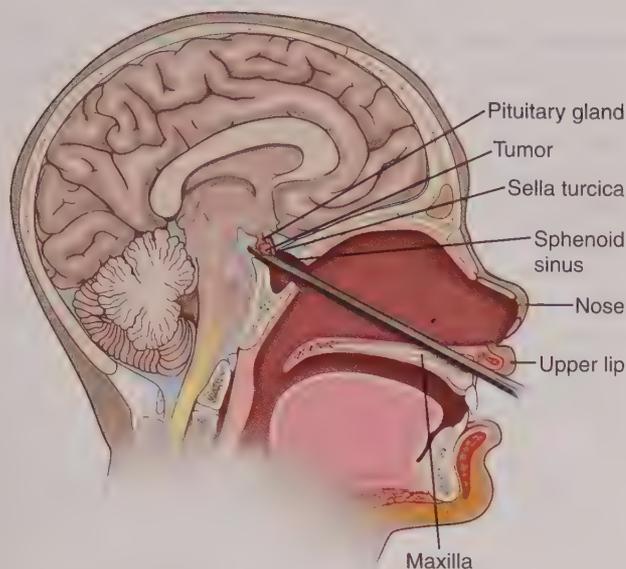

Hormone	Clinical Manifestations
<b>Adrenocorticotropic hormone (ACTH)</b>	<ul style="list-style-type: none"> <li>Increased glucocorticoids                             <ul style="list-style-type: none"> <li>● Hyperglycemia</li> <li>● Increased cortisol levels</li> </ul> </li> <li>Increased mineralocorticoids                             <ul style="list-style-type: none"> <li>● Hyponatremia</li> <li>● Hypertension</li> <li>● Hypokalemia</li> </ul> </li> </ul>
<b>Growth hormone</b>	<ul style="list-style-type: none"> <li>Increased bone density</li> <li>Coarse facial features</li> <li>Menstrual irregularities</li> </ul>
<b>Thyroid-stimulating hormone (TSH)</b>	<ul style="list-style-type: none"> <li>Increased levels of T3 and T4                             <ul style="list-style-type: none"> <li>● Increased metabolic rate</li> <li>● Weight loss</li> <li>● Exophthalmos</li> </ul> </li> </ul>

**Medications**

The goals of medical management of hyperpituitarism are aimed at decreasing secretion of the involved hormones and treating clinical manifestations secondary to target gland or cell hyperfunction (hyperglycemia, hypertension, etc.). Dopamine agonists (bromocriptine mesylate [Parlodel]) inhibit the release of anterior pituitary hormones. Medications that inhibit release of growth hormone include somatostatin analogs and growth hormone receptor blockers. In some cases, these medications are used to decrease the size of the tumor in advance of surgical removal.

**Surgical Management**

Hypersecreting tumors of the pituitary gland are surgically removed by a transsphenoidal **hypophysectomy**. The sublabial transseptal approach to a pituitary tumor involves an incision made under the top lip, with entry to the nasal cavity made through the floor of the nose. The nasal septum is moved to the side, and the sphenoid sinus is opened to access the sella turcica and the pituitary gland (Fig. 41.2). A muscle graft is placed after removal of the tumor, and often comes from the patient's thigh. The graft aids in healing and prevents cerebrospinal fluid (CSF) **rhinorrhea** (CSF draining from the nose). Nasal packing is placed after

**FIGURE 41.2** Sublabial transseptal approach to surgical removal of pituitary tumor. The sublabial transseptal approach to a pituitary tumor involves an incision made under the top lip, with entry to the nasal cavity made through the floor of the nose. The nasal septum is moved to the side, and the sphenoid sinus is opened to access the sella turcica and the pituitary gland.

the incision is closed and a loose dressing is placed below the nares (moustache dressing). Postoperative management of the patient is similar to that for patients undergoing intracranial surgery for other types of brain tumor (discussed in Chapter 36). Postoperatively, these patients must be monitored for increased intracranial pressure, development of diabetes insipidus (presented later in this chapter), meningitis, and cerebrospinal leakage. The patient is instructed to avoid activities that could increase pressure at the incision site, for example coughing, sneezing, and bending over. Smaller pituitary tumors may also be removed via

an endoscopic approach, which poses fewer postoperative complications than the sublabial transseptal approach. This surgical procedure gains access to the pituitary tumor through a fiberoptic device inserted through an incision in the lining of the nose (Fig. 41.3).

**Stereotactic radiosurgery**, a minimally invasive procedure, is another surgical approach that may be indicated for residual or recurrent pituitary tumors after surgical resection. Delivering high-dose radiation to a precisely targeted area of the brain, the goal is eradication of the tumor with minimal effects to adjacent normal brain tissue. The procedure involves the placement of a stereotactic headframe to allow localization of the target area and immobilization during the procedure. There are minimal complications to this procedure and the patient is typically discharged on the same day, with instruction to monitor pin sites (from the headframe) for bleeding or drainage, and to take acetaminophen for headache.

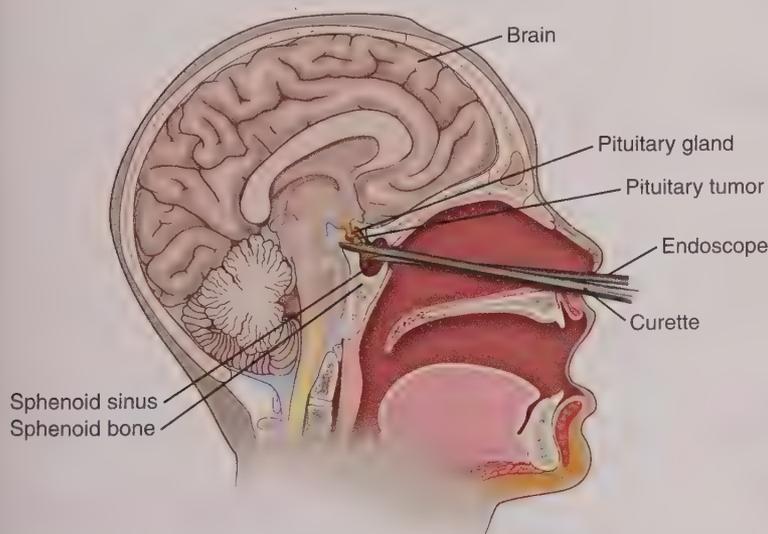

### Connection Check 41.2

The nurse questions which order in the patient who has undergone transsphenoidal hypophysectomy for a pituitary tumor?

- A. Offer clear fluids once alert and awake
- B. Oxygen 2 L via nasal cannula
- C. Maintain head of the bed at a 45- to 60-degree angle
- D. Apply lip balm prn

### Complications

Patients with hyperpituitarism may develop complications related to excess hormone secretion. Excess ACTH with a resultant increase in glucocorticoids and mineralocorticoids leads to hyperglycemia, hypertension, and acromegaly.

**FIGURE 41.3** Endoscopic approach to surgical removal of pituitary tumor. The endoscopic approach gains access to the pituitary tumor through a fiberoptic device inserted into the nostril and then the sella turcica is entered for tumor removal.

Additionally, an excess of TSH leading to an increase in thyroid hormone secretion may result in severe hyperthyroidism and may deteriorate to thyroid storm (discussed in Chapter 43). After transsphenoidal hypophysectomy, the patient is at risk for CSF rhinorrhea that increase the risk of meningitis (see Evidence-Based Practice). Damage to the posterior pituitary gland may lead to disorders of antidiuretic hormone secretion (discussed in the next section of this chapter).

## Evidence-Based Practice

### Postoperative Cerebrospinal Fluid Leak in Patients With Lower Airway Disease

Cerebrospinal fluid (CSF) rhinorrhea is a potential postoperative complication in patients after transsphenoidal hypophysectomy. This study examined the relationship between postoperative CSF rhinorrhea and lower airway disease (including chronic obstructive pulmonary disease and asthma) in patients after transsphenoidal hypophysectomy. This retrospective review of Healthcare Care and Utilization Project's 2013 National Inpatient Sample compared hospital stays and surgical outcomes in patients with lower airway disease with a disease-free population. Of the patients with lower airway disease in this study, 92% had asthma and had a greater risk for postoperative CSF leak and for the development of diabetes insipidus. Patients with CSF leak had longer hospital stays. Findings from this study recommend perioperative lower airway assessment for patients scheduled for transsphenoidal hypophysectomy to potentially decrease postoperative complications.

Hanba, C., Svider, P.F., Jacob, J.T., Guthikonda, M., Liu, J.K., Eloy, J.A., & Folbe, J.A. (2017). Lower airway disease and pituitary surgery: Is there an association with postoperative cerebrospinal leak? *Laryngoscope*, 127(7), 1543–1550.

## Nursing Management

### Assessment and Analysis

Clinical manifestations observed in the patient with hyperpituitarism are directly related to specific hormone excesses. Common findings may include:

- Hyperglycemia related to increased secretion of ACTH, resulting in increased secretion of cortisol
- Hyponatremia and hypertension secondary to increased secretion of aldosterone
- Hypokalemia secondary to increased secretion of aldosterone
- Increased bone density secondary to increased secretion of growth hormone

## Nursing Diagnoses

- **Fluid volume excess** related to increased glucocorticoid and mineralocorticoid secretion secondary to increased secretion of ACTH from the anterior pituitary gland
- **Body image disturbance** related to thickening of the bones (brow, facial bones, hands, and feet) secondary to excessive growth hormone secretion
- **Pain** related to compression of peripheral nerves secondary to thickening of bones

## Nursing Interventions

### Assessments

- Vital signs  
*Hypertension may develop secondary to excessive secretion of mineralocorticoid, leading to reabsorption of sodium and water.*
- Neurological assessment, including vision  
*Pituitary tumors may cause an increase in intracranial pressure. As tumors enlarge and extend beyond the sella turcica, they may compress CN II and CN III.*
- Intake and output  
*Urinary output may decrease secondary to increased reabsorption of sodium and water. Excessive output of dilute urine may occur if the patient develops diabetes insipidus.*
- Daily weight  
*Reabsorption of sodium and water secondary to increased mineralocorticoid may lead to increases in weight.*
- Serum electrolytes  
*Increased secretion of ACTH leads to increased cortisol and aldosterone, leading to sodium retention and potassium loss.*
- Changes in size of hands, feet, and bone structure  
*Increased secretion of growth hormone leads to thickening of the bones.*
- Neurovascular status  
*In patients with acromegaly, bone growth may compress peripheral nerves causing numbness, tingling, or pain in the hands and feet*

### Actions

- Administer dopamine agonists  
*Inhibit release of anterior pituitary hormones*
- Administer somatostatin analogs  
*Inhibit release of growth hormone*
- Administer hormone supplements  
*Replacement of sexual hormones is required to facilitate normal function and conception.*

### Teaching

- Disease process and importance of adherence to prescribed medications  
*Because of the complexity of the disease process and possible side effects of medications (that may decrease secretion of other anterior pituitary hormones), the patient and family need to understand the specific changes to be reported to the healthcare provider. Collaborate with the pharmacist for medication teaching.*

## Nursing Interventions for a Patient After Transsphenoidal Hypophysectomy

### ■ Assessments

- Vital signs  
*Hypotension and tachycardia are seen if the patient develops postoperative DI. Temperature elevation may occur if there is postoperative infection from the surgical incision or secondary to a CSF leak.*
- Neurological status  
*An increase in intracranial pressure secondary to the surgical procedure may lead to changes in the level of consciousness and papillary changes. Visual field changes may develop secondary to postoperative cerebral edema.*
- Intake and output  
*Lack of ADH leads to an increase in excretion of large amounts of dilute urine.*
- Mucus membranes and mouth  
*Because of nasal packing after transsphenoidal hypophysectomy, the patient breathes primarily through the mouth, leading to increased dryness.*
- Urine-specific gravity  
*Urine-specific gravity decreases, usually less than 1.005 secondary to lack of ADH and subsequent excretion of dilute urine.*
- Serum sodium and osmolality  
*Serum sodium and osmolality increase because of increased excretion of water secondary to lack of ADH.*

### ■ Actions

- Administer humidified oxygen as ordered  
*The surgical approach (via the sphenoid) does not allow the patient to breathe through the mouth. The patient is an obligate mouth breather, and humidification facilitates maintaining moist mucous membranes.*
- Maintain IV access and administer ordered IV solutions  
*In patients with a decrease in level of consciousness, IV fluids are usually indicated. The solution ordered is based on the serum sodium level*
- Administer desmopressin or vasopressin as ordered  
*Synthetic ADH is administered to cause water reabsorption in the kidneys.*
- Maintain head of the bed at 45 to 60 degrees  
*Facilitates ease of breathing by dropping diaphragm, and promotes outflow via jugular veins to minimize changes in intracranial pressure*
- Provide adequate oral fluids  
*If the patient is alert and awake, the patient is allowed to drink fluids.*
- Provide mouth care  
*The patient is at risk for fluid volume deficit related to lack of ADH and requires mouth care to minimize complications of dry mucous membranes.*

### ■ Teaching

- Signs of meningitis  
*The surgical approach increases the risk of meningitis, and the nurse needs to monitor for elevated temperature, nuchal rigidity (stiff neck), and photophobia.*

- Signs and symptoms of DI: Instruct patient to notify his or her healthcare provider for increased urine output and excessive thirst. Signs and symptoms of fluid overload: Instruct patient to notify his or her healthcare provider for weight gain.

*The patient must understand the pathophysiology of this disorder and the importance of fluid volume balance. Over-correction of DI with DDAVP or Pitressin may lead to fluid overload.*

- Use a soft toothbrush after transsphenoidal hypophysectomy  
*Decreases potential to damage incision line after transsphenoidal activity*
- Avoid activities (coughing, sneezing, bending at the waist) after transsphenoidal hypophysectomy  
*These activities can put strain on the surgical site.*
- Report any increase in drainage of clear fluid from the nose after transsphenoidal hypophysectomy  
*Clear drainage from the nose may indicate a CSF leak that increases risk of meningitis.*

### Evaluating Care Outcomes

The patient with hyperpituitarism may achieve normal function through the administration of medications that suppress excess hormone secretion, particularly growth hormone. Removal of a hypersecreting tumor of the anterior pituitary with no associated injury to the gland usually results in normal function. Changes in bone structure will not return to normal, but there is no further growth in bone secondary to excessive growth hormone in the adult. After transsphenoidal hypophysectomy, the patient should be neurologically intact with normal fluid and electrolyte balance.

### CASE STUDY: EPISODE 2

The result of Carol Andrews' MRI is positive for a pituitary adenoma, and she is scheduled for a transsphenoidal hypophysectomy for removal of the tumor. The operative procedure is uneventful, and she is admitted to the neurosurgical intensive care unit. Postoperative orders include vital signs with neurological assessments every hour, hourly intake and output measurements, head of bed at 45 degrees, oxygen at 35% with humidification via a face tent, a nasal drainage pad to be maintained under the nose and monitored for drainage, and an IV of lactated Ringer's (LR) solution at 80 mL per hour. She has an indwelling urinary catheter and is placed on continuous electrocardiogram monitoring. Laboratory orders include hourly measurements of urine-specific gravity and serum and urine electrolytes every 6 hours...

## DISORDERS OF THE POSTERIOR PITUITARY GLAND

### Diabetes Insipidus

#### Epidemiology

Diabetes insipidus (DI) is classified as either central or nephrogenic. Central DI is caused by a decreased secretion of antidiuretic hormone (ADH) from the posterior pituitary gland. Nephrogenic DI occurs when the kidneys are resistant to ADH and are unable to concentrate urine, and this type of DI is observed in patients with chronic renal insufficiency, hypercalcemia, hypokalemia, and interstitial disease of the renal tubules. This chapter focuses on central DI.

Approximately 30% of cases of DI are idiopathic, whereas 25% are secondary to brain tumors, 20% develop after intracranial surgery, and 16% occur after head trauma. Idiopathic DI develops secondary to destruction of the cells of the hypothalamus that produce ADH and is often an autoimmune process. Primary brain tumors leading to DI include craniopharyngiomas (arising near the pituitary gland) and pineal tumors. Postneurosurgical DI varies by type of surgical procedure. In patients undergoing traditional craniotomy, DI is reported in 60% to 80% of the patients, whereas with the transsphenoidal approach (see Fig. 41.1), only approximately 10% to 20% of the patients develop postoperative DI. In some of these cases, particularly in postoperative DI, the disorder is transient.

#### Pathophysiology

The decrease or absence of ADH in the patient with DI results from lack of production in the hypothalamus. Antidiuretic hormone, stored and released from the posterior pituitary gland, works on the receptor cells in the collecting ducts of the kidney, leading to water reabsorption back into the circulation. With a lack of ADH, the collecting ducts are less permeable to water, and it is excreted as urine. In patients with DI, the lack of ADH leads to excretion of large volumes of very dilute urine.

#### Clinical Manifestations

The clinical presentation of the patient with DI is dependent on the significance of water loss. Polyuria, polydipsia, and nocturia are the primary clinical manifestations seen in patients with DI. The excessive loss of water leads to

hemoconcentration that is observed with elevations in serum sodium and hematocrit. The patient may present with hypotension and tachycardia secondary to hypovolemia. Other signs of fluid volume deficit including thirst, skin tenting, and fatigue may also be observed.

#### Management

##### Medical Management

##### Diagnosis

Diagnostic evaluation of DI includes serum and urine electrolytes, serum and urine osmolality, urine-specific gravity, and CT or MRI of the head (Table 41.4). Urine-specific gravity of less than 1.005 and urine osmolality less than 200 mOsm/kg are key indicators of DI. While the patient loses free water, increases in serum sodium, serum osmolality, and hematocrit develop secondary to hemoconcentration. The water deprivation test is also used in the diagnosis of DI. In this test, all water is withheld, and urine osmolality and body weight are measured hourly. During the test, the patient's weight and urine osmolality are evaluated because normally the withholding of water leads to a urine osmolality 2 to 4 times greater than the serum osmolality. The diagnosis of DI is made when serum osmolality continues to increase and there is no resultant increase in urine osmolality.

##### Fluid Management and Medications

Management of DI is focused on maintaining adequate fluid volume status. Most patients who are awake and alert are able to replace water loss by drinking fluids. In an emergency or in the unconscious patient, IV fluid administration is indicated. Water losses are replaced with a hypotonic fluid (in relation to the patient's serum osmolality) such as dextrose in water. During IV administration, the patient is monitored for hyperglycemia, volume overload, and correction of hypernatremia. Decreasing the serum sodium by 0.5 mmol/L every hour minimizes the chances of overly rapid correction of hypernatremia.

Desmopressin (DDAVP), a synthetic analog of ADH, is the drug of choice in patients with DI and is available in subcutaneous, intranasal, and oral preparations. There is also a synthetic vasopressin (Pitressin) used to treat DI that is less expensive than desmopressin. Patients receiving either of these medications require frequent monitoring of fluid status, serum electrolytes, and urine output.

**Table 41.4 Laboratory Tests For Posterior Pituitary Disorders**

Test	Normal Range for Adults	Significance
<b>Hematocrit</b>	Male: 43%–49%	Increased in diabetes insipidus (DI)
	Female: 38%–44%	Decreased in syndrome of inappropriate antidiuretic hormone (SIADH)
<b>Serum sodium</b>	135–145 mEq/L	Increased in DI
		Decreased in SIADH
<b>Urine-specific gravity</b>	1.005–1.030	Decreased with DI
		Increased in SIADH

### Connection Check 41.3

The nurse correlates which laboratory value as an indication that desmopressin is effective in the treatment of diabetes insipidus (DI)?

- A. Serum sodium of 140 mEq/L
- B. Serum osmolality of 305 mOsm/kg
- C. Urine-specific gravity of 1.004
- D. Serum hematocrit of 48%

#### Complications

The patient with DI may develop dehydration and hypovolemia, progressing to circulatory collapse without adequate fluid administration. Patients with permanent DI who require daily administration of hormone replacement are particularly at risk for hypovolemia. Hemoconcentration secondary to DI also increases the risk for hypernatremia. The clinical presentation of hypernatremia is related to central nervous system dysfunction secondary to shrinkage of brain cells and results in confusion, neuromuscular excitability, seizures, or coma.

#### Nursing Management

##### Assessment and Analysis

Because DI is directly related to the lack of ADH, there is loss of free water. Assessment findings include polyuria, urine-specific gravity less than 1.005, and low urine osmolality (especially in relation to serum osmolality). Secondary to hemoconcentration, laboratory analyses reveal an increase in serum sodium, osmolality, and hematocrit. Changes in blood pressure and heart rate are related to the volume of fluid loss. Patients who are awake and alert with an intake thirst mechanism are usually able to maintain fluid volume by drinking adequate fluids.

##### Nursing Diagnoses

- **Fluid volume deficit** related to loss of free water secondary to lack of ADH
- **Risk for ineffective therapeutic regimen management** related to required administration of desmopressin (DDAVP)
- **Sensory perceptual alteration (vision)** related to compression of CN II and III secondary to pituitary tumor

##### Nursing Interventions

###### Assessments

- Vital signs  
*Lack of ADH leads to excessive water loss with resulting decrease in blood pressure and increase in heart rate as a compensatory mechanism.*
- Intake and output  
*Fluid replacement is largely dependent on the volume of urine output secondary to lack of ADH.*
- Daily weight  
*Increased output of dilute urine, secondary to lack of ADH, leads to decrease in weight.*
- Visual acuity  
*Growth of the pituitary tumor may compress CN II or CN III.*

###### Serum sodium and osmolality

*Lack of ADH causes an increase in water excretion leading to the concentration of serum sodium (hypernatremia) and an increase in serum osmolality.*

###### Urine-specific gravity

*Lack of ADH results in the excretion of large volumes of dilute urine; specific gravity is usually less than 1.005.*

###### Actions

###### Maintain IV access and administer ordered IV solutions

*In patients with a decrease in level of consciousness, IV fluids are usually indicated. The solution ordered is based on serum sodium level. It is important to maintain vascular access because placement of an IV catheter in a profoundly hypotensive patient is difficult.*

###### Administer desmopressin or vasopressin as ordered

*Synthetic ADH is administered to cause water reabsorption in the kidney.*

###### Provide adequate oral fluids

*If the patient is alert and awake and has an intact gag reflex, the patient is allowed to drink fluids.*

###### Provide mouth care

*The patient is at risk for fluid volume deficient related to lack of ADH and requires mouth care to minimize complications of dry mucous membranes.*

###### Teaching

###### Importance of taking medications (ADH replacement) as ordered

*Taking the medications (Vasopressin/Pitressin) at the same time daily mimics normal release and supports water reabsorption in the kidneys*

###### Weigh daily at same time and on same scale

*Weight is directly associated with water loss or gain, and changes of more than 2 lb per day should be reported to the healthcare provider.*

###### Clinical manifestations of DI

*The patient must understand the pathophysiology of this disorder and the importance of fluid volume balance.*

###### Clinical manifestations of fluid overload

*Overcorrection of DI with DDAVP or Pitressin may lead to fluid overload.*

### Connection Check 41.4

The patient experiencing diabetes insipidus (DI) is ordered to receive DDAVP. The nurse monitors for which therapeutic effect of these medications?

- A. Increased urine output
- B. Increased urine-specific gravity
- C. Increased serum sodium
- D. Increased serum potassium

#### Evaluating Care Outcomes

Diabetes insipidus may be transient after head injury or craniotomy, or it may be a permanent disorder. Definitive treatment with synthetic ADH replacement results in water

reabsorption and normalization of urine output, urine-specific gravity, and serum electrolytes. Vital signs are normal, output is proportional to intake, and body weight is stable in patients with well controlled DI.

### CASE STUDY: EPISODE 3

Approximately 8 hours after Ms. Andrews arrives in the neurosurgical intensive care unit after undergoing transsphenoidal hypophysectomy, the nurse notes that the patient has had 200 to 300 mL/hr urine output for the last 3 hours. Urine-specific gravity is 1.002, and serum electrolyte results include a sodium level of 148 mEq/L and an osmolality of 292 mOsm/kg. The patient's blood pressure is 92/56 mm Hg with a heart rate of 110 bpm. The neurosurgeon is notified, and the patient is started on a Pitressin (vasopressin) IV infusion...

**Safety Alert** Fluid administration must be closely monitored in the patient after transsphenoidal hypophysectomy. The administration of hypotonic solutions in the postoperative patient with a normal serum sodium level after transsphenoidal hypophysectomy increases the risk of fluid shifts and can lead to cerebral edema and an increase in intracranial pressure.

## Syndrome of Inappropriate Antidiuretic Hormone

### Epidemiology

The syndrome of inappropriate antidiuretic hormone (SIADH) is a disorder related to an increase in ADH. Because the action of ADH is to reabsorb water in the kidneys, SIADH is characterized by water overload and resultant hyponatremia caused by hemodilution. Causes of SIADH vary and include CNS disorders such as tumors in the brain or neck, side effects of medications such as NSAIDs, psychotropic medications, and bronchogenic carcinoma. There are no specific relationships between the developments of SIADH and race, ethnicity, sex, or age.

### Pathophysiology

The excess secretion of ADH in the patient with SIADH leads to reabsorption of water in the kidneys. Hyponatremia develops that is secondary to hemodilution; there is no decrease in total body sodium. The excess ADH results in decreased urine output with an increase in the concentration (increased specific gravity) and osmolality of the urine.

### Clinical Manifestations

The clinical presentation of the patient with SIADH is primarily associated with the resultant hyponatremia. Earlier findings include anorexia, nausea, and malaise followed by

headache, irritability, confusion, and weakness. While serum sodium levels continue to decrease, the patient may have seizures or become comatose, particularly when serum sodium levels fall below 120 mEq/L. The neurological signs associated with the hyponatremia are related to osmotic fluid shifts in the brain that lead to cerebral edema and increased intracranial pressure.

## Management

### Medical Management

#### Diagnosis

Diagnostic evaluation of SIADH includes monitoring and trending urine-specific gravity and serum and urine osmolality and electrolytes (see Table 41.4). Hyponatremia (serum sodium level less than 135 mEq/L) develops, along with a decrease in serum osmolality (<275 mOsm/kg). Urine output decreases, and there are increases in both urine-specific gravity (>1.030) and urine osmolality. This results in a clinical presentation that is unusual. Typically, patients presenting with scant, concentrated urine would have signs indicative of dehydration, including elevated serum sodium, serum osmolality, and urine-specific gravity. However, in patients with SIADH caused by excessive ADH secretion, they present with scant urine output and elevated urine-specific gravity but a decrease in serum sodium and osmolality. This inconsistent clinical presentation is often a key in recognizing the patient with SIADH.

#### Fluid Management and Medications

Medical management is primarily focused on treating the hyponatremia. The patient is placed on fluid restriction, usually less than 1,000 mL/day. With severe hyponatremia, IV administration of 3% saline may be administered, but this requires very close monitoring because of the hyperosmolarity of this solution and it is typically infused via a central venous access device. Diuretics may be administered to increase urine output. Demeclocycline (Declomycin), a tetracycline derivative, may also be used because it increases water excretion by the kidneys.

## Connection Check 41.5

The nurse correlates which finding to a diagnosis of SIADH?

- Polyuria
- Polyphagia
- Decreased urine output
- Glucosuria

### Complications

The primary complications seen in patients with SIADH are related to decreasing serum sodium levels. While the sodium concentration drops below 120 mEq/L, life-threatening complications are likely to occur, including seizures and coma. Because of fluid shifts in the cerebral cortex, cerebral edema and increased intracranial pressure may develop, further exacerbating neurological complications.

## Connection Check 41.6

The nurse monitors the patient with SIADH for which complication secondary to a serum sodium level of 120 mEq/L?

- A. Hypotension
- B. Hyperglycemia
- C. Seizures
- D. Bradycardia

## Nursing Management

### Assessment and Analysis

In the patient with SIADH, the increased reabsorption of water is directly a result of excessive secretion of ADH. Assessment findings include oliguria, increased specific gravity, and increased urine osmolality. The resulting hemodilution secondary to water retention leads to a decrease in serum sodium and osmolality. While water retention increases, the patient may complain of anorexia and nausea, weakness, and headache. While serum sodium levels continue to decrease, the nurse monitors for confusion and irritability. If the serum sodium level drops below 120 mEq/L, the patient is at risk of seizures.

### Nursing Diagnoses

- **Fluid volume excess** related to increased water reabsorption secondary to increased ADH secretion
- **High risk for injury** related to cerebral edema and CNS dysfunction
- **Knowledge deficit** related to required fluid restriction

### Nursing Interventions

#### Assessments

- **Neurological status**  
*Fluid overload with resulting hyponatremia may lead to confusion, headache, and changes in level of consciousness.*
- **Intake and output**  
*Excess secretion of ADH leads to reabsorption of water in the renal tubules.*
- **Serum sodium and osmolality**  
*Serum sodium and osmolality levels decrease secondary to dilution.*
- **Urine-specific gravity and urine osmolality**  
*With reabsorption of water in the kidneys, the urine is concentrated, resulting in increased specific gravity and urine osmolality.*
- **Skin integrity**  
*Fluid reabsorption may result in skin tautness.*

#### Actions

- **Restrict fluids**  
*Fluids are restricted to concentrate serum sodium. The nurse needs to plan how the fluid will be distributed over the day.*
- **Administer demeclocycline (Declomycin)**  
*Demeclocycline increases excretion of water from the kidneys.*

- Administer 3% saline as ordered via central IV line  
*Hypertonic saline solution to increase serum sodium levels*
- Implement seizure precautions  
*Risk of seizures increases with hyponatremia, particularly when serum sodium levels fall below 120 mEq/L.*

#### Teaching

- **Disease process and management**  
*Because of complications associated with hyponatremia, it is important for the patient and family to understand the pathophysiology and treatment of SIADH.*
- **Follow fluid restriction**  
*It is important that the patient follow restrictions to decrease exacerbating fluid overload.*
- **Signs of fluid overload**  
*Signs of fluid overload may be associated with falling serum levels that increase the risk of seizures and other neurological changes.*

### Evaluating Care Outcomes

Syndrome of inappropriate antidiuretic hormone (SIADH) is managed with the combination of fluid restriction and specific medications that increase serum sodium levels. Stable body weight and relatively equal intake and output are indicative of effective management of SIADH in this patient population. Serum sodium, serum osmolality, urine-specific gravity, and urine osmolality return to normal with effective treatment. The patient and family should be knowledgeable of the signs of water overload and the clinical manifestations they should report to their healthcare provider. Table 41.5 provides a comparison of the clinical manifestations of DI and SIADH.

**Table 41.5 Comparison of Diabetes Insipidus and Syndrome of Inappropriate Antidiuretic Hormone**

Clinical Manifestations	DI	SIADH
<b>Urine output</b>	Increased	Decreased
<b>Urine-specific gravity</b>	Decreased	Increased
<b>Serum sodium (Na)</b>	Increased	Decreased
<b>Serum osmolality</b>	Increased	Decreased
<b>Hematocrit</b>	Increased	Decreased
<b>Blood pressure</b>	Decreased	May be slightly increased
<b>Heart rate</b>	Increased	No specific change in rate
<b>Pulse</b>	Weak, accelerated	Full, bounding
<b>Thirst</b>	Increased	No specific change

DI, Diabetes insipidus; SIADH, syndrome of inappropriate antidiuretic hormone.

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Andrews responds favorably to the IV Pitressin, and after 24 hours she is started on DDAVP intranasally. Her blood pressure is 110/68 mm Hg with a heart rate of 88 bpm. Urine output has decreased to an average of 50 mL/hr, and IV fluids are discontinued because she is taking oral fluids. Discharge planning is initiated, and she is scheduled to be discharged on the fourth postoperative day. She is discharged on DDAVP. The nurse incorporates teaching about activity restrictions related to transsphenoidal hypophysectomy.

#### Case Study Questions

- On review of Ms. Andrews' admission clinical presentation, which clinical manifestations are most related to excessive growth hormone?
  - Headache
  - Enlarged hands
  - Visual changes
  - Nausea
- Ms. Andrews is ordered to receive bromocriptine mesylate (Parlodel) for the treatment of her tumor. The nurse correlates which rationale for this medication?
  - Decreases serum glucose levels
  - Decreases water reabsorption in the kidneys
  - Decreases secretion of growth hormone
  - Decreases secretion of ADH
- Which laboratory result does the nurse correlate with a diagnosis of diabetes insipidus (DI)?
  - Serum osmolality, 285 mOsm/kg
  - Serum sodium, 132 mEq/L
  - Hematocrit, 32%
  - Urine-specific gravity, 1.001
- In providing care to Ms. Andrews after she undergoes a transsphenoidal hypophysectomy, the nurse prioritizes which intervention?
  - Maintaining the patient in a flat, supine position
  - Instructing the patient to cough and deep breathe
  - Monitoring for clear fluid drainage from the nose
  - Limiting exposure to bright lights
- The nurse monitors for which therapeutic effect as a result of the administration of Pitressin?
  - Decreased urine output
  - Decreased blood pressure
  - Decreased serum glucose
  - Decreased thirst

## CHAPTER SUMMARY

Disorders of the hypothalamus and pituitary gland adversely affect many normal body functions. Anterior pituitary disorders are classified as hypofunction and hyperfunction, and the clinical presentations of each disorder are directly related to the involved hormones and their target glands or tissues. Hormones secreted from the anterior lobe of the pituitary include adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), growth hormone (GH), prolactin, and thyroid-stimulating hormone (TSH). The posterior lobe of the pituitary gland stores and secretes antidiuretic hormone (ADH) and oxytocin.

Deficiencies of one of the anterior pituitary hormones results in changes in metabolic or sexual function dependent on which hormone level is decreased. The effects of a decrease in one or more of the anterior pituitary hormones determine the pathophysiology of hypopituitarism. A decrease in ACTH leads to a decrease in release of the mineralocorticoids and glucocorticoids from the adrenal cortex. A decrease in secretion of TSH leads to a decrease in thyroid gland hormone secretion. Alterations in sexual and reproductive functioning are caused by decreased secretion of the gonadotropins (LH and FSH), and decreases in growth hormone affect the strength and integrity of bones and other tissues.

Hyperpituitarism is characterized by excess secretion of one or more of the anterior pituitary hormones. As with hypopituitarism, the pathophysiology and clinical presentation depend on which anterior pituitary hormone secretion is elevated. Treatment of these disorders is guided by the hormones involved. Hypersecretion of growth hormone is characterized by increases in bone density and changes in appearance and size of face, hands, and feet.

Diabetes insipidus develops secondary to a lack of ADH, which results in decreased water reabsorption in the kidney

and increased output of large amounts of dilute urine. The urine-specific gravity falls below 1.005, and the patient develops hypernatremia secondary to water loss. Treatment focuses on preventing dehydration and replacing deficient ADH. Daily doses of DDAVP are usually used to treat DI.

Syndrome of inappropriate antidiuretic hormone (SIADH) is a disorder that develops secondary to CNS disorders, most often a tumor, from specific lung cancers, or as a side

effect of certain medications. Oversecretion of SIADH leads to increased water reabsorption in the kidneys, resulting in a decrease in urine output, drop in serum sodium level less than 135 mEq/L, and decreased serum osmolality. Treatment focuses on reestablishing normal serum levels because the patient is at risk of seizures, water intoxication, and other neurological complications secondary to hyponatremia. Transsphenoidal hypophysectomy is a surgical approach used to remove pituitary tumors.

# Chapter 42

## Coordinating Care for Patients With Adrenal Disorders

*Janice Hoffman*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of adrenal disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Adrenal cortex insufficiency
  - b. Adrenal cortex hyperfunction
  - c. Pheochromocytoma
3. Describing the diagnostic results used to confirm the diagnoses of adrenal disorders
4. Discussing the medical management of:
  - a. Adrenal cortex insufficiency
  - b. Adrenal cortex hyperfunction
  - c. Pheochromocytoma
5. Explaining the presentation and management of adrenal crisis
6. Developing a comprehensive plan of nursing care for patients with adrenal disorders
7. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with adrenal disorders

### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Medication
- Metabolism

### ESSENTIAL TERMS

Acute adrenal crisis  
Adrenal insufficiency  
Adrenalectomy  
Addison's disease  
Aldosterone  
Catecholamine  
Conn's syndrome  
Cortisol  
Cushing's disease  
Cushing's syndrome  
Glucocorticoids  
Hyperaldosteronism  
Hypercortisolism  
Mineralocorticoids  
Pheochromocytoma  
Virilization

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Melinda Davis, a 32-year-old female, makes an appointment with her adult nurse practitioner because of changes in her menstrual cycle and concerns about difficulty getting pregnant. Ms. Davis is employed in a day-care center, and she and her spouse have been trying to conceive for approximately 10 months...

## INTRODUCTION

One adrenal gland is located on top of each kidney, and each measures approximately 5-cm long, 1-cm thick, and 3-cm wide. Each adrenal gland has an inner core, the medulla, and a thick outer covering, the cortex, both with distinct endocrine functions.

Under the control of the anterior pituitary gland, the adrenal cortex secretes **glucocorticoids** (cortisol), **mineralocorticoids** (aldosterone), and sex hormones (androgens and estrogens). (See Chapters 64–67 for details about the sex hormones.) **Cortisol** is the primary glucocorticoid, and its actions include carbohydrate, fat, and protein metabolism; suppression of the immune response; and control of the body's stress response. **Aldosterone** is the primary mineralocorticoid, and its primary actions are to promote sodium and water reabsorption and potassium excretion in the kidneys. Table 42.1 presents an overview of adrenal gland hormones and their actions.

## ADRENAL CORTICAL INSUFFICIENCY

### Epidemiology

**Adrenal insufficiency** may result from destruction of the adrenal glands (primary insufficiency or **Addison's disease**), decreased secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland (secondary insufficiency), or dysfunction of the hypothalamus (tertiary insufficiency). Nonspecific autoimmune destruction of the adrenal gland is the most common cause of primary adrenal insufficiency. Other causes of primary adrenal insufficiency include infectious, cancerous, and traumatic processes that lead to direct insults to the adrenal cortex. Secondary and tertiary adrenal insufficiencies are related to disorders of the anterior pituitary gland and hypothalamus, respectively. Despite the etiology, the clinical presentations of adrenal insufficiency are similar. Females are most often affected by adrenal insufficiency, and it has a peaked incidence in people 30 to 50 years of age.

### Connection Check 42.1

The nurse recognizes which patient is at greatest risk for adrenal insufficiency?

- A. A 19-year-old male
- B. A 35-year-old female
- C. A 45-year-old male
- D. An 80-year-old female

### Pathophysiology

The pathophysiology of adrenal insufficiency may be associated with decreased secretion of corticotropin-releasing hormone (CRH) from the hypothalamus, decreased secretion of ACTH from the anterior pituitary gland, or decreased

**Table 42.1 Overview of Adrenal Gland Hormones**

Gland	Hormone	Target	Action
Adrenal cortex	Glucocorticoids (cortisol)	Liver	Promotes gluconeogenesis (increasing blood glucose)
		Cells of the body	Decreases glucose use Promotes protein catabolism Promotes fat synthesis
		Bone marrow	Suppresses inflammatory processes
	Mineralocorticoids (aldosterone)	Distal tubules and collecting ducts in the kidney	Promotes sodium reabsorption and potassium excretion by the kidney
Adrenal medulla	Catecholamines (epinephrine and norepinephrine)	Cells of the body	Mimics actions of the sympathetic nervous system

secretion of glucocorticoids and mineralocorticoids from the adrenal cortex. Patients who are prescribed exogenous corticosteroids for longer than 2 weeks are at risk for acute adrenal insufficiency (**acute adrenal crisis**) if the medications are abruptly discontinued.

### Clinical Manifestations

Clinical manifestations of adrenal insufficiency usually present after 90% of the adrenal cortex is destroyed or nonfunctional. While the circulating levels of cortisol and aldosterone fall, the hypothalamus and anterior pituitary gland increase secretion of CRH and ACTH, respectively. Because melanocyte-stimulating hormone (MSH) and ACTH share a progenitor (ancestor) hormone, there is an associated increase in secretion of MSH, leading to a darkened, bronzed hyperpigmentation that accompanies the increased secretion of ACTH (Fig. 42.1).

Secondary to the decreased secretion of cortisol and aldosterone, the patient presents with weakness, weight loss, fatigue, nausea, abdominal pain, gastroenteritis, and emotional lability. Changes in mood include irritability, depression, and inability to concentrate. Hyperpigmentation of the skin and mucous membranes and decreased pubic and axillary hair (secondary to decreased secretion of sex hormones) are also observed. As the loss of sodium and water continues, the patient may develop dehydration and hypotension.

**FIGURE 42.1** Darkened, bronzed hyperpigmentation that accompanies the increased secretion of adrenocorticotropic hormone (ACTH) is observed in adrenal insufficiency.

### Connection Check 42.2

The nurse correlates which clinical manifestation with the pathophysiology of adrenal insufficiency?

- Heat intolerance
- Weight gain
- Peripheral edema
- Hypoglycemia

### Management

#### Medical Management

##### Diagnosis

Diagnostic evaluation of adrenal insufficiency includes tests of the hypothalamic-pituitary axis and adrenal cortex, as well as serum electrolytes (Table 42.2). Hyponatremia and hyperkalemia develop secondary to decreased aldosterone secretion. Direct measurement of serum cortisol levels is performed in the morning because of changes in levels associated with daily activities. Cortisol levels are highest in the morning (between 6 a.m. and 8 a.m.), and levels up to 25 mcg/dL are considered normal. Levels less than 3 mcg/dL are diagnostic for adrenal insufficiency. Serum corticotropin (ACTH) levels may also be obtained, and levels greater than 100 mg/mL are diagnostic of primary adrenal insufficiency. Diagnostic evaluations of the hypothalamic-pituitary axis

**Table 42.2 Laboratory Tests for Adrenal Disorders**

Test	Normal Range for Adults	Significance
<b>Cortisol</b>	5–25 mcg/dL (morning)	Decreased in hypocortisolism (Addison's)
	3–16 mcg/dL (afternoon)	Elevated in hypercortisolism (Cushing's)
<b>Glucose</b>	65–99 mg/dL	Decreased in hypocortisolism (Addison's)
		Increased in hypercortisolism (Cushing's)
<b>Potassium</b>	3.5–5.0 mEq/L	Increased in hypofunction of the adrenal cortex
		Decreased in hyperfunction of the adrenal cortex
<b>Sodium</b>	135–145 mEq/L	Decreased in hypocortisolism
		Increased in hypercortisolism
		Decreased in hypoaldosteronism
		Increased in hyperaldosteronism

to evaluate secondary and tertiary adrenal insufficiency are presented in Table 42.3.

Imaging studies are also used in the evaluation of adrenal insufficiency. Both computed tomography (CT) and magnetic resonance imaging (MRI) may be used to assess for changes in the size and morphology of the adrenal gland. Shrinking of the adrenal gland is associated with autoimmune destruction, whereas adrenal gland enlargement is often observed with infectious processes.

### Medications and Fluid Management

Replacement of cortisol is the definitive treatment for adrenal insufficiency. Patients presenting with acute adrenal insufficiency require emergency stabilization with IV fluids and glucose, along with IV administration of glucocorticoids (cortisol) such as 50 to 100 mg of hydrocortisone sodium succinate (Solu-Cortef) or 4 to 12 mg of dexamethasone (Decadron). One of the advantages of hydrocortisone is that it has both glucocorticoid and mineralocorticoid actions. The patient requires close monitoring, including frequent assessments of vital signs, level of consciousness, and serum sodium, glucose, and potassium levels to ensure an adequate dosage of cortisol. In patients presenting with hyperkalemia, treatment with potassium binding or excreting agents (Kayexalate) are indicated.

### Complications

Acute adrenal insufficiency, or adrenal crisis, is a life-threatening emergency that leads to severe hypovolemia and hypotension. Risk factors for adrenal crisis are seen in patients who have underlying adrenal hypofunction and who undergo stressful events such as trauma, surgery, and infections. Because of the decrease in aldosterone and cortisol, the patient loses sodium accompanied by fluid loss.

The patient is also at risk for hyperkalemia and hypoglycemia associated with lack of both mineralocorticoids and glucocorticoids. Patients with primary adrenal insufficiency require additional doses of glucocorticoid during periods of stress such as surgery, trauma, or infection.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of adrenal insufficiency, whether acute or chronic, are directly related to the actions of the adrenal cortex hormones. The nurse correlates adrenal insufficiency with the following clinical manifestations:

- Hypotension associated with loss of sodium (hyponatremia) and water
- Hypoglycemia associated with decreased cortisol
- Hyperkalemia associated with decreased aldosterone
- Muscular weakness associated with decreased glucocorticoid and hyperkalemia
- Abdominal pain, nausea, weight loss
- Emotional lability

#### Nursing Diagnoses

- **Fluid volume deficit** associated with sodium and water losses secondary to lack of aldosterone and cortisol
- **Risk for unstable blood glucose level** associated with decreased cortisol secretion from the adrenal cortex
- **Risk for decreased cardiac output** associated with acute adrenal crisis (loss of sodium and water)
- **Body image disturbance** associated with hyperpigmentation secondary to increased secretion of MSH from the anterior pituitary gland

**Table 42.3 Evaluation of the Hypothalamic-Pituitary Axis in Adrenal Insufficiency**

#### Hypothalamic-Pituitary Axis

Test	Procedure	Results
<b>Corticotropin (Cortrosyn) stimulation test</b>	Cortrosyn, a synthetic corticotropin (form of adrenocorticotrophic hormone), 350 mg, is administered intravenously followed by measurement of serum cortisol levels 30 and 60 minutes later.	Cortisol levels of 13–17 mcg/dL are indeterminate. Cortisol levels of less than 13 mcg/dL suggest adrenal insufficiency because Cortrosyn should lead to an increase in cortisol levels. Peak serum cortisol levels greater than 18 mcg/dL exclude the diagnosis of adrenal insufficiency.
<b>Insulin tolerance test</b>	The insulin tolerance test uses hypoglycemic stress to induce cortisol production. The peak serum cortisol response is measured after an insulin challenge of 0.1–0.15 units/kg.  The test requires close monitoring of the patient and is contraindicated in patients with a history of seizures or cardiovascular disease.	A cortisol level of less than 18 mcg/dL and a serum glucose level of less than 40 mg/dL suggest adrenal insufficiency.

## Nursing Interventions

### ■ Assessments

- Vital signs  
*Decreased blood pressure occurs secondary to lack of aldosterone, leading to loss of sodium and water. While blood pressure decreases, there is a compensatory increase in pulse rate. Irregular heart rate may also be associated with hyperkalemia.*
- Monitor intake and output  
*Fluid loss occurs secondary to lack of mineralocorticoid and glucocorticoid, leading to loss of sodium followed by loss of water through the kidneys.*
- Serum sodium, glucose, and potassium  
*Decreased gluconeogenesis occurs because of lack of glucocorticoid. Lack of glucocorticoid and mineralocorticoid leads to loss of sodium and water and retention of potassium.*
- Hematocrit and blood urea nitrogen (BUN)  
*Fluid losses lead to hemoconcentration that may increase hematocrit and serum BUN levels.*
- Serum cortisol levels  
*Random serum cortisol levels of less than 3 mcg/dL or levels of less than 13 mcg/dL with a corticotropin stimulation test suggest adrenal insufficiency.*

### ■ Actions

- Ensure vascular access for administration of IV fluids containing sodium and glucose  
*Loss of water occurs secondary to increased excretion of sodium (direct action of aldosterone). Initiating IV access is complicated with hypovolemia.*
- Administer corticosteroid  
*Definitive treatment of acute adrenal insufficiency (adrenal crisis) is administration of IV cortisone.*
- Maintain safety precautions such as placing the patient's bed in the lowest position and always providing assistance when the patient is getting out of bed  
*Postural hypotension may develop secondary to fluid losses, placing the patient at greater risk of falls.*

### ■ Teaching

- Take oral hormone replacement daily  
*Adrenal cortex replacement is required to maintain fluid balance and normal glucose levels.*
- Wear medical alert bracelet at all times  
*Wearing the medical alert bracelet reduces time to definitive treatment in an emergency situation.*
- Clinical manifestations of adrenal insufficiency  
*It is important that the patient (and family) is able to detect early signs of adrenal insufficiency because it can deteriorate to adrenal crisis, which is a life-threatening emergency.*
- Signs of corticosteroid excess  
*Over-replacement of glucocorticoids results in adverse effects including weight gain and osteoporosis.*

## Evaluating Care Outcomes

Patients with adrenal insufficiency can achieve normal adrenal cortex function with treatment with exogenous

corticosteroids. Positive outcomes include vital signs within normal limits, increased energy, stable weight, and emotional stability. During periods of stress, such as invasive procedures, an increase in exogenous corticosteroids is often necessary. It is important for all healthcare providers to be aware of adrenal insufficiency, particularly when prescribing medications such as sedatives, narcotics, or anesthetic agents. The patient and family should be knowledgeable about the clinical manifestations of adrenal insufficiency and what changes require immediate reporting to the healthcare provider.

### Connection Check 42.3

A patient has been receiving doses of prednisone for treatment of rheumatoid arthritis for the past 3 months. If this medication is suddenly discontinued, for which complication is the patient at risk?

- Hypovolemia
- Hyponatremia
- Hypothermia
- Hyperglycemia

## ADRENAL CORTEX HYPERFUNCTION

### Epidemiology

Adrenal cortex hyperfunction may be secondary to excessive secretion of glucocorticoids (**hypercortisolism**) or excessive secretion of aldosterone (**hyperaldosteronism**). Hypercortisolism is categorized as primary (adrenal cortex disorder), secondary (anterior pituitary gland disorder), or tertiary (hypothalamic etiology). The term *Cushing's* is often used to describe hyperfunction of the adrenal cortex. **Cushing's disease** describes a condition caused by excessive hormone production from an anterior pituitary tumor (70%) producing excessive ACTH or excess hormone secretion from a primary tumor of the adrenal cortex (15%). Approximately 15% of cases of hyperfunction are related to ectopic tumors, usually in the lung, that secrete ACTH. **Cushing's syndrome** is a more broad term and may be used to describe an excess of hormone production (CRH, ACTH, glucocorticoids) or administration of exogenous corticosteroid medications. Despite the etiology, the clinical presentations of hypercortisolism are similar. Females are five times more likely to develop this disorder, and the peak incidence of hypersecreting tumors of the adrenal and pituitary glands is in the 25- to 40-year age range.

Patients may also present with hyperaldosteronism (**Conn's syndrome**). Because the primary actions of aldosterone are sodium and water reabsorption and potassium excretion, hypertension and hypokalemia develop. The incidence of hyperaldosteronism is significantly greater in African Americans than in Caucasians. There is an autosomal dominant pattern of inheritance for primary hyperaldosteronism, with females more at risk than males.

## Pathophysiology

Excessive circulating glucocorticoid (cortisol) is the pathophysiological process associated with primary hypercortisolism. Excessive secretion of ACTH from the anterior pituitary gland leads to hypercortisolism through its effects on the adrenal cortex.

## Clinical Manifestations
