The clinical manifestations of adrenal cortex hyperfunction (Fig. 42.2) are directly related to hypersecretion of these hormones and include hyperglycemia, fluid retention, hypokalemia, abnormal fat distribution, and decreased muscle mass. The maldistribution of fats and changes in muscle are related to the effects that glucocorticoids have on fat and protein metabolism. In female patients, clinical manifestations include **virilization** (male sexual characteristics developing in females), breast atrophy, vocal changes (deepening), and **amenorrhea**. Overproduction of cortisol also affects the immune system by decreasing inflammatory and immune responses. Lymphocytes are also destroyed

secondary to high levels of circulating cortisol, further placing the patient at risk for infection.

Hyperaldosteronism, usually secondary to a hypersecreting tumor of the adrenal cortex, or hyperplasia, results in increased aldosterone production. Secondary to the action of this hormone, sodium and water reabsorption and potassium excretion are increased. Elevated blood pressure is associated with the sodium and water retention, and cardiac irregularities (atrial or ventricular tachyarrhythmias or appearance of U waves) are secondary to hypokalemia.

## Management

### Diagnosis of Hypercortisolism

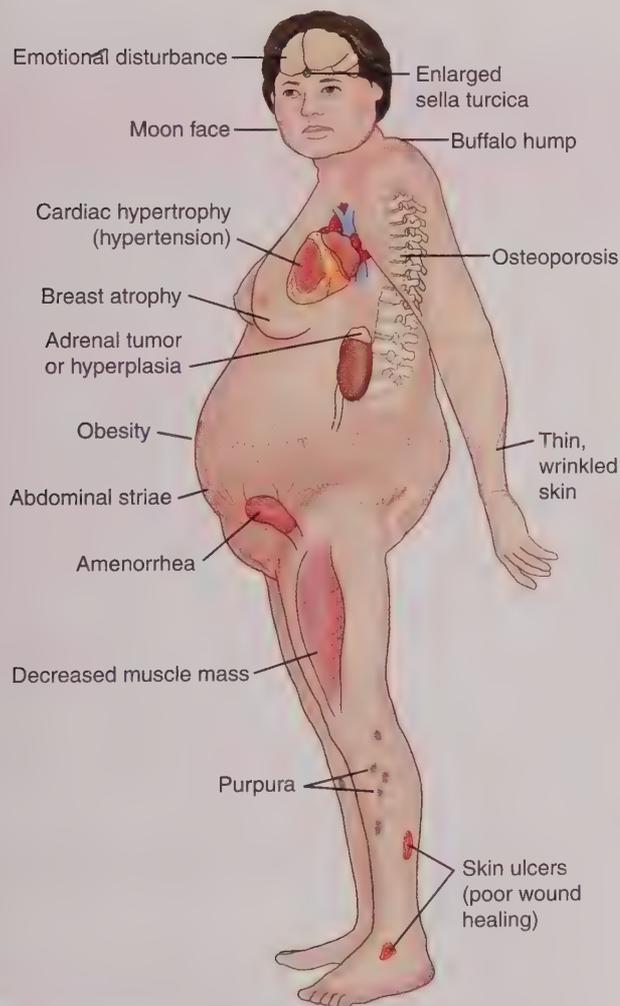

Diagnostic evaluation of hypercortisolism includes assessment of cortisol levels, results of suppression tests, and serum electrolytes (see Table 42.2). Because aldosterone secretion results in both sodium and water reabsorption, there may not be an increase in serum sodium (secondary to water reabsorption); however, the patient does present with hyperglycemia (secondary to glucocorticoid activity) and hypokalemia. Measurement of urinary free cortisol is used as an initial screening tool because it measures urine cortisol during a 24-hour period. The overnight dexamethasone suppression test is another tool to evaluate hypercortisolism, specifically whether the administration of exogenous glucocorticoid (dexamethasone) inhibits the secretion of ACTH that, in turn, decreases stimulation of cortisol release. In this diagnostic study, dexamethasone, 1 mg, is administered at 11 p.m. followed by the collection of a serum cortisol level at 8 a.m. the next morning. The results are based on whether suppression of cortisol secretion occurs secondary to the administration of exogenous glucocorticoid. If the morning level is less than 2 to 3 mg/dL, normal functioning of the hypothalamic-pituitary-adrenal axis is determined. The ACTH level can also be measured, and changes may be secondary to changes in the secretion of CRH from the hypothalamus.

### Medical Management of Hypercortisolism

Medical management of hypercortisolism focuses on preventing complications associated with fluid overload, changes in immune status, changes in skin integrity, and changes in body structure. Medications that interfere with ACTH and glucocorticoid production are used in the treatment of hypercortisolism. Aminoglutethimide is an example of a medication that interferes with cortisol production in the adrenal cortex, and cyproheptadine impacts ACTH production. With both types of medications, the nurse must monitor for signs of adrenal suppression including hypoglycemia and hyponatremia. Pasireotide (Signifor), a subcutaneous somatostatin analog, is a medication used to inhibit release of corticotropin in patients with Cushing's disease secondary to a pituitary adenoma.

### Surgical Management of Hypercortisolism

Surgical management of hypercortisolism is based on the etiology of the disorder. If the etiology is a pituitary tumor, a transsphenoidal hypophysectomy (discussed in Chapter 41)

**FIGURE 42.2** Clinical manifestations of hypercortisolism.

is performed. With hypersecreting tumors of the adrenal cortex, an **adrenalectomy** (removal of the adrenal gland) may be indicated (presented later in this chapter). Radiation therapy, including stereotactic radiosurgery of the pituitary gland, may also be used in the management of tumors of the pituitary gland (see Evidence-Based Practice).

## Evidence-Based Practice

### Stereotactic Radiosurgery for Cushing's Disease

Cushing's disease (CD) caused by adrenocorticotropic hormone-secreting pituitary tumors may be treated with stereotactic radiosurgery (SRS). This international, multicenter study examined the control of hypercortisolism (defined as normalization of free urinary cortisol). The cumulative initial control of hypercortisolism was 80% at 10 years, with a 14.5 month mean time to cortisol normalization. The overall rate of hypercortisolism control was 64% in 10 years. The findings of this study support SRS for CD because it frequently controls hypercortisolism but recommend long-term endocrine follow-up after SRS because recurrences can occur.

Mehta, G.U., Ding, D., Patibandia, M.R., Kano, H., Sisterson, N., Su, Y.H., ... Liscak, R. (2017). Stereotactic radiosurgery for Cushing disease: results of an international, multicenter study. *Journal of Clinical Endocrinology & Metabolism*, 102(11), 4284–4291.

### Diagnosis of Hyperaldosteronism

Hyperaldosteronism is diagnosed through evaluation of serum electrolytes as well as imaging studies. Elevated serum aldosterone levels as well as hypokalemia and hypernatremia are observed. Because hyperaldosteronism is usually secondary to hypersecreting tumors or hyperplasia, CT, or MRI may demonstrate enlargement or changes of the adrenal cortex.

### Medical Management of Hyperaldosteronism

Management aims focus on controlling hypertension, managing hypokalemia, and determining the etiology of hyperaldosteronism. Hypertension is treated with spironolactone (Aldactone), a potassium-sparing diuretic. The patient's potassium and sodium levels are measured closely while on this medication. Potassium supplementation may also be required in treating hyperaldosteronism because loss of potassium is caused by elevated aldosterone.

### Surgical Management of Hyperaldosteronism

Surgical management includes an adrenalectomy to remove hypersecreting tumors of the adrenal cortex.

## Complications

### Complications of Hypercortisolism

Patients with hypercortisolism are at risk for complications associated with excessive cortisol levels. Osteoporosis may develop relative to the effects of cortisol on bone density and can increase the risk of pathological fractures. In patients with hypercortisolism secondary to exogenous corticosteroid therapy, acute adrenal crisis may result with the abrupt withdrawal of this medication. Elevated serum glucose may complicate the management of diabetes mellitus in patients with this disorder. Gastrointestinal bleeding may develop as a result of decreased mucus production in the gastrointestinal tract, decreased blood flow, and release of hydrochloric acid secondary to the effects of cortisol.

**Safety Alert** Patients receiving exogenous cortico-steroids (for their inflammatory actions) are often prescribed medications that serve as gastrointestinal prophylaxis. Because of the effects of corticosteroids on the gastrointestinal tract, the patient must be assessed for complaints of gastrointestinal distress and gastrointestinal bleeding.

### Complications of Hyperaldosteronism

Complications of hyperaldosteronism are primarily related to hypertension and severe hypokalemia. Untreated hypertension leads to damage to other organs including the heart, vasculature, kidneys, and eyes. Additionally, uncontrolled high blood pressure increases the risk for acute myocardial infarction and acute stroke (cerebrovascular accident). Cardiac dysrhythmias are associated with severe hypokalemia.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations observed in the patient with adrenal cortex hyperfunction are directly related to elevated circulating levels of cortisol or aldosterone. Common findings in patients with hypercortisolism include:

- Hypertension
- Hyperglycemia
- Dependent edema
- Thin, friable skin
- Fat maldistribution (truncal obesity, “moon face,” and “buffalo hump”) (Fig. 42.2)
- Loss of bone density
- Decreased inflammatory process
- Increased risk of infection

Patients with hyperaldosteronism present with the following manifestations:

- Hypertension
- Hypernatremia
- Hypokalemia
- Headache

## Nursing Diagnoses

### Hypercortisolism:

- **Fluid volume excess** associated with increased sodium and water reabsorption secondary to excess glucocorticoid secretion
- **Body image disturbance** associated with development of truncal obesity and fat deposition secondary to excess glucocorticoid secretion
- **Risk for infection** associated with immunosuppression
- **Deficient knowledge** associated with diagnosis of hypercortisolism

### Hyperaldosteronism:

- **Fluid volume excess** associated with increased sodium and water reabsorption secondary to excess aldosterone secretion
- **Risk for decreased cardiac output** associated with cardiac dysrhythmias secondary to hypokalemia
- **Deficient knowledge** associated with management of hyperaldosteronism

## Nursing Interventions

### Assessments

- Vital signs  
*Suppressed immune function secondary to hypercortisolism increases the risk of infection. Small increases in body temperature may be significant, and signs of infection may be masked because of immune suppression. Blood pressure and heart rate may increase secondary to fluid retention.*
- Intake and output  
*Monitoring is important to evaluate trends once treatment has been started. Urine output should increase and signs of fluid overload should decrease if treatment is effective.*
- Serum glucose, potassium  
*Glucose levels rise secondary to increased secretion of glucocorticoid. Potassium levels also fall secondary to increased excretion via the kidneys secondary to glucocorticoid and mineralocorticoid activity.*
- Daily weight  
*Weight gain occurs secondary to fluid retention secondary to sodium and water reabsorption. Peripheral edema may develop.*
- Skin  
*Thinning skin and increased friability develop secondary to excess cortisol.*
- Fat distribution  
*Actions of glucocorticoid affect fat metabolism, leading to maldistribution of fat including truncal obesity, moon face, and buffalo hump.*
- Muscle mass  
*Muscle atrophy develops secondary to altered protein metabolism.*
- Wound healing  
*Delayed wound healing occurs associated with the suppressed inflammatory response.*

### Actions

- Administer medications that interfere with production/secretion of cortisol  
*Decreases secretion of cortisol*
- Head of bed elevated 45 degrees  
*Decreases work of breathing that may develop secondary to fluid retention*
- Turn patient frequently and protect skin from injury  
*Thinning of skin along with increased friability of skin accompanied by fluid retention increase the chances of skin injury caused by pressure or friction.*

### Teaching

- Overview of disease process  
*It is important that the patient (and family) is able to detect early signs of both hypercortisolism and adrenal insufficiency.*
- Importance of taking prescribed medications  
*Medications that interfere with cortisol production are key to disease management.*
- Modify salt in diet as directed by provider  
*Excessive salt intake may further exacerbate fluid retention.*

## Connection Check 42.4

The nurse monitors for which effects of daily cortisol therapy on a patient's circulating levels of adrenocorticotropic hormone (ACTH) and aldosterone?

- Decreased ACTH, decreased aldosterone
- Decreased ACTH, increased aldosterone
- Increased ACTH, decreased aldosterone
- Increased ACTH, increased aldosterone

## Evaluating Care Outcomes

Patients with hypercortisolism are usually best managed once the etiology of the disorder is determined. If the etiology is a hypersecreting tumor of the pituitary gland or adrenal cortex, surgical intervention (transsphenoidal hypophysectomy, adrenalectomy, or stereotactic radiosurgery) is indicated. The patient should be closely monitored postoperatively and may require lifelong corticosteroid replacement on the basis of the surgical outcome. Stable vital signs and fluid volume status, serum electrolytes within normal limits, and intact skin are expected outcomes with treatment of hyperfunction of the adrenal cortex.

## CASE STUDY: EPISODE 2

Ms. Davis is seen by her nurse practitioner about her complaints of inability to conceive and changes in menstrual cycles. During the history, she reports increased swelling of her hands and feet and is unable to wear her wedding ring. Additionally, she has gained approximately 8 pounds in the last month. She complains of increasing fatigue and has noticed that she seems to

bruise “just by bumping into things.” Her blood pressure is higher than previous measurements. On the basis of these findings, the nurse practitioner orders a complete metabolic panel, abdominal x-rays, cortisol levels, and a dexamethasone suppression test...

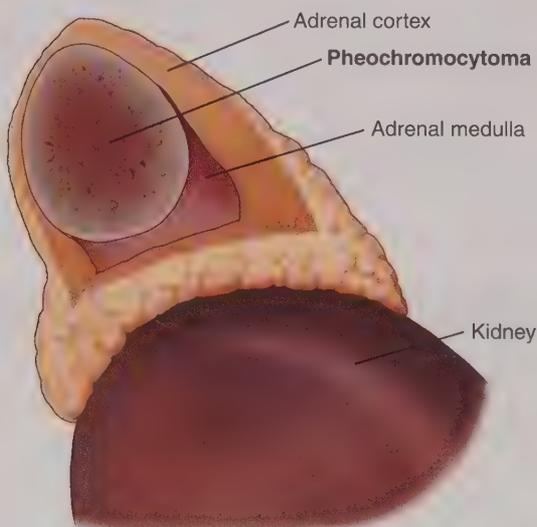

## PHEOCHROMOCYTOMA

### Epidemiology

**Pheochromocytomas** are rare catecholamine-secreting tumors of the adrenal medulla and, in 50% of cases, are diagnosed only on autopsy. Because of excessive **catecholamine** (epinephrine and norepinephrine) secretion, pheochromocytomas may precipitate life-threatening hypertension or cardiac arrhythmias, leading to sudden death. Occurring in all races, the incidence is higher in Caucasians. In relation to age, the peak incidence is in people 30 to 50 years of age. It is estimated that 25% of pheochromocytomas are familial and specific gene mutations. There are approximately 1,000 cases of pheochromocytoma diagnosed in the United States annually.

### Pathophysiology

Pheochromocytomas are catecholamine-secreting tumors of the adrenal medulla and are usually unilateral (Fig. 42.3). The release of the epinephrine and norepinephrine is typically paradoxical, rather than continuous, and leads to vasoconstriction, increased heart rate, increased stroke volume leading to a rise in systolic blood pressure and a widening of pulse pressure. Catecholamine release also stimulates gluconeogenesis, resulting in hyperglycemia.

**FIGURE 42.3** Pheochromocytoma.

### Clinical Manifestations

Clinical manifestations of this disorder are associated with the systematic actions of epinephrine and norepinephrine and include tachycardia, hypertension, severe headaches, palpitations, hyperhidrosis (excessive sweating), hypermetabolism, and hyperglycemia. The severity of attacks correlates to the amount of catecholamine release. Paroxysmal (sudden-onset) hypertension is seen in some patients, with blood pressure elevations in excess of 250/140 mm Hg, posing a life-threatening emergency.

### Management

#### Medical Management

#### Diagnosis

The classic presentation of pheochromocytoma is marked by a sudden elevation of blood pressure accompanied by other clinical manifestations of catecholamine excess. This clinical presentation, along with specific diagnostic studies, assists in making a definitive diagnosis. Diagnostic assessments for this disorder include measurements of urine and plasma levels of **catecholamines** and catecholamine metabolites as well as imaging studies.

Direct measurements of plasma catecholamines require specific patient preparation to prevent elevations of circulating catecholamines. The patient is placed supine and rests for 30 minutes prior to the test. Additionally, small IV catheters are placed approximately 30 minutes prior to the actual collection of the blood samples. Catecholamine metabolites such as metanephrine and vanillylmandelic acid (VMA) and free catecholamines are also measured in urine. These tests require 24-hour urine collections. Preparation for these tests requires the patient to avoid specific foods, **beverages**, and medications prior to and during the urine collection. The patient is instructed to avoid bananas, chocolate, vanilla, and tea or coffee (including decaffeinated varieties) because these are high in amines and can lead to a false elevation of VMA.

Imaging studies, including CT or MRI scans, are also indicated in the diagnostic work-up for pheochromocytomas. Data from these studies determine whether tumors are unilateral or bilateral. Additionally, imaging data are very important in guiding the surgeon performing the adrenalectomy.

#### Medications and Monitoring

Patients presenting with signs of hypertension, tachycardia, and other clinical manifestations of pheochromocytoma require bedrest with the head of the bed elevated, usually in a critical care setting. The patient is placed on a cardiac monitor to assess for cardiac dysrhythmias. Pharmacological management focuses on quickly lowering the blood pressure and includes alpha-adrenergic blocking agents or smooth muscle relaxants. Other medications that may be administered include beta-adrenergic blocking agents and calcium channel blockers to decrease blood pressure and heart rate.

## Surgical Management

Adrenalectomy is the definitive treatment for pheochromocytoma, and the goals include complete tumor resection, minimal tumor manipulation, and adequate exposure of the adrenal gland to avoid injury to other organs. There are several approaches for adrenalectomy, including open anterior transabdominal, open thoracoabdominal, open posterior or lateral retroperitoneal, lateral transabdominal laparoscopic, and posterior retroperitoneal laparoscopic approaches.

Traditionally, the standard approach in patients with pheochromocytoma was an open transabdominal anterior approach through a bilateral subcostal incision as it provides complete exposure of the abdominal cavity. However, in more recent studies, the laparoscopic approach has demonstrated good outcomes, particularly in medical centers with surgeons and operative teams with significant experience in this approach.

Patient preparation focuses on control of blood pressure and heart rate. Treatment with alpha-adrenergic blockers is started 7 to 10 days prior to the scheduled operative procedure with a goal blood pressure of 120/80 mm Hg or lower in a seated position. A beta blocker may be used to control heart rate but only after blood pressure is lowered. Fluid management is also important during the preoperative phase because of vasodilation secondary to the alpha-adrenergic blockers. During the surgical procedure, the patient is at risk of hypertensive crisis because the vascular pheochromocytoma is manipulated and removed. In the event of an intraoperative hypertensive episode, sodium nitroprusside (Nipride) or alpha-adrenergic blockers are cautiously administered.

Postoperative management of adrenalectomy focuses on monitoring blood pressure, heart rate, and blood glucose levels. Because of the sudden decrease in circulating catecholamines as a result of tumor removal, the patient may develop hypotension or hypoglycemia postoperatively. The patient is also monitored for blood loss due to the vascular nature of the adrenal gland. Several days postoperatively, plasma and urine samples are collected for measurement of catecholamine levels and catecholamine metabolites.

Patients with bilateral pheochromocytomas require bilateral adrenalectomy, and this necessitates lifelong adrenal cortex hormone replacements. These patients are required to take cortisol daily and may require additional doses during episodes of physiological or emotional stress. Patients who undergo bilateral adrenalectomy are at risk for adrenal insufficiency for the remainder of their lives. (Catecholamines from the adrenal medulla do not require replacement because they are also produced in the sympathetic nervous system).

## Nursing Management

### Assessment and Analysis

The clinical presentation of pheochromocytoma is directly related to the effects of increased levels of circulating epinephrine and norepinephrine:

- Hypertension (often paroxysmal attacks)
- Tachycardia

- Hyperglycemia
- Pounding headaches

### Nursing Diagnoses

- **Risk for injury:** Cerebrovascular hemorrhage related to severe hypertension
- **Acute pain:** Headache related to increased levels of circulating catecholamines secondary to the hyper-secreting tumor (pheochromocytoma)
- **Risk for injury:** Postoperative hemorrhage related to adrenalectomy

### Nursing Interventions

#### ▣ Assessments

- Vital signs  
*Hypertension and tachycardia develop secondary to excessive circulating catecholamines from pheochromocytoma. In the patient who undergoes adrenalectomy, the patient may develop signs of hypovolemia and shock secondary to hemorrhage.*
- Cardiac monitoring  
*The patient is at risk of tachydysrhythmias secondary to elevated catecholamines.*
- Headache  
*Pounding headaches develop secondary to hypertension.*
- Plasma catecholamine levels  
*Increased secretion of catecholamines from the tumor leads to elevated free plasma levels.*
- Plasma and catecholamine metabolite measurements (VMA)  
*Elevated levels of catecholamines result in increased levels of catecholamine metabolites.*

#### ▣ Actions

- Administer sodium nitroprusside (Nipride)  
*Quickly decreases blood pressure through direct action on blood vessels, leading to peripheral vasodilation*
- Administer alpha-adrenergic blocking agents  
*This decreases blood pressure by blocking the alpha-adrenergic effects on blood vessels that lead to vasoconstriction. The blocking action results in vasodilation.*
- Administer beta-adrenergic blocking agents  
*Beta-adrenergic agents lead to increased chronotropic (rate) and inotropic (force) effects on the heart. Beta-adrenergic blocking agents decrease the heart rate and force of contraction.*
- Bed rest with head of bed elevated  
*Bed rest decreases secretion of catecholamines and elevating the head of the bed facilitates orthostatic hypotension.*
- Maintain calm, quiet environment  
*Because of increased circulating levels of catecholamines, it is important to minimize stimuli that could potentially cause stress and additional catecholamine secretion.*
- Administer glucocorticoid the morning of surgery for adrenalectomy  
*Minimizes the risk of adrenal insufficiency postoperatively caused by the surgical manipulation of the adrenal glands, particularly in the patient undergoing bilateral adrenalectomy.*

### ■ Teaching

- Clinical manifestations of adrenal insufficiency  
*In patients with bilateral adrenalectomy, lifelong cortisol replacement is required. The patient is at risk of adrenal insufficiency, especially during times of physiological or emotional stress.*
- Postoperative teaching related to adrenalectomy  
*The patient should monitor body temperature as well as surgical site for signs of infection.*

### Evaluating Care Outcomes

Definitive treatment of pheochromocytoma with adrenalectomy results in complete resolution of this disease process. Because there is the possibility of incomplete resection of the pheochromocytoma or recurrence in patients with a family history of this disorder, patients need to have periodic checks of their blood pressure. Only patients with bilateral tumors requiring bilateral adrenalectomy require lifelong cortisol replacement.

### Connection Check 42.5

Which assessment maneuver is contraindicated in the patient suspected of having a pheochromocytoma?

- Having the patient attempt to touch the chin to the chest
- Inflating the blood pressure cuff above 200 mm Hg
- Attempting to dorsiflex the feet
- Palpating the abdomen

- The nurse assesses for which clinical manifestations in the patient admitted with primary hypercortisolism? (*Select all that apply.*)
  - Elevated serum glucose
  - Elevated serum potassium
  - Elevated urine-specific gravity
  - Elevated blood pressure
  - Elevated temperature
- Which of the following patients is at greatest risk for primary hypercortisolism?
  - A 65-year-old male
  - A 56-year-old female
  - A 44-year-old male
  - A 28-year-old female
- The nurse questions which intervention in the patient diagnosed with hypercortisolism?
  - Limit salt intake
  - Limit foods containing potassium
  - Increase weight-bearing exercises
  - Avoid use of skin tape
- The nurse monitors for which complication in Ms. Davis secondary to her hypercortisolism?
  - Osteoporosis
  - Hypoglycemia
  - Muscle loss
  - Hyperkalemia

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Davis returns to the nurse practitioner the following week to review the results of her diagnostic evaluation. Her serum glucose level is 154 mg/dL, and her potassium level is 3.0 mEq/L. Her blood pressure remains elevated, and she has gained another pound in the last week. The abdominal x-rays are suggestive of a mass on the right adrenal gland, and a follow-up CT scan of the abdomen demonstrates a mass on the right adrenal gland. On the basis of this finding and the abnormal results of the dexamethasone suppression test, Ms. Davis is diagnosed with primary hypercortisolism secondary to a hypersecreting tumor and undergoes a right adrenalectomy.

#### Case Study Questions

- The nurse correlates primary hypercortisolism to dysfunction of which gland?
  - Hypothalamus
  - Anterior pituitary gland
  - Adrenal cortex
  - Adrenal medulla

## CHAPTER SUMMARY

The adrenal glands are composed of a cortex and a medulla that secrete hormones with distinct functions. Disorders of the adrenal cortex may be primary (adrenal cortex), secondary (anterior pituitary gland), or tertiary (hypothalamus) as well as related to hyposecretion or hypersecretion. Adrenal insufficiency is a life-threatening disorder associated with decreased secretion of glucocorticoids and mineralocorticoids, resulting in sodium and water loss, potassium retention, hypoglycemia, muscle loss, weakness, and weight loss. Acute adrenal crisis is a life-threatening disorder that requires emergent hormone (glucocorticoid) replacement.

Hyperfunction of the adrenal cortex may present as excess glucocorticoid secretion (hypercortisolism) or excess mineralocorticoid secretion (hyperaldosteronism). Patients with hypercortisolism present with hyperglycemia, hypokalemia, fluid retention, thinning of the skin, fat maldistribution, increased protein metabolism, and suppressed inflammatory and immune responses. Hyperaldosteronism is characterized by increased sodium and water retention,

leading to elevated blood pressure and heart rate as well as hypokalemia.

Pheochromocytomas are catecholamine-secreting tumors of the adrenal medulla leading to profound hypertension, hyperglycemia, and other signs of excess catecholamines.

Blood pressure management is essential to prevent damage to the heart, brain, kidneys, and eyes. Treatment usually involves unilateral adrenalectomy. Postoperatively, the patient must be monitored closely for hemorrhage and hypovolemic shock.

# Chapter 43

## Coordinating Care for Patients With Thyroid and Parathyroid Disorders

*Janice Hoffman*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of thyroid and parathyroid disorders
2. Correlating clinical manifestations to the pathophysiological processes of:
  - a. Hypothyroidism
  - b. Hyperthyroidism
  - c. Hypoparathyroidism
  - d. Hyperparathyroidism
3. Describing the diagnostic results used to confirm the diagnoses of thyroid and parathyroid disorders
4. Discussing the medical management of:
  - a. Hypothyroidism
  - b. Hyperthyroidism
  - c. Hypoparathyroidism
  - d. Hyperparathyroidism
5. Developing a comprehensive plan of nursing care for patients with thyroid and parathyroid disorders
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with thyroid and parathyroid disorders
7. Coordinating the interprofessional plan of care for the patient undergoing treatment for thyroid cancer

### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Medication
- Metabolism
- Nutrition
- Perioperative

### ESSENTIAL TERMS

Euthyroid  
Exophthalmos  
Glycosaminoglycans  
Goiter  
Graves' disease  
Hashimoto's thyroiditis  
Myxedema  
Myxedema coma  
Osteoclastic  
Tetany  
Thyrocalcitonin  
Thyroid storm  
Thyrotoxicosis  
Thyroxine  
Triiodothyronine

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Patricia Matthews is a 28-year-old administrative assistant who presents to her family nurse practitioner (FNP) with complaints of weight loss despite “eating all the time,” restlessness, insomnia, and changes in her menstrual cycle. On the basis of these findings, the FNP orders diagnostic evaluation of thyroid function and female reproductive hormones...

## INTRODUCTION

The thyroid and parathyroid glands are integral to normal body functions. Metabolic activity and rate are primarily under the control of two hormones released from the thyroid glands, **triiodothyronine (T3)** and **thyroxine (T4)**. The release of thyroid hormone is under the control of the anterior pituitary gland (secretion of thyroid-stimulating hormone [TSH]) and the hypothalamus (thyroid-releasing hormone or thyrotropin-releasing hormone [TRH]). Disorders affecting either of these structures can result in hypothyroidism or hyperthyroidism. Serum calcium levels are controlled through the release of **thyrocalcitonin** from the thyroid glands and parathyroid hormone (parathormone [PTH]) from the parathyroid glands (Table 43.1). See

Chapter 40 for an overview of the structure, function, and analyses of thyroid and parathyroid glands and hormones. Table 43.2 provides an overview of laboratory tests used to diagnose thyroid disorders.

## HYPOTHYROIDISM

### Epidemiology

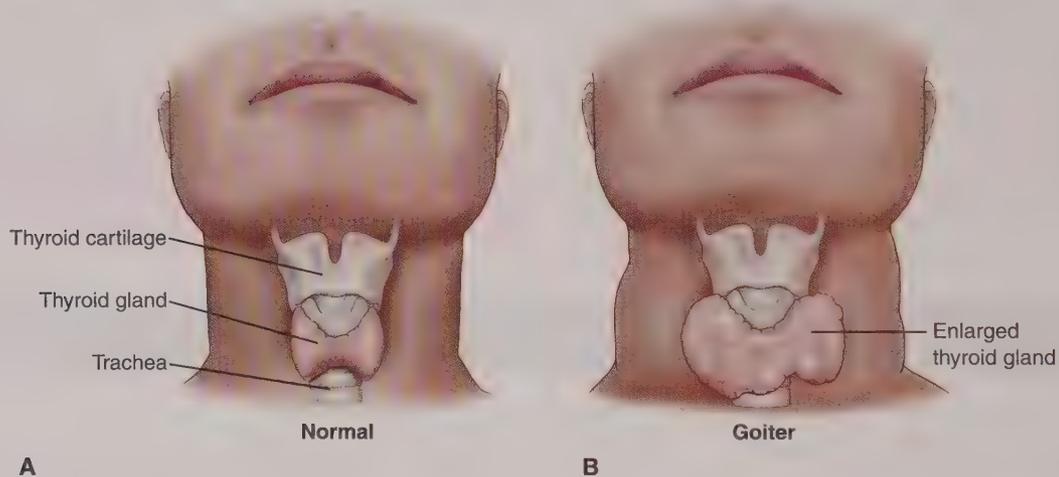

The release of thyroid hormone is under the control of the anterior pituitary gland (secretion of TSH) and the hypothalamus (TRH). Disorders affecting either of these structures can result in hypothyroidism. In the United States, hypothyroidism is largely associated with autoimmune disease, thyroid surgery, or radioactive iodine therapy used in the treatment of hyperthyroidism. **Hashimoto's thyroiditis** is the most common type of hypothyroidism and is caused by an autoimmune response that leads to destruction of the thyroid gland by immunological processes. Hypothyroidism can also be associated with iodine and tyrosine deficiencies because they are needed for the synthesis of thyroid hormone, but they are rarely observed in the United States because of the use of iodized salt. Other causes of primary hypothyroidism include congenital thyroid disorders, autoimmune thyroid destruction, and thyroid cancer. Hypothyroidism is a major cause of **goiter** (enlargement of the thyroid gland; Fig. 43.1) and develops secondary to thyroid gland hypertrophy in an attempt to produce normal amounts of T3 and T4. Women are affected 7 to 10 times more often than men. Hypothyroidism occurs most often in women between the ages of 30 and 60, and the incidence increases with age.

**Table 43.1 Overview of Thyroid and Parathyroid Hormones**

Gland	Hormone Secreted	Target	Action
<b>Hypothalamus</b>	Thyrotropin-releasing hormone (TRH)	Anterior pituitary gland	Stimulates release of thyroid-stimulating hormone (TSH)
<b>Anterior pituitary</b>	TSH	Thyroid glands	Increases secretion of thyroid hormones (triiodothyronine [T3] and thyroxine [T4])
<b>Thyroid gland</b>	T3	Cells of the body	Increases metabolic rate
	T4		Increases response to catecholamines
	Thyrocalcitonin (calcitonin)	Bones	Decreases osteoclastic (breakdown of bone)
		Kidneys	Decreases reabsorption of calcium in renal tubules
		Intestines	Decreases reabsorption of calcium in the intestines
<b>Parathyroid gland</b>	Parathyroid hormone (PTH)	Bones	Increases osteoclastic (bone breakdown) activity
		Kidney	Increases renal tubule reabsorption of calcium
		Intestines	Increases gastrointestinal reabsorption of calcium (vitamin D required)

**Table 43.2 Laboratory Tests for Thyroid Disorders**

Test	Normal Range for Adults	Significance
<b>Free T3 (triiodothyronine)</b>	2.6–4.8 pg/mL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Total T3 (triiodothyronine)</b>	70–204 ng/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Free T4 (thyroxine)</b>	0.8–1.5 ng/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>Total T4 (thyroxine)</b>	4.6–12 mcg/dL	Decreased in hypothyroidism Increased in hyperthyroidism
<b>TSH (thyroid-stimulating hormone)</b>	0.4–4.2 microinternational units/mL	Increased in primary hypothyroidism Decreased in secondary or tertiary hypothyroidism Decreased in primary hyperthyroidism Increased in secondary and tertiary hyperthyroidism

**FIGURE 43.1** A. Normal thyroid gland B. Goiter (hyperplasia of the thyroid gland)

### Connection Check 43.1

The nurse recognizes that which patient is at greatest risk for hypothyroidism?

- A. A 19-year-old male
- B. A 35-year-old female
- C. A 45-year-old male
- D. An 80-year-old female

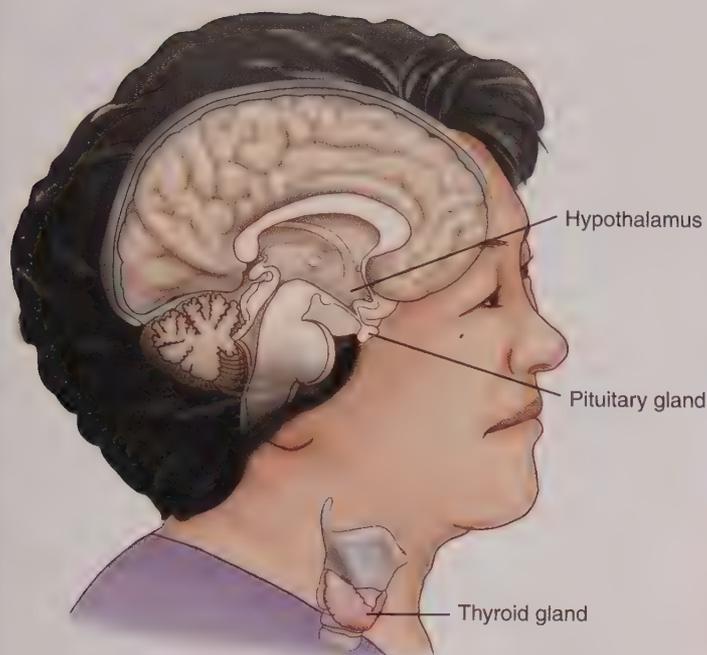

### Pathophysiology

Decreased metabolism is the hallmark of hypothyroidism and affects most body systems. Primary hypothyroidism develops as a result of a disorder of the thyroid gland itself,

whereas secondary hypothyroidism is caused by a disorder of the anterior pituitary gland (Fig. 43.2). Tertiary hypothyroidism is associated with a lack of TRH from the hypothalamus.

### Clinical Manifestations

The hypometabolic state is characterized by decreased energy, increased sleep, fatigue, weight gain, decreased appetite, and susceptibility to cold temperatures. Patients with hypothyroidism may develop **myxedema**, a condition resulting from an increased deposition of **glycosaminoglycans** (a type of polysaccharide) in cells and tissues (Fig. 43.3). The increased deposition of glycosaminoglycans causes an osmotic edema and a fluid collection that is associated with

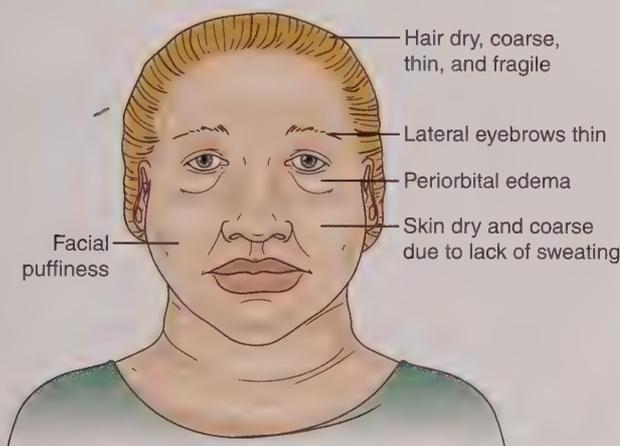

**Tertiary:**  
due to a disorder of  
the hypothalamus

**Secondary:**  
due to a disorder of the  
anterior pituitary gland

**Primary:**  
due to a disorder of the  
thyroid gland itself

**FIGURE 43.2** Primary, secondary, and tertiary hypothyroidism.

**FIGURE 43.3** Myxedema, related to hypothyroidism.

a generalized nonpitting edema. Cardiac alterations secondary to myxedematous changes include decreased contractility, cardiac enlargement, pericardial effusion, decreased pulse, and decreased cardiac output. Decreased gastrointestinal activity results in constipation and abdominal distention. Skin changes may result over time secondary to cold intolerance, and a lack of sweating may leave the skin dry and coarse. Hair becomes thin and fragile, and hair loss occurs.

## Management

### Medical Management

#### Diagnosis

The diagnosis of hypothyroidism is confirmed through analysis of laboratory data, including T<sub>3</sub>, T<sub>4</sub>, and TSH. If the etiology is primary hypothyroidism, the TSH level is

elevated as a result of the feedback system to the hypothalamus and anterior pituitary gland caused by low circulating levels of thyroid hormones (T<sub>3</sub> and T<sub>4</sub>). In secondary or tertiary hypothyroidism, the TSH may be high or near normal because the disorder is a result of pathophysiology in the anterior pituitary gland or hypothalamus, respectively. When Hashimoto's thyroiditis is suspected, an evaluation of antithyroid antibodies should be performed.

#### Medications

Replacement of thyroid hormone is the primary treatment for hypothyroidism. The most commonly prescribed medication is levothyroxine (Synthroid). The medication is started at a low dose and increased as needed to treat symptoms of hypothyroidism. Because thyroid hormone affects metabolism, the medication is to be taken in the morning. This replacement therapy is a lifelong regimen, and it is important for the patient to take the medication at the same time every day. Additionally, it is important for the patient to inform all healthcare providers of his or her history of hypothyroidism and the dosage of hormone replacement (see Evidence-Based Practice).

## Evidence-Based Practice

### Levothyroxine as Primary Treatment for Hypothyroidism

A Medline search was conducted related to the historical evolution and use of levothyroxine as the treatment for hypothyroidism. Although this medication has been used for the treatment of hypothyroidism for over 130 years, this literature confirmed the documented effectiveness and

safety of the medication. The studies described refinements in hormone preparation, pharmaceutical production, and regulation of this medication that have contributed to its continued use. According to this study, levothyroxine monotherapy is described in recent guidelines of all major endocrine societies as the first line of treatment for hypothyroidism.

Hennessey, J.V. (2017). The emergence of levothyroxine as a treatment for hypothyroidism. *Endocrine*, 55(1), 6–18.

**Safety Alert** In patients with a history of cardiovascular disease, the increases in dosage of levothyroxine are made cautiously because sudden increases in cardiac rate and contractility secondary to the medication may lead to angina or congestive heart failure.

## Complications

The most severe type of hypothyroidism is termed **myxedema coma** and is characterized by hypoxia and carbon dioxide retention (secondary to hypoventilation), fluid and electrolyte imbalances, and hypothermia. Because of significant decreases in cardiac function, the patient is bradycardic and hypotensive. Additionally, hypoglycemia and hyponatremia develop. Along with significant hypothermia during times of myxedema crises, these patients are particularly sensitive to sedatives, analgesics, and anesthetic agents because metabolism of these medications is significantly slowed, leading to accumulation in the body. Definitive treatment is aimed at replacing thyroid hormone and supportive measures.

**Safety Alert** Patients with hypothyroidism who are receiving sedatives, hypnotics, or narcotics require close observation because the metabolism of the medication is slower, and respiratory compromise may occur with normal dosages. The dose, as well as the interval between doses, may need to be adjusted in the patient with severe hypothyroidism.

## Nursing Management

### Assessment and Analysis

Many of the clinical manifestations observed in the patient with hypothyroidism are directly related to the decreased metabolic rate of most body tissues. Common findings include:

- Bradycardia
- Decreased respiratory rate

- Hypothermia
- Weight gain despite decreased caloric intake
- Elevated serum cholesterol secondary to decreased liver metabolism
- Increased sleeping
- Weakness and muscle aches
- Anorexia
- Constipation
- Cold intolerance
- Decrease in libido

Other clinical manifestations not directly linked to decreased metabolism include the development of goiter or generalized edema. Because of decreased levels of thyroid hormone, TSH from the anterior pituitary gland may cause hyperplasia of the thyroid gland leading to goiter. While cellular metabolism decreases, energy is decreased, and metabolites such as proteins and sugars accumulate inside cells. While these metabolites build up inside the cell, myxedema develops and is characterized by generalized nonpitting edema, particularly in the hands, in the feet, between the shoulder blades, and around the eyes. Edema of the tongue and around the larynx results in changes in speech resulting in a husky tone.

### Nursing Diagnoses

- **Decreased cardiac output** linked to decreased heart rate and decreased contractility secondary to impaired cardiac metabolism
- **Altered nutrition greater than body requirements** linked to decreased cellular metabolism secondary to decreased thyroid hormone activity
- **Fluid volume excess** linked to accumulation of mucinous edema secondary to altered cellular metabolism

### Nursing Interventions

#### Assessments

- Oxygen saturation  
*Severe hypothyroidism may impair respiratory function, leading to decreased ventilation, which results in lower oxygen saturation.*
- Vital signs  
*Decreased body temperature, heart rate, respiratory rate, and blood pressure are secondary to the hypometabolic state caused by thyroid hormone deficit.*
- Serum calcium levels  
*In patients with hypothyroidism secondary to surgical resection/removal of the thyroid gland, damage or removal of parathyroid tissue may lead to decreased serum calcium levels.*
- Daily weight  
*Decreased cellular metabolism may result in weight gain.*
- Skin texture, color, and turgor  
*Skin changes are associated with decreased sweating and oil production and are secondary to a hypometabolic state. With severe hypothyroidism, myxedema may develop linked to deposition of metabolites under the skin.*

- Bowel elimination

*Patient is at increased risk of constipation secondary to decreased gastrointestinal motility.*

### ■ Actions

- Administer thyroid replacement therapy at the same time every day  
*Lifelong thyroid hormone replacement is required in patients with hypothyroidism to increase metabolic activities of most body systems. To mimic the normal circadian rhythm, Synthroid is administered in the morning.*
- Administer narcotics and sedatives with caution  
*Because of decreased metabolism on medication, secondary to hypothyroidism, the patient must be monitored closely for signs of overmedication such as decreased respiratory rate or difficulty arousing the patient after medication administration.*
- Provide warming blankets as needed  
*Decreased metabolism results in decreased energy production and cold intolerance. Patients should avoid warming too quickly because it can result in vasodilation and hypotension.*
- Turn patient and reposition to promote skin integrity  
*Because of myxedema, the skin integrity is altered requiring special actions to prevent pressure.*

### ■ Teaching

- Immediately report chest pain or chest discomfort  
*Cardiovascular disease may develop in patients with hypothyroidism. Because of the decreased metabolism of cholesterol, patients with hypothyroidism are at greater risk of elevated cholesterol levels.*
- Take thyroid replacement hormones as prescribed; must be taken daily  
*Thyroid hormone replacement is required for metabolic activities. Increasing the dose of medication without prescriber input may lead to accelerated cardiovascular function that the heart is unprepared to tolerate because of the long-term effects of hypothyroidism.*
- Signs of hypothyroidism and hyperthyroidism  
*It is important that the patient (and family) are able to detect early signs of both hypothyroidism (the underlying disorder that could progress to myxedema) and hyperthyroidism (secondary to thyroid hormone supplementation).*

### Evaluating Care Outcomes

Patients with hypothyroidism can achieve normal thyroid function by complying with the prescribed therapy. Vital signs within normal limits, increased energy, stable weight, and normal skin turgor and texture are indicative of thyroid health in this patient population. During periods of stress, such as invasive procedures, an adjustment in thyroid medications may be indicated. It is important for all healthcare providers to be aware of the hypothyroidism, particularly when prescribing medications such as sedatives, narcotics, or anesthetic agents. The patient and family should be knowledgeable about the signs of hypothyroidism and hyperthyroidism and which clinical manifestations they should report to the healthcare provider.

### Connection Check 43.2

The nurse correlates which clinical manifestation to the pathophysiology of hypothyroidism?

- Cold intolerance
- Weight loss
- Insomnia
- Diarrhea

## HYPERTHYROIDISM

### Epidemiology

Hyperthyroidism can be present at any age but is most commonly diagnosed in women between the ages of 20 and 40 years; it is also 10 times more prevalent in women. **Graves' disease** is the most common cause of hyperthyroidism and is an autoimmune disorder involving antibodies (thyroid-stimulating immunoglobulins) that bind to the thyroid gland, resulting in the enlargement of the thyroid gland and subsequent hypersecretion of thyroid hormone.

### Pathophysiology

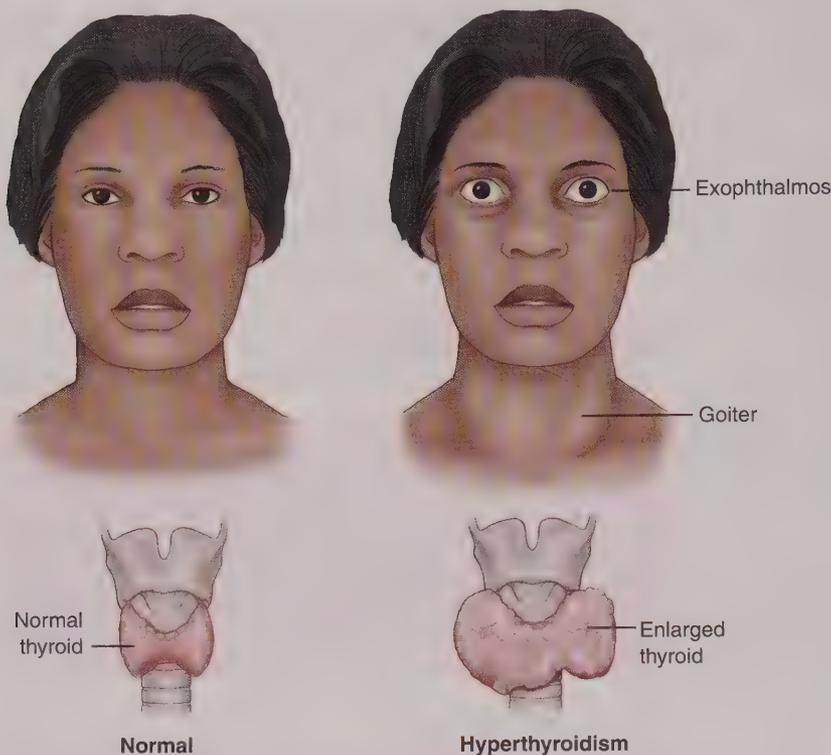

Accelerated metabolism is characteristic of hyperthyroidism and affects most body systems. Primary hyperthyroidism is secondary to excess triiodothyronine (T<sub>3</sub>) or thyroxine (T<sub>4</sub>) from the thyroid gland. With increased secretion of thyroid-stimulating hormone (TSH) from the anterior posterior gland, secondary hyperthyroidism develops. Tertiary hyperthyroidism occurs as a result of excessive secretion of thyroid-releasing hormone or thyrotropin-releasing hormone (TRH) from the hypothalamus.

### Clinical Manifestations

The increase in metabolic rate results in the following clinical manifestations:

- Elevated heart rate, cardiac dysrhythmias, and increased heart sounds
- Thyroid bruit linked to increased blood flow
- Heat intolerance
- Increased gastric activity resulting in increased bowel movements
- Increased appetite
- Weight loss
- Fatigue
- Nervousness
- Insomnia
- Light to absent menses
- Hair loss

Other clinical manifestations include **exophthalmos** (protrusion of the eyeball) and goiter (Fig. 43.4). Exophthalmos is characteristic of hyperthyroidism and results in visual changes. Goiter is also associated with hyperthyroidism and is often the result of hyperplasia of the gland in response to the action of TSH on thyroid tissue.

**FIGURE 43.4** Exophthalmos and goiter are characteristic of hyperthyroidism.

## Management

### Medical Management

#### Diagnosis

Laboratory findings in patients with hyperthyroidism include elevated serum T<sub>3</sub>, elevated serum T<sub>4</sub>, and decreased TSH in primary disorders. Table 43.2 provides an overview of diagnostic studies for patients with suspected thyroid disorders. Antibodies to TSH are also evaluated, and high titers are correlated with Graves' disease. In patients with goiter, thyroid scans may be performed to assess the size, position, and function of the gland. The uptake of radioactive iodine (RAIU) is measured after oral administration, and normal uptake varies according to the time of measurement (see Table 43.2). Elevations in RAIU are consistent with a diagnosis of hyperthyroidism.

#### Treatment

Control of the hypermetabolic state associated with hyperthyroidism is the priority in its management. Although there are specific pharmacological agents used in the treatment of hyperthyroidism, the management of clinical manifestations, particularly in relation to cardiac function and body temperature, is a priority. Nonsurgical treatment focuses on ensuring adequate fluid intake because insensible losses are greater secondary to the hypermetabolic state, monitoring for cardiovascular complications, and promoting a quiet, nonstressful environment. Pharmacological agents that may be used for symptom management include beta-adrenergic blocking agents because these agents slow heart rate and decrease palpitations.

**Safety Alert** Patients with hyperthyroidism require close monitoring of their fluid and electrolyte status because the hypermetabolic state increases insensible water loss through perspiration as well as elevated metabolic rate.

#### Medications

For long-term management of hyperthyroidism, antithyroid medications are used, including propylthiouracil (PTU), methimazole (Tapazole), and lithium carbonate (Lithonate). These medications reduce clinical manifestations of hyperthyroidism by interfering either with the formation or release of thyroid hormone. For short-term management, iodine preparations may be administered, particularly to patients before thyroidectomy, to decrease blood flow through the thyroid gland in order to decrease thyroid hormone release. Table 43.3 provides an overview of medications used in treating hyperthyroidism.

**Safety Alert** Thyrotoxicosis is a medical emergency requiring definitive treatment to prevent respiratory compromise and cardiac collapse.

#### Surgical Management

Although most cases of hyperthyroidism are treated successfully with antithyroid medications, surgical management

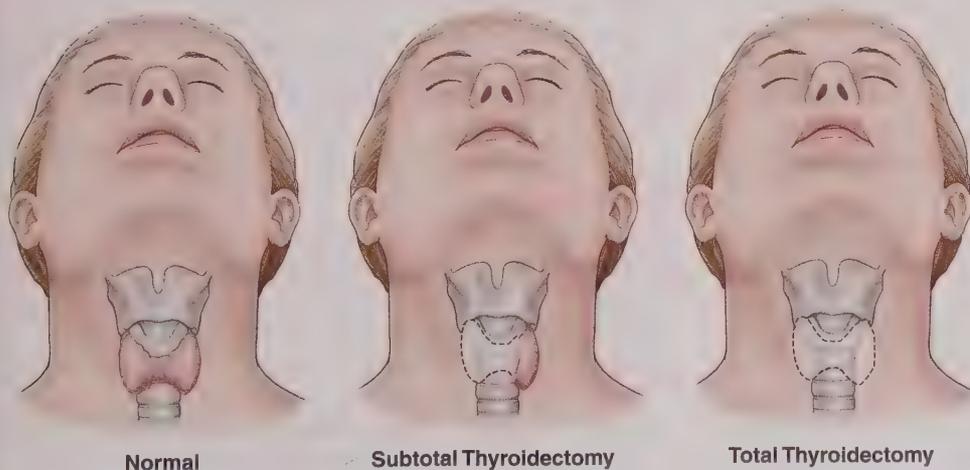

**Table 43.3 Pharmacological Management of Hyperthyroidism**

Medication	Actions	Nursing Implications
<b>Propylthiouracil (PTU)</b>	Inhibits the synthesis of thyroid hormone by diverting iodine pathways  Interferes with conversion of thyroxine (T4) to triiodothyronine (T3)	<ul style="list-style-type: none"> <li>● Take the medication at the same time daily, usually in the morning</li> <li>● Monitor weight 2–3 times per week</li> <li>● Teach patient signs of hypothyroidism</li> <li>● Monitor white blood cell count because agranulocytosis may occur</li> </ul>
<b>Methimazole (Tapazole)</b>	Inhibits the synthesis of thyroid hormone by blocking the combination of iodine with a protein called thyroglobulin  Methimazole also interferes with the conversion of T4 to T3.	<ul style="list-style-type: none"> <li>● Take the medication at the same time daily, usually in the morning</li> <li>● Monitor weight 2–3 times per week</li> <li>● Teach patient signs of hypothyroidism</li> <li>● Monitor white blood cell count as agranulocytosis may occur</li> </ul>
<b>Lithium carbonate (Lithonate)</b>	Lithium is concentrated in the thyroid gland and interferes with thyroid hormone synthesis and can cause formation of thyroid antibodies.	<ul style="list-style-type: none"> <li>● Monitor for signs of toxicity including vomiting, diarrhea, drowsiness, and lack of coordination</li> <li>● Drink at least 2–3 L of fluids when initially starting the medication</li> <li>● Assess for changes in signs of thyroid dysfunction</li> </ul>
<b>Iodine (SSKI - saturated solutions of potassium iodide)</b>	Inhibits the release of thyroid hormone by decreasing vascularity of the thyroid gland	<ul style="list-style-type: none"> <li>● Assess for signs of iodism including metallic taste, stomatitis, skin lesion, cold symptoms, and severe gastrointestinal distress</li> <li>● Mix solutions in full glass of fruit juice or water</li> <li>● Administer after food to decrease gastrointestinal distress</li> </ul>

may be indicated for patients with hypersecreting tumors that are unresponsive to the medications or in patients experiencing tracheal compression due to goiter. Because most patients demonstrate clinical manifestations of hyperthyroidism while being prepared for surgery, it is a priority to establish “normal,” or **euthyroid**, function before surgery. This is most often accomplished with iodine preparations to decrease vascularity of the thyroid gland in addition to other

prescribed antithyroid medications, and medications to decrease blood pressure and heart rate, as needed.

For patients with hyperthyroidism, total or subtotal thyroidectomy procedures are performed (Fig. 43.5). With total thyroidectomy, the patient needs to take thyroid replacement hormone for the remainder of his or her life. Potential complications during thyroidectomy include the removal of all parathyroid tissue, resulting in hypoparathyroidism

**FIGURE 43.5** Subtotal and total thyroidectomy.

or damage to the laryngeal nerve that affects swallowing and voice.

Postoperative priorities after thyroidectomy include monitoring for airway compromise, hemorrhage, hypocalcemia secondary to removal of all parathyroid gland tissue, and damage to the laryngeal nerve. Because hemorrhage is most likely in the first 24 hours, it is important to observe for bleeding around the dressing as well as down the back of the neck. Sandbags may be used to help keep the head in proper alignment, and care is used when repositioning the patient to prevent tension on the suture line.

Postoperatively, the patient is positioned in a semi-Fowler's position to ease the work of breathing and to decrease the risk of aspiration of oral secretions associated with lying flat on the back. Humidified air is administered to help decrease the viscosity of secretions, and oral suctioning equipment is maintained at the bedside. A tracheostomy tray is maintained at the bedside because of the risk of respiratory compromise secondary to postoperative swelling, tetany (intermittent muscle spasms), and laryngeal damage. Tetany develops secondary to hypocalcemia as a result of damage or removal of parathyroid glands during surgery and results in laryngospasm, making oral intubation difficult or impossible. Suctioning equipment and supplemental oxygen, in addition to the tracheostomy tray, are maintained at the patient's bedside for at least the first 48 hours after surgery.

Assessing for damage to the laryngeal nerve is also a priority in the postoperative period following thyroidectomy. Changes in voice quality, particularly hoarseness or a husky tone, may be indicative of laryngeal nerve damage. Voice assessments are conducted every 1 to 2 hours in the immediate postoperative period to monitor for changes.

### Complications

**Thyroid storm or thyrotoxicosis** may develop with poorly managed hyperthyroidism. Clinical manifestations include tachycardia, fever, systolic hypertension, abdominal pain, tremors, and changes in level of consciousness. Airway management and fluid resuscitation are priorities. Antithyroid medications may be administered along with iodine preparations. For management of tachycardia, beta-adrenergic blockers may be administered. Glucocorticoids may also be administered because in high doses these medications decrease the conversion of T<sub>4</sub> to the more active T<sub>3</sub>, as well as decreasing the release of TSH from the anterior pituitary gland. Cooling blankets may be used to treat the hyperthermia. During crisis, the patient must be monitored closely for respiratory complications, cardiac dysrhythmias, and seizures.

### Connection Check 43.3

The nurse correlates an increase in which laboratory value to the diagnosis of primary hyperthyroidism?

- Thyroxine (T<sub>4</sub>)
- Thyroid-stimulating hormone (TSH)
- Serum calcium
- Serum iodine

### Nursing Management

#### Assessment and Analysis

Because hyperthyroidism accelerates the metabolic rate of almost all cells, the clinical presentation of the patient includes changes in many body systems. The clinical manifestations of hyperthyroidism are directly linked to actions of the excessive thyroid hormones and the associated increase in basal metabolic rate that may increase by 60% to 100%. Clinical presentation includes:

- Weight loss because basal metabolic rate can increase by 60% to 100% in the patient with hyperthyroidism, leading to accelerated use of glucose, fats, and proteins
- Increased gastric motility
- Increased appetite
- Hypoglycemia
- Increased systolic blood pressure; tachycardia that may exacerbate to cardiac dysrhythmias
- Visual changes
- Corneal abrasions (secondary to exophthalmos)

#### Nursing Diagnoses

- **High risk for decreased cardiac output** linked to tachycardia and dysrhythmias
- **Altered nutrition less than body requirements** linked to increased metabolic rate secondary to elevated thyroid hormone levels
- **Hyperthermia** linked to accelerated metabolic rate secondary to increased circulating thyroid hormones

#### Nursing Interventions

##### Assessments

- **Vital signs**  
*Hypermetabolism results in acceleration of the respiratory and cardiovascular systems, leading to elevated heart rate and increased respiratory rate. An elevation in temperature is associated with the hypermetabolic state.*
- **Intake and output**  
*Increases in insensible fluid loss develop secondary to the hypermetabolic state, leading to increased respiratory rate, increased diaphoresis, and diarrhea.*
- **Eyes and vision**  
*Exophthalmos leads to changes in shape and structure of the eye that lead to eyeball protrusion and visual changes.*
- **Thyroid hormone levels**  
*Increased T<sub>3</sub> and increased T<sub>4</sub> levels with decreased TSH are characteristic of primary hyperthyroidism.*
- **Goiter**  
*Common in Graves' disease and associated with hyperplasia of thyroid tissue*
- **Seizures**  
*Increased risk for seizure activity linked to hyponatremia and elevated temperature associated with hypermetabolism*
- **Daily weight**  
*Weight loss occurs despite increased appetite, secondary to the hypermetabolic state. Use of protein stores leads to loss of muscle mass that contributes to weight loss.*

### ■ Actions

- Administer antithyroid medications as ordered  
*Decreases thyroid hormone levels by preventing synthesis of hormone in the thyroid gland or by preventing the conversion of T4 to T3*
- Administer iodine preparations  
*Decreases vascularity of thyroid tissue resulting in decreased thyroid hormone synthesis and release*
- Administer beta-adrenergic blocking agents as ordered  
*Used as supportive therapy to treat the associated clinical manifestations of hypermetabolism, including tachycardia, palpitations, and diaphoresis*
- Implement cooling measures with elevated temperature  
*Temperature elevation and increased insensible fluid loss result secondary to accelerated metabolic rate. Instituting cooling measures decreases risks associated with hyperthermia.*
- Administer eye lubricant  
*To decrease possible eye dryness and potential for corneal irritation secondary to incomplete eyelid closure with exophthalmos*

### ■ Teaching

- Overview of disease process  
*It is important that the patient (and family) are able to detect early signs of both hyperthyroidism (the underlying disorder that could progress to thyroid storm) and hypothyroidism (secondary to thyroid hormone-blocking agents).*
- Take the antithyroid medication at the same time every day  
*Compliance with antithyroid medications is essential for minimizing complications associated with thyrotoxicosis.*
- Consume adequate calories to minimize weight loss  
*Weight gain or maintenance of current weight indicates the therapeutic effects of antithyroid medications.*

### Connection Check 43.4

The patient experiencing thyroid storm is ordered to receive beta-adrenergic agents. The nurse monitors for which therapeutic effect of these medications?

- Increased respiratory rate
- Increased appetite
- Decreased heart rate
- Decreased bowel sounds

### Evaluating Care Outcomes

Patients with hyperthyroidism are usually managed with antithyroid medications. Vital signs within normal limits and stable weight indicate stabilizing thyroid function. The patient and family must be knowledgeable of signs of both hypothyroidism and hyperthyroidism in order to know when to seek healthcare advice. Patients with hyperthyroidism should have an evaluation of thyroid function before undergoing surgical or invasive procedures. Adjustments in antithyroid medications may also be indicated during times

of stress, which can further accelerate the metabolic rate. With proper attention to the treatment plan, patients with hyperthyroidism should be able to maintain a healthy, active lifestyle.

### CASE STUDY: EPISODE 2

Ms. Matthews' thyroid hormones (T3 and T4) are elevated, and her TSH is decreased. On the basis of these findings, she is diagnosed with primary hyperthyroidism. The nurse practitioner prescribes the patient to start propylthiouracil (PTU). Ms. Matthews is instructed to ensure that she consumes adequate fluids and monitors her weight weekly. She is scheduled to return to the clinic in 4 weeks...

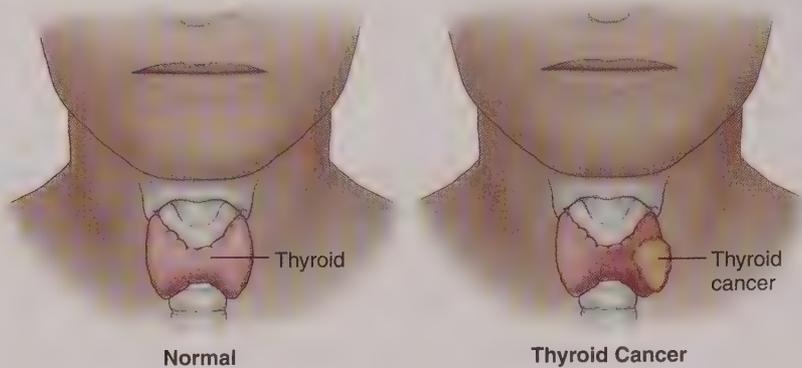

### THYROID CANCER

Patients with thyroid cancer usually present with a nodule on the thyroid gland (Fig. 43.6). According to the American Cancer Society, approximately 53,900 new cases of thyroid cancer were diagnosed in 2018 (40,900 in women and 13,090 in men), and there were approximately 2,060 deaths. The death rate from thyroid cancer has been fairly steady for years and remains very low compared with most other cancers. There are four types of thyroid cancer: papillary, follicular, medullary, and anaplastic. In all types of thyroid cancer other than anaplastic, thyroidectomy is the treatment of choice in the absence of distant metastasis. Following surgery, patients require close monitoring for clinical manifestations of both hypothyroidism and hypoparathyroidism, and their care is similar to that of the patient undergoing thyroidectomy secondary to hyperthyroidism. In patients with anaplastic carcinoma, because of the aggressive nature of this fast-growing tumor, radiation therapy is the treatment of choice. Chemotherapy may be used in patients who are not responsive to radiation therapy. Depending on the diagnosis and treatment of thyroid cancer, coordination between the endocrinologist, surgeon, oncologist, dietitian, social worker, and nurse is essential in promoting health. Often, the overall coordination of this interprofessional care is managed by a registered nurse case manager or care coordinator.

### HYPOPARATHYROIDISM

#### Epidemiology

Hypoparathyroidism is classified as idiopathic (unknown etiology), acquired, or reversible. The most common cause of acquired hypoparathyroidism is secondary to removal of the parathyroid glands during total thyroidectomy or bilateral resection for cancer of the head and neck. Reversible hypoparathyroidism may develop secondary to iodine therapy for hyperthyroidism and with metastasis of malignant tumors. Autoimmune disease is suspected in patients with

**FIGURE 43.6** Thyroid cancer.

spontaneous presentation of hypoparathyroidism with no identifiable cause. In these cases, antiparathyroid antibodies have been detected in patients with other autoimmune disorders such as diabetes mellitus or adrenal insufficiency. There is also a congenital absence of parathyroid glands known as DiGeorge syndrome; considered an autoimmune disorder, it is usually reversible in children.

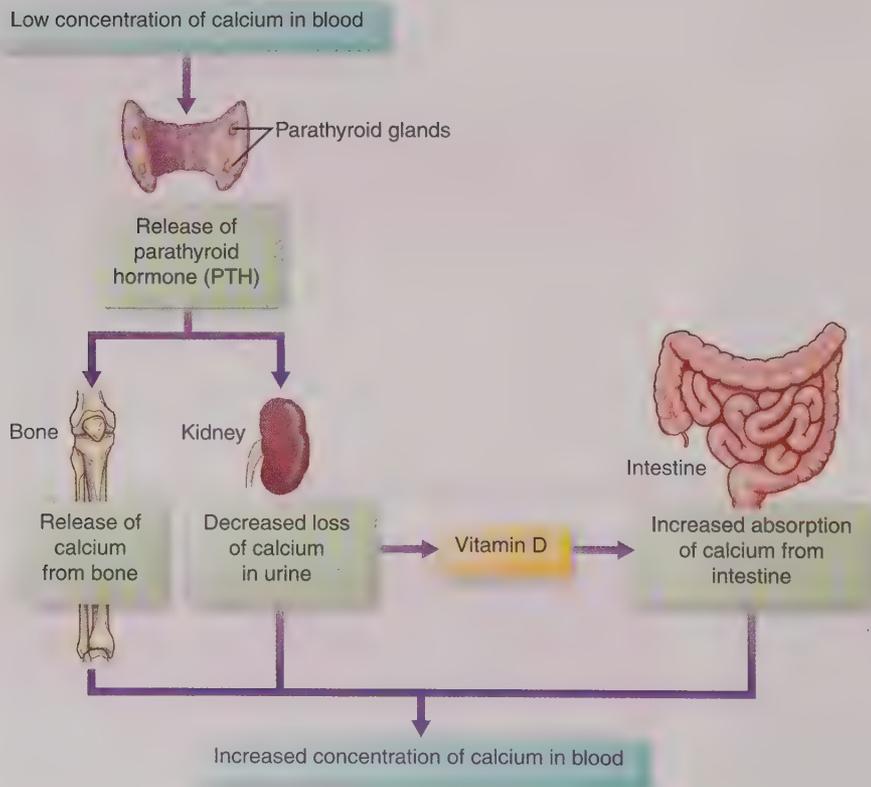

**Pathophysiology**

Hypocalcemia is the primary disorder associated with hypoparathyroidism (Fig. 43.7). Because of a lack of parathyroid hormone (PTH), calcium is not mobilized from the bones, conserved in the kidneys, or absorbed in the small intestines. Vitamin D enters the body in an inactive form through dietary intake or ultraviolet rays and is activated

in the kidneys based on actions of PTH. It is this activated vitamin D that leads to calcium absorption in the intestines. Calcium plays a major role in membrane potential and neuronal excitability and is needed for cardiac, skeletal, and smooth muscle contraction. Table 43.4 provides an overview of diagnostic results seen in parathyroid dysfunction.

**Clinical Manifestations**

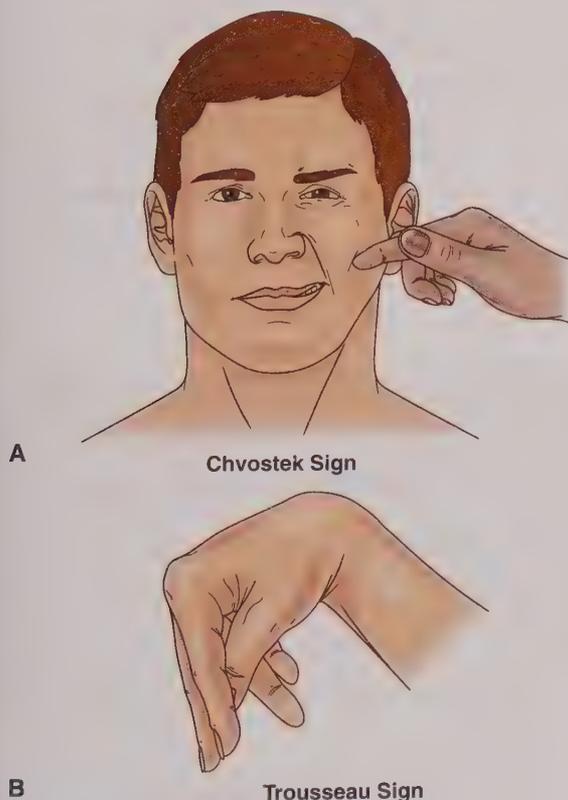

In addition to decreased serum calcium levels, the clinical manifestations of hypoparathyroidism include numbness and tingling around the mouth or in the hands and feet, severe muscle cramps, spasms of the hands and feet, and tetany. Two specific assessments observed in hypocalcemia are Chvostek sign (Fig. 43.8A) and Trousseau sign (Fig. 43.8B) and are associated with an increased risk of tetany that can result in

**FIGURE 43.7** Actions of parathyroid hormone (PTH). In response to low circulating serum calcium levels, PTH is released from the parathyroid glands and acts on the bones, kidneys, and intestines to increase serum calcium levels. Note that vitamin D is activated in the kidneys and leads to increased calcium absorption in the intestine.

**Table 43.4** Laboratory Tests for Parathyroid Disorders

Test	Normal Range for Adults	Significance
<b>Calcium</b>	8.2–10.2 mg/dL	Decreased in hypoparathyroidism Increased in hyperparathyroidism
<b>Ionized Calcium</b>	4.6–5.3 mg/dL	Decreased in hypoparathyroidism Increased in hyperparathyroidism
<b>Magnesium</b>	1.6–2.2 mg/dL	Decreased in hypoparathyroidism
<b>Phosphorus</b>	2.5–4.5 mg/dL	Increased in hypoparathyroidism Decreased in hyperparathyroidism
<b>Vitamin D</b>		
<b>Vit D 25-hydroxy</b>	30–100 ng/mL	Decreased in hypoparathyroidism
<b>Vit D 1, 25-dihydroxy</b>	18–72 pg/dL	Variable in hyperparathyroidism

**FIGURE 43.8** Assessments for hypocalcemia. A, Chvostek sign; B, Trousseau sign.

laryngospasm and airway compromise (see management of tetany above).

**Safety Alert** Hypocalcemia is a medical emergency when associated with tetany and laryngospasm because this complicates placement of the endotracheal tube. A tracheostomy tray (set-up) is often placed at the bedside of patients at risk as a result of thyroid surgery or severe hypocalcemia.

## Management

### Medical Management

#### Diagnosis

Diagnostic results consistent with hypoparathyroidism include low serum calcium levels, high serum phosphate levels, and low serum PTH levels. Serum magnesium levels are often evaluated to rule out hypomagnesemia as the cause of hypoparathyroidism, as low serum magnesium levels inhibit synthesis of PTH. Additionally, serum albumin levels are monitored because the majority of serum calcium is plasma protein bound. In the patient with both low serum calcium and albumin, an ionized (free) calcium evaluation is required to determine the extent of the hypocalcemia.

#### Treatment

Hypoparathyroidism treatment is based on whether the presentation is acute or insidious and focuses primarily on raising serum calcium levels. Intravenous calcium (usually calcium gluconate or calcium chloride) is administered to the patient presenting with acute hypocalcemia and then followed up with oral calcium and vitamin D supplementation. In patients with a history of cardiac disease, IV administration should be slow to minimize hypotension and bradycardia. Chronic hypoparathyroidism is treated with oral calcium and vitamin D based on close monitoring of serum calcium levels.

### Connection Check 43.5

The nurse correlates a positive Chvostek sign to hyposecretion of which hormone?

- Thyroxin (T4)
- Thyrocalcitonin
- Parathyroid hormone (PTH)
- Triiodothyronine (T3)

### Nursing Management

#### Assessment and Analysis

The clinical presentation of hypoparathyroidism is primarily linked to the effects of low serum calcium levels and includes the following findings:

- Decreased serum calcium levels
- Tetany, muscle cramps, carpopedal spasm

- Positive Chvostek and Trousseau signs
- Paresthesias of the hands and feet
- Tingling of circumoral areas
- Seizures
- Prolonged QT interval
- Resistance to digitalis linked to loss of inotropic effect
- Hypotension and cardiac dysrhythmias
- Bone pain and skeletal deformities

### Connection Check 43.6

The nurse monitors the calcium levels closely in the patient taking digoxin (Lanoxin) because hypocalcemia may lead to which complication?

- A. Elevated heart rate
- B. Dysrhythmias
- C. Increased cardiac contractility
- D. Hypertension

### Nursing Diagnoses

- **High risk for ineffective airway clearance** linked to laryngospasm secondary to hypocalcemia
- **Decreased cardiac output** linked to suppressed myocardial contractility secondary to hypocalcemia

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Hypotension may occur secondary to decreased myocardial contractility and cardiac dysrhythmias.*
- Cardiac monitoring  
*Hypocalcemia may cause cardiac dysrhythmias secondary to effects on cardiac automaticity.*
- Ionized calcium levels  
*Ionized calcium is the free and active form of calcium.*
- Serum magnesium levels  
*Hypomagnesemia interferes with PTH synthesis and contributes to hypocalcemia.*
- Acid-base status  
*An alkaline pH increases binding of calcium to protein and results in decreased ionized calcium.*
- Neuromuscular activity  
*Insufficient free, ionized calcium at the neuromuscular junction results in excessive neuronal firing.*

#### ■ Actions

- Administer calcium replacements  
*Raise serum calcium levels. IV calcium is usually administered over 10 to 15 minutes.*
- Administer vitamin D  
*Vitamin D is needed for calcium absorption from the bowel.*

#### ■ Teaching

- Medication regimen  
*Lifelong supplementation with calcium is necessary secondary to decreased synthesis or secretion of PTH.*

- Eat foods high in calcium but low in phosphorus  
*Foods high in calcium assist in raising serum calcium levels (Box 43.1). Foods high in phosphorus are to be avoided because phosphorus can bind with calcium in the serum, further decreasing calcium levels.*
- Signs of hypocalcemia and hypercalcemia  
*This information is needed to prevent complications associated with extremes of either calcium abnormality.*

### Evaluating Care Outcomes

Compliance with the medication regimen, particularly daily calcium supplements, usually results in stable serum calcium levels. Because of intake of calcium supplements, it is important to ensure that the patient maintains adequate hydration. Equipped with an understanding of the clinical manifestations of both elevated and low calcium levels, the patient and family are knowledgeable about changes that require notification of the healthcare provider.

## HYPERPARATHYROIDISM

### Epidemiology

Parathyroid adenomas account for 85% of the cases of primary hyperparathyroidism, whereas 15% of cases are secondary disorders associated with hyperplasia of the parathyroid glands. Secondary disorders are most often observed in patients with chronic renal failure or chronic malabsorption of calcium. The incidence of hyperparathyroidism is greatest in people older than 50 years of age and occurs in women more often than men.

### Pathophysiology

Hyperparathyroidism causes hypercalcemia secondary to its actions on bone, kidneys, and the bowel. The action of PTH on bone leads to **osteoclastic** (breakdown of bone) activity and bone demineralization, which causes pathological fractures and bone lesions. Osteoclasts are large cells that secrete enzymes and acids to dissolve microscopic bits of bone, and then the minerals and amino acids are reabsorbed

### Box 43.1 High Calcium Foods Used in the Treatment of Hypoparathyroidism

#### Fruits and Fruit Juices

- Calcium and vitamin D–fortified orange juice
- Rhubarb
- Stewed figs

#### Dark Green, Leafy Vegetables

- Collard greens
- Kale
- Mustard spinach

#### Soy Products

(resorption). Osteoclastic activity increases release of calcium from the bone and leads to loss of bone density. Increased renal reabsorption of calcium leads to elevated serum calcium levels. Increased calcium levels in the urine filtrate cause hypercalciuria that increases the potential for calcium-containing renal stones. Reabsorption of calcium in the bowel is also increased in patients with hyperparathyroidism.

Patients with chronic renal failure may develop secondary hyperparathyroidism. Decreased serum calcium and inactivated vitamin D develop in early renal failure, and PTH secretion increases in response to the hypocalcemia. Over time, parathyroid gland hyperplasia develops because of low calcium levels. Hyperparathyroidism can be differentiated from other causes of hypercalcemia, such as elevated calcium secondary to malignancy, through intact PTH assays. In hyperparathyroidism, intact PTH levels are intact in 75% to 90% of patients, whereas they are normal in patients with hypercalcemia secondary to malignancy.

### Clinical Manifestations

Although some patients with hyperparathyroidism may be asymptomatic, others present with polyuria, anorexia, and constipation associated with elevated serum calcium levels that impact the kidneys and gastrointestinal tract. Cardiac changes associated with elevated calcium levels include a prolonged PR interval and a shortened QT interval due to the shortening of the ST segment. The patient may also develop abdominal pain because hypercalcemia leads to increased secretion of gastrin in the stomach and associated peptic ulcer disease. Other clinical manifestations include lethargy, confusion, muscle weakness, fatigue, and generalized bone pain (secondary to bone demineralization caused by osteoclastic activity).

### Management

#### Medical Management

##### Diagnosis

Direct measurement of intact PTH is diagnostically definitive for hyperparathyroidism. Diagnostic evaluation of patients with suspected hyperparathyroidism also includes measurements of serum calcium, albumin, phosphorus, and ionized calcium levels. Because serum calcium levels are measurements of serum protein-bound calcium, an evaluation of serum albumin is needed; a low serum calcium level may be associated with a low serum albumin. Measurements of ionized calcium are more accurate because they reflect the active form of calcium. The finding of elevations in both intact PTH and ionized calcium is diagnostic for primary hyperparathyroidism.

##### Treatment

The treatment of hyperparathyroidism focuses primarily on lowering serum levels. Increased fluid intake is indicated to minimize potential renal injury secondary to elevated serum calcium, and in patients with mild disease, increased oral fluid intake may treat the disorder. More severe cases

of hypercalcemia require IV infusions of normal saline to protect against renal calculi. Patients with hyperparathyroidism are also taught to decrease consumption of calcium-containing antacids and vitamin D. Thiazide diuretics are also to be avoided in patients with hyperparathyroidism because these medications increase reabsorption of calcium in the kidney.

### Connection Check 43.7

The nurse prioritizes which nursing diagnosis in the patient after partial parathyroidectomy?

- High risk for ineffective airway clearance linked to hypocalcemia
- High risk for ineffective breathing pattern linked to hypercalcemia
- High risk for hyperventilation linked to hypersecretion of triiodothyronine
- High risk for airway compromise linked to insufficient iodine stores

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of hyperparathyroidism are largely related to elevated serum calcium and include:

- Elevated ionized and serum calcium levels
- Decreased serum phosphorus levels
- Muscle weakness and atrophy
- Low back pain
- Increased incidence of pathological fractures
- Prolonged PR interval
- Shortened QT interval
- Constipation, anorexia, and nausea and vomiting
- Renal stones

#### Nursing Diagnoses

- **Acute pain** related to pressure in renal tubules secondary to development of calcium-based renal calculi
- **High risk for injury: falls** related to bone demineralization and calcium resorption

#### Nursing Interventions

##### Assessments

- Serum calcium levels  
*Excessive PTH leads to release of calcium from the bone, increased renal reabsorption, and increased intestinal absorption, all leading to hypercalcemia.*
- Serum phosphorus levels  
*Parathyroid hormone increases renal excretion of phosphorus.*
- Cardiac monitoring  
*Elevated serum calcium may lead to shortening of the QT interval related to decreased depolarization and repolarization of the ventricles.*
- Acid-base status  
*An acid pH decreases binding of calcium to protein and results in elevated ionized calcium.*

**Actions**

- Increase fluid intake to 3,000 mL/day  
*Increase fluid administration to decrease incidence of renal calculi. Normal saline is the fluid choice for IV administration.*
- Administer furosemide (Lasix) as ordered  
*This diuretic medication increases renal excretion of calcium.*
- Administer oral phosphates as ordered  
*Oral phosphates inhibit calcium loss from the bone and interfere with calcium absorption in the kidneys and bowel.*
- Administer calcium chelators  
*Binding of calcium decreases the free, activated calcium and lowers serum levels.*
- Use a lift sheet in patients with chronic hyperparathyroidism to prevent bone injury  
*Sustained hyperparathyroidism results in loss of calcium from the bone and increases the chances of bone trauma and pathological fractures.*
- Strain urine with suspected renal calculi  
*Confirmation of renal calculi composition is needed to implement corrective therapy.*

**Teaching**

- Signs of hypocalcemia and hypercalcemia  
*This information is needed to prevent complications associated with the extremes of either calcium abnormality.*
- Low-calcium diet  
*Decreased consumption of calcium may lead to lower serum calcium levels.*
- Increase fluids and fiber to decrease complications of constipation  
*Delayed gastric motility secondary to effects of calcium on smooth muscle leads to constipation.*

**Evaluating Care Outcomes**

Hyperparathyroidism is a manageable disease process if patients are compliant with prescribed interventions. Prevention of complications secondary to sustained hypercalcemia is paramount for a healthy lifestyle. In patients who are not responsive to medical management of hyperparathyroidism, a subtotal parathyroidectomy may be performed. Postoperative care for these patients is similar to that for the patient undergoing thyroidectomy.

**Connection Check 43.8**

The nursing diagnosis “Acute pain related to ureteral pressure and obstruction secondary to calcium-containing renal stones” is most appropriate for the patient with which endocrine disorder?

- Hypothyroidism
- Hypoparathyroidism
- Hyperthyroidism
- Hyperparathyroidism

**Making Connections****CASE STUDY: WRAP-UP**

Ms. Matthews returns to the clinic 2 weeks after starting the PTU because she continues to have the same complaints of restlessness and insomnia and has lost another 6 pounds since her last appointment. The nurse practitioner discusses the option of radioactive iodine therapy, but Ms. Matthews refuses because she would like to get pregnant once her hyperthyroidism is controlled. Radioactive iodine therapy is contraindicated in pregnancy because of potential adverse effects to the developing fetus unless the potential benefits of the intervention outweigh the risks to the fetus and mother. She is referred for a surgical consult, and the decision is made for her to undergo a partial thyroidectomy to remove the hypersecreting thyroid tissue.

**Case Study Questions**

- Which of Ms. Matthews’ demographic variables are consistent with a diagnosis of hyperthyroidism? (Select all that apply.)
  - Age
  - Socioeconomic status
  - Occupation
  - Race
  - Gender
- The nurse recognizes that the rationale for the administration of propylthiouracil (PTU) is based on which action of this medication?
  - Decreases thyroid hormone release from the anterior pituitary gland
  - Blocks conversion of T4 to T3
  - Increases TRH release from the hypothalamus
  - Augments iodine absorption by the thyroid gland
- The nurse recognizes which rationale for the instructions to Ms. Matthews to increase her intake of fluids secondary to her hyperthyroidism?
  - There is an increased water loss because of the hypermetabolic state.
  - There is increased blood flow through the renal system.
  - There is a decreased availability of TSH.
  - There is increased water reabsorption in the gastrointestinal tract.
- What is a nursing priority for Ms. Matthews in preparation for the thyroid surgery?
  - Maintain weight loss at less than 2 pounds per week
  - Increase intake of green leafy vegetables
  - Heart rate within normal parameters
  - Decrease intake of calcium

5. The nurse recognizes which action of radioiodine therapy that impacts women during their childbearing years?
- It interferes with production of estrogen.
  - It decreases blood flow to the placenta during pregnancy.
  - It interferes with normal menstrual cycles.
  - It may adversely impact fetal development.

## CHAPTER SUMMARY

Metabolic function is largely under the control of the thyroid glands. The parathyroid glands play a key role in the regulation of calcium and phosphorus levels. Diseases of both of these endocrine glands may manifest as disorders secondary to hypofunction or hyperfunction. Thyroid disorders are classified according to the origin of the hormonal changes: a primary disorder is secondary to changes in the release of the hormones triiodothyronine (T3) and thyroxine (T4) from the thyroid glands, secondary disorders are related to secretion changes of TSH from the anterior pituitary gland, and tertiary processes occur because of changes in secretion of TRH from the hypothalamus. Management of these disorders focus on raising hormone levels or affecting the actions and functions of target tissues.

Hypothyroidism is caused by a decrease in T3 and T4. The clinical presentation of this disorder is characterized by decreased metabolic activity in all cells of the body. Patients with hypothyroidism may exhibit cold intolerance because of decreased metabolic activity. Other clinical

manifestations include fatigue, weight gain, bradycardia, dry coarse skin, and sensitivity to narcotics and barbiturates. Severe hypothyroidism, myxedema coma, is associated with significant changes in cardiac function that may result in decreased cardiac contractility and cardiac output.

Hyperthyroidism develops secondary to elevated levels of circulating thyroid (T3 and T4) hormones. Patients with this disorder present with clinical manifestations associated with hypermetabolic activity including tachycardia, restlessness, fatigue, weight loss, and diarrhea secondary to increased gastric emptying. Management of hyperthyroidism focuses on decreasing thyroid hormone levels through medications that decrease synthesis and secretion or surgical procedures that remove the hypersecreting tissue or tumor.

Disorders of the parathyroid glands relate to changes in secretion of parathormone (PTH) and directly affect serum calcium levels. In parathyroid disease, there is a direct relationship between levels of PTH and serum calcium levels; increased PTH leads to increased serum calcium levels, and decreased PTH results in decreased serum calcium levels. Clinical manifestations of hypoparathyroidism include increased neuromuscular transmission, tetany, muscle cramps, and paresthesias of the hands and feet. Management of hypoparathyroidism is focused on increasing serum calcium levels with calcium and vitamin D supplementation. Hyperparathyroidism with resulting hypercalcemia leads to muscle weakness, atrophy, low back pain, and increased incidence of pathological fractures secondary to loss of calcium from bones and an increased incidence of calcium-containing renal stones. Management of hyperparathyroidism is focused on decreasing serum calcium levels through hydration and decreasing intake of calcium.

## Coordinating Care for Patients With Diabetes Mellitus

*Susan Renda*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Discussing the epidemiology of diabetes mellitus
2. Describing the pathophysiology of type 1 and type 2 diabetes mellitus
3. Correlating clinical manifestations of type 1 and type 2 diabetes mellitus with the pathophysiology of each disorder
4. Describing the diagnostic studies used to diagnose and monitor diabetes mellitus
5. Comparing indications, administration, actions, and nursing considerations for insulin and oral hypoglycemic agents
6. Explaining complications associated with type 1 and type 2 diabetes mellitus
7. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations based on the disease process
8. Correlating rationales for nursing interventions with the underlying pathophysiological processes
9. Teaching self-care strategies to patients in relation to the management of diabetes mellitus and pharmacological management

### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Medication
- Metabolism
- Nutrition
- pH Regulation

### ESSENTIAL TERMS

Basal insulin  
Continuous glucose monitoring  
Dawn phenomenon  
Diabetes mellitus (DM)  
Diabetic ketoacidosis (DKA)  
Fasting blood glucose  
Gestational diabetes  
Glucosuria  
Glycemic control  
Hemoglobin A1c  
Hyperglycemia  
Hyperosmolar hyperglycemic state (HHS)  
Insulin deficiency  
Insulin pumps  
Insulin resistance  
Kussmaul respirations  
Metabolic syndrome  
Oral glucose tolerance test  
Polydipsia  
Polyphagia  
Polyuria  
Prediabetes  
Prolonged hyperglycemia  
Self-monitoring of blood glucose  
Somogyi effect  
Type 1 diabetes  
Type 2 diabetes

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mrs. Edith Simpson is a 63-year-old African American female admitted for unstable angina. She is now 4 days postoperative following a triple cardiac bypass. She has a 15-year history of type 2 diabetes and is managed at home on metformin (Glucophage) and glyburide (Glynase). Her past medical history (PMH) also includes hypertension, hyperlipidemia, and a past surgical history of cholecystectomy. She works as an administrative assistant for the city government. She is married with four grown children. She smoked 1 ppd  $\times$  25 years but quit 2 years ago. Her labs indicate an elevated creatinine of 2.2 mg/dL, glomerular filtration rate (GFR) of 27 mL/min/1.73 m<sup>2</sup>, white blood cell (WBC) count elevated at 12.5  $10^3$ /mm<sup>3</sup>, and a blood glucose of 220 mg/dL...

## INTRODUCTION

There are continuous, dynamic, and intricate balancing mechanisms that support the control of circulating fasting blood glucose levels within a tight range of 65 to 99 mg/dL. This level of control occurs despite differences in ages, weight, intake of food, and activity levels. The two hormones primarily responsible for this homeostasis are released by the pancreas: insulin, released from the beta cells of the pancreas, and glucagon, released from the alpha cells of the pancreas.

The normal process of blood glucose level control is as follows (Fig. 44.1):

1. Glucose arrives in the bloodstream from one of three sources:
  - Carbohydrates eaten by mouth, converted to glucose via digestion, and absorbed through the gastrointestinal tract;
  - Glucose released from stored glycogen in muscles and liver cells; or
  - Glucose newly created (gluconeogenesis) in the liver or kidney cells.
2. Once in the bloodstream, the glucose is transported to the target cells.
3. In response to increased blood glucose levels, insulin is released from the pancreatic beta cells.
4. At the target cells, insulin facilitates the transport of glucose across the cell membrane to the cell's interior. Insulin is the key to the cell, allowing glucose to cross the cell membrane to be metabolized (Fig. 44.2).

5. Inside the cell, glucose is metabolized as fuel, releasing the energy necessary for normal cellular functioning.
6. If blood glucose levels are high, more insulin is secreted by the pancreas.
7. When blood glucose is driven into the cells and metabolized, glucose levels in the blood fall as a result.
8. If blood glucose levels fall too low, insulin release is suppressed, and glucose remains in the bloodstream instead of being driven into the cells.
9. In addition, in response to falling blood glucose levels, the hormone glucagon is released from the pancreatic alpha cells. Glucagon stimulates the production and release of glucose from glycogen stores in the liver so that blood glucose levels rise to normal.

When there is a disruption in the production of insulin (**insulin deficiency**) or when there are defects in the effective action of insulin at the cell membrane (**insulin resistance**), glucose cannot effectively cross cell membranes to enter the cell. Instead, glucose remains in the bloodstream, and blood glucose levels rise above normal. The resulting **hyperglycemia** is the hallmark of **diabetes mellitus (DM)**.

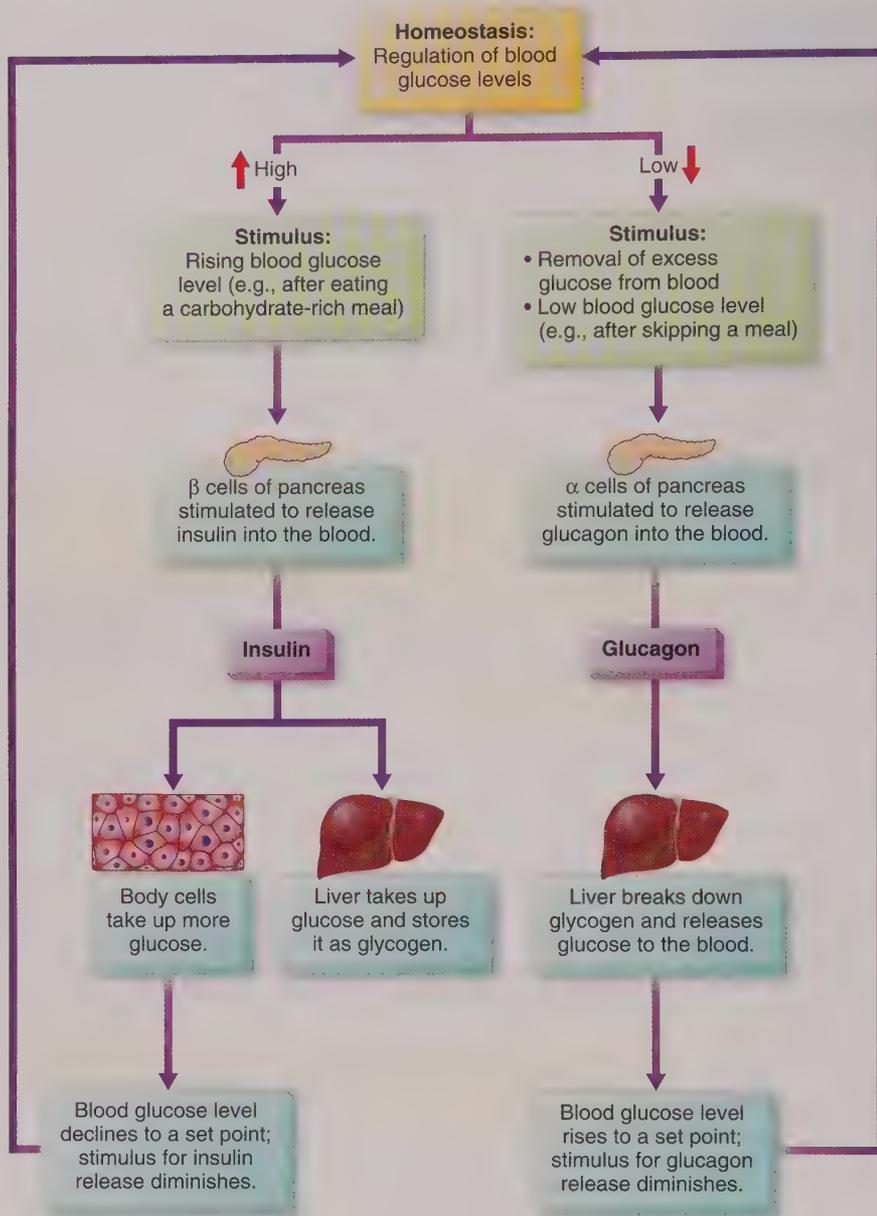

Diabetes mellitus is a group of disorders characterized by elevated blood glucose levels and results from defects in insulin production, insulin action, or both. According to estimates from the Centers for Disease Control and Prevention (CDC), over 30 million people in the United States, representing 9.4% of the population, have diabetes. Additionally, 84.1 million adults 18 years or older have prediabetes, which represents approximately 33.9% of the U.S. adult population. In the older adult population, 23.1 million people aged 65 years or older have prediabetes. There are numerous etiologies for these defects, but two types of diabetes, **type 1 diabetes** and **type 2 diabetes**, make up more than 90% of cases.

Another form of diabetes is **gestational diabetes**. It is defined as any degree of glucose intolerance with onset during pregnancy. If the mother's blood glucose is elevated above recommended targets, there is a risk of adverse outcomes to the mother, fetus, and infant. It complicates approximately 7% of all pregnancies, resulting in more than 200,000 cases annually. Women with a history of gestational diabetes have a greatly increased risk of developing type 2 diabetes within 15 years of the birth.

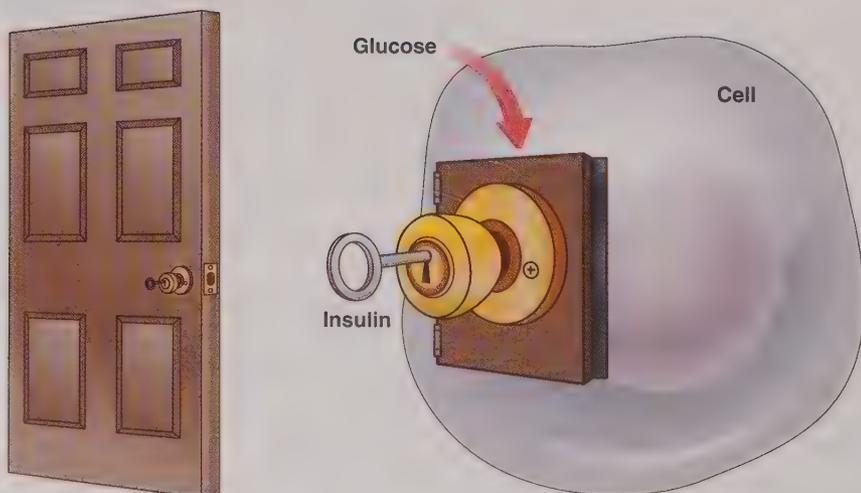

There are other, less common types of diabetes that are due to specific causes. These include:

- Diseases of the exocrine pancreas (such as cystic fibrosis or chronic pancreatitis)
- Surgical removal or resection of the pancreas
- Medication- or chemical-induced elevations in blood glucose levels, such as those that develop secondary to the use of corticosteroids
- Genetic defects in cell function
- Genetic defects in insulin action

The focus of this chapter is type 1 and type 2 DM.

**FIGURE 44.1** Glucose homeostasis. Changes in blood glucose levels are regulated by insulin and glucagon release from the pancreas. With increased blood glucose, insulin is released. As blood glucose levels fall, glucagon is released to increase blood glucose.

**FIGURE 44.2** Insulin as the key to the cell. Insulin facilitates transport of glucose across the cell membrane to the cell's interior to be metabolized.

## TYPE 1 DIABETES MELLITUS

### Epidemiology

Although most commonly diagnosed before age 30, type 1 diabetes can occur at any stage of life, even into the eighth and ninth decades. Previously referred to as *juvenile-onset diabetes* because of the typical age of onset, it now affects more than 400,000 children under 14 years of age, with a total of 1.25 million people with type 1 diabetes in the United States. It is the primary cause of diabetes in children under 10 years of age. The prevalence of type 1 diabetes varies by ethnic background, with people of European ancestry having the highest incidence. In adults, type 1 diabetes accounts for 5% to 10% of all diagnosed cases, or 11 to 22 million cases worldwide. The overall incidence of type 1 diabetes is increasing by 2% to 3% each year.

There are both genetic and environmental factors involved in the development of type 1 diabetes. The risk of developing type 1 diabetes increases if family members have type 1 diabetes or other associated autoimmune disorders, such as autoimmune thyroid disease, celiac disease, or Addison's disease. Environmental triggers also play a part in genetically sensitive individuals. Although the specific triggers are not yet fully understood, they are thought to include viruses such as mumps, rubella, and Coxsackie B4; toxic chemicals; exposure to cow's milk with the development of bovine antibodies; and cytotoxins (substances that are toxic to and kill living cells).

### Pathophysiology

Type 1 diabetes is typically triggered by an autoimmune process in which the insulin-producing beta cells of the pancreas are destroyed, resulting in an absolute lack of insulin. In children and young adults, this process is usually rapid, with total insulin deficiency occurring within 1 year, after which lifelong insulin therapy is required. If the disease begins in adulthood, the autoimmune destruction of beta cells has a more variable but generally slower time frame. Adult patients with new autoimmune type 1 diabetes, often referred to as late autoimmune diabetes of adulthood (LADA), may retain some insulin-secreting ability for years. Eventually, however, they develop total insulin deficiency. Once beta-cell destruction has progressed to the point of total insulin deficiency, patients with type 1 diabetes require externally delivered insulin (provided via a pump or injection) for the remainder of their lives.

Patients undergoing pancreatic resection as a result of cancer or other diseases of the pancreas may also present with surgically induced diabetes appearing as type 1 diabetes because of a lack of insulin after the surgical procedure. Like patients diagnosed with type 1 diabetes caused by the autoimmune process, these patients will also require lifelong insulin therapy.

### Connection Check 44.1

The nurse understands that type 1 DM is caused by which of the following conditions? (*Select all that apply.*)

- A. Gestational diabetes
- B. A history of mumps or rubella
- C. Family history of autoimmune disorders
- D. Autoimmune destruction of the beta cells of the pancreas
- E. Obesity

### Clinical Manifestations

Clinical manifestations caused by the hyperglycemia of type 1 diabetes are evident in many body systems. Predominant features include **polyuria**, **polydipsia**, **polyphagia**, fatigue, and weight loss. Polyuria, increased volumes of urine, is due to an increased concentration of glucose in the urine, or **glucosuria**. Glucose is typically totally reabsorbed in the renal tubules. Hyperglycemia results in glucose excretion in the urine, which creates an osmotic effect that effectively reduces water reabsorption into the renal tubules, leading to excessive volume loss through the kidneys. Hyperglycemia also causes hyperosmolality in the blood, which causes a shift of fluid from the intracellular space to the vascular space. The loss of intracellular water combined with the volume loss through the kidneys creates excessive thirst in the patient, or polydipsia. The lack of insulin necessary to move glucose into the cells leads to the breakdown of proteins and fat as a source of energy. This starvation of the cells leads to polyphagia, increased appetite. Despite an increased appetite leading to consumption of large amounts of food, the continual breakdown of fats and proteins leads to weight loss and fatigue.

### Connection Check 44.2

The nurse monitors for which clinical manifestations in the patient newly diagnosed with type 1 DM? (*Select all that apply.*)

- A. Polyuria
- B. Fatigue
- C. Weight loss
- D. Polyphagia
- E. Decreased appetite

### Management

#### Medical Management

#### Diagnosis

Type 1 DM in the nonpregnant adult is diagnosed by various methods:

- **Hemoglobin A1c (glycosylated hemoglobin) value.** The HgbA1c test measures the average blood glucose

concentration over time by measuring the amount of glucose that binds to red blood cells (RBCs). Reflecting the average life span of an RBC, the test gives an accurate indication of long-term, time-averaged glucose levels over the 6 to 12 weeks prior to the HgbA1c blood draw. When blood glucose concentrations are high, more hemoglobin is affected. On the day the HgbA1c sample is collected, eating, physical activity, or acute stresses do not affect the result, and the test can be done at any time of day and does not require fasting. Because of these characteristics, it is a good tool to monitor the effectiveness of insulin therapy as well as the patient's adherence to the diabetes management plan.

The HgbA1c levels do not show fluctuations, and swings between hypoglycemia and hyperglycemia can be masked in the "average" blood glucose levels. Measurement depends on the RBC survival and the composition of RBC hemoglobin, so HgbA1c results are inaccurate in several clinical situations, such as recent blood loss or transfusions. In addition, it is not accurate in the setting of anemia and treatment with erythropoietin, both of which are common in patients with diabetic renal disease.

- **Fasting blood glucose.** Fasting is defined as no caloric intake for at least 8 hours. Without adequate oral intake, glucagon is released from the pancreas, facilitating the release of glycogen stores from the liver and increasing circulating blood glucose levels. Normally, insulin is released, moving that glucose into the cells, preventing hyperglycemia. Without adequate insulin, hyperglycemia results.
- **Two-hour postprandial (after meals) or the oral glucose tolerance test (OGTT).** This test is performed by asking the patient to consume a beverage containing a glucose load, the equivalent of 75 g of carbohydrate, after fasting for 8 to 12 hours. Blood samples are taken prior to consuming the drink to get a fasting level, then again at 1 hour and 2 hours after consumption. The diagnostic value is based on the blood glucose level 2 hours after consumption.
- **Random blood glucose.** A random blood glucose level of greater than or equal to 200 mg/dL in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis may be indicative of diabetes mellitus.

See Table 44.1 for a summary of the diagnostic laboratory values for diabetes.

### Connection Check 44.3

The nurse correlates which laboratory value with the diagnosis of DM?

- Fasting blood glucose greater than 140 mg/dL
- Hemoglobin A1c, 5.8%
- Random blood glucose, 150 mg/dL
- OGTT, 155 mg/dL

**Table 44.1 Laboratory Values Diagnostic for Diabetes Mellitus**

Laboratory Test	Value*	Interpretation
<b>Fasting blood glucose</b>	Greater than or equal to 126 mg/dL	DM
<b>OR</b>	100–125 mg/dL	Prediabetes
<b>2-hr postprandial</b>	Greater than or equal to 200 mg/dL	DM
<b>OR</b>	140–199 mg/dL	Prediabetes
<b>Hemoglobin A1c</b>	Greater than or equal to 6.5%	DM
<b>OR</b>	5.7%–6.4%	Prediabetes
<b>Random blood glucose level</b>	Greater than or equal to 200 mg/dL	DM if accompanied by classic signs/symptoms of hyperglycemia

\*In the absence of unequivocal signs of hyperglycemia, criteria 1 to 3 should be confirmed by repeated testing on a different day. DM, Diabetes mellitus.

### Treatment

Successful treatment of type 1 DM involves several different strategies, including pharmacological interventions, nutrition management, patient education and self-management, and detection and prevention of complications. Nutrition, patient education and self-management, and detection and prevention of complications are similar for both type 1 and type 2 DM and are discussed under the management of type 2 DM section later in this chapter. The focus here is on the pharmacological interventions for type 1 DM.

#### Pharmacological Interventions

The primary pharmacological intervention used in the treatment of type 1 DM is insulin administered subcutaneously. Another insulin option is a newer inhaled version of short-acting insulin that may be used in combination with subcutaneous long-acting or intermediate-acting insulin as basal. Oral administration of insulin is not effective because it is broken down and rendered ineffective during the digestive process. The goal of treatment is to maximize glycemic control, the maintenance of blood glucose levels within normal ranges, in an effort to prevent the complications of hyperglycemia. In setting glycemic goals, it is important to consider that the closer the goals are to normal ranges, the lesser the risk of complications from diabetes. This has been demonstrated in several large, randomized controlled trials, including the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) study and the United Kingdom Prospective Diabetes Study (UKPDS). The

recommended guidelines for setting individualized targets focus on weighing the potential risks of hypoglycemia with the benefits of tight glycemic control. Treatment goals should be determined and reassessed periodically on the basis of patient-specific factors such as health status, adverse medication reactions, adherence to treatment, ability to recognize low blood glucose, and patient preferences. If glycemic goals are not met, the patient should be assessed for knowledge; performance skills; and psychosocial, personal, or financial barriers. See Table 44.2 for definitions of glycemic control.

**Safety Alert** Insulin is a high-risk medication with a narrow therapeutic margin. Tight glycemic control increases the risk of hypoglycemia in patients who rely on insulin and oral agents that stimulate the release of insulin to manage their diabetes. The benefits of tighter glucose control may not outweigh the risks for some patients. This includes patients with a limited life expectancy, those with comorbidities where a hypoglycemic event will have more serious consequences, or those unwilling or unable to do the monitoring necessary to prevent hypoglycemia. This risk is especially pronounced in patients with a tendency toward hypoglycemia, such as older adults, the malnourished, or those with renal or liver disease.

### Blood Glucose Management Plans

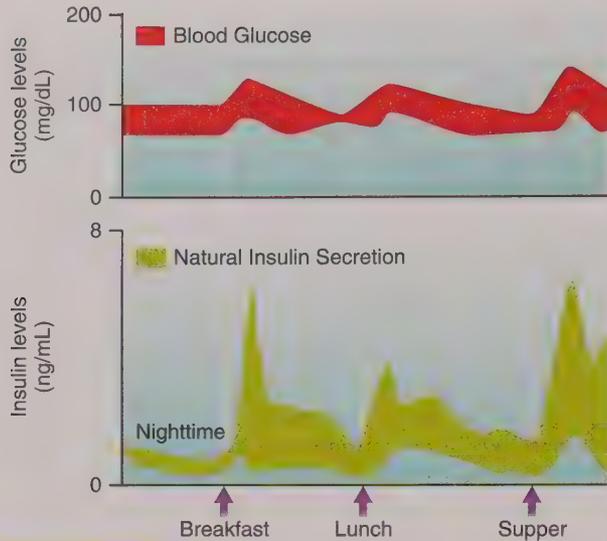

Treatment plans that mimic the response of the healthy pancreas to blood glucose levels during the course of a day (Fig. 44.3) are the most effective at maintaining tight glucose control.

The insulin level is never zero because the healthy pancreas always maintains a basal (minimal) level of insulin throughout the day. At mealtimes, there is a sharp increase in insulin secretion in response to the increase in blood glucose levels. The availability of more modern insulin analogs and insulin pumps makes it possible to more closely mimic the actions of a healthy pancreas, creating a physiological approach to diabetes management. An approach using a combination of long-acting or intermediate-acting insulin once or twice a day to provide **basal insulin** is most effective in maintaining tight glycemic control. These approaches include rapid-acting and short-acting insulin taken at mealtimes to cover the incoming carbohydrates, *prandial insulin* or *nutritional insulin*, and a “sliding scale” of additional supplemental or *correctional insulin* to compensate for blood glucose elevations. The need for correctional insulin is determined by a random blood glucose level done via finger stick immediately prior to eating. The prandial and correctional insulins are then administered at the same time prior to eating. In hospitalized patients with questionable or minimal oral intake, prandial and correctional insulins can be given immediately after the meal to confirm adequate carbohydrate intake. This approach best mimics the way the healthy pancreas releases insulin, but it does require

**Table 44.2 Glycemic Goals**

	American Diabetes Association (ADA)	American Association of Clinical Endocrinologists (AACE)
		<i>All Patients With Diabetes Mellitus:</i>
		Encourage patients to achieve glycemic levels as near normal as possible without inducing clinically significant hypoglycemia.
<b>Fasting</b>	Target fasting or preprandial blood glucose values to a goal of 70–130 mg/dL for an HgbA1c goal of less than 7%.  Target blood glucose readings can be higher or lower depending on individualized HgbA1c goal.	Fasting blood glucose concentration less than 110 mg/dL
<b>2-hour postprandial</b>	Average 2-hour postprandial (after eating) blood glucose value less than 180 mg/dL  The 2-hour postprandial blood glucose can be helpful for adjusting mealtime medications.	2-hour postprandial glucose concentration less than 140 mg/dL
<b>HgbA1c</b>	Lowering HgbA1c to below or around 7% has been shown to reduce the microvascular and neurological complications of type 1 and type 2 diabetes. Therefore, for microvascular disease prevention, the HgbA1c goal for nonpregnant adults in general is less than 7%.	A1c less than or equal to 6.5%

HgbA1c, Glycosylated hemoglobin.

**FIGURE 44.3** Normal pancreatic response to glucose levels during the day. Insulin is released as blood glucose levels rise after meals.

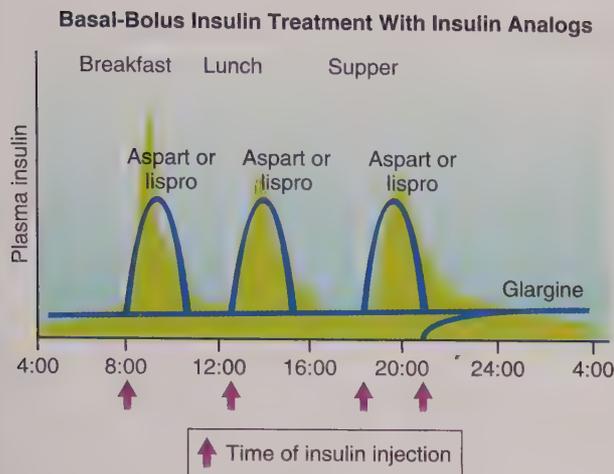

multiple blood glucose evaluations (finger sticks) and injections daily. See Table 44.3 for the various types of insulin and Figure 44.4 for the use of long-acting and rapid-acting insulin to mimic normal pancreatic functioning.

Subcutaneous insulin can be drawn up from a vial and administered via needle and insulin syringe, or it can be administered through an insulin pen (Fig. 44.5) or via an insulin pump. If insulin syringes are used, it is important to match the syringe size to the insulin concentration. The most typical insulin concentration is U-100, which means 100 units of insulin per milliliter. U-100 insulin syringes come in several sizes: 1 mL that holds 100 units, 0.5 mL that holds 50 units, and 0.3 mL that holds 30 units. The patient should choose the insulin syringe size according to his or her insulin dosage. For example, using the small 0.3-mL syringe allows patients who are prescribed very small doses to more accurately draw up their insulin. If insulin requirements are massive because of extreme insulin resistance, a U-500 (500 units per milliliter) insulin

**Table 44.3** Types of Insulin

Brand Name	Onset	Peak	Duration	Purpose
<b>RAPID-ACTING*</b>				
				Prandial insulin used within 0–15 minutes prior to eating or used as correction insulin for blood glucose elevations; used in combination with long-acting insulin
<b>Humalog/Lispro</b>	15–30 min	30–90 min	3–5 hr	Also available in U-200 concentrated form for people requiring larger dosages
<b>NovoLog/Aspart</b>	10–20 min	40–50 min	3–5 hr	
<b>Apidra/Glulisine</b>	20–30 min	30–60 min	1–2.5 hr	
<b>SHORT-ACTING</b>				
				Prandial insulin used for meals eaten within 30 to 60 min after administration; used in combination with long-acting insulin
<b>Regular Humulin/Novolin</b>	30–60 min	2–5 hr	5–8 hr	
<b>INTERMEDIATE-ACTING</b>				
				Covers insulin needs for approximately half the day or overnight; used in combination with rapid-acting or short-acting insulin
<b>NPH</b>	1–2 hr	4–12 hr	18–24 hr	
<b>LONG-ACTING</b>				
				Basal insulin; used in combination with rapid-acting or short-acting insulin
<b>Lantus, Toujeo, and Basaglar/glargine</b>	1–1.5 hr	No peaks or valleys	20–24 hr	Glargine as Toujeo is U-300, three times the concentration for patients on large dosages.
<b>Levemir/Detemir</b>	1–2 hr	No peaks or valleys	24 hr	
<b>Degludec/Tresiba</b>	1 hr	Steady state achieved at 8 days	24–42 hr	The very long half-life helps maintain glycemic control if dosage is late. Also available in U-200 for people who require large dosages.

\*Prandial insulin of choice for both multiple injections and the insulin pump.

**FIGURE 44.4** Basal and bolus insulin therapy. Exogenous insulin is administered to coincide with blood glucose spikes after meals.

concentration is available by special order. In contrast to the insulin syringe and needle, the insulin pen allows the patient to dial in the exact dosage, avoiding the potential errors inherent in measuring and drawing up insulin in the traditional way.

An alternative approach to the administration of insulin is the use of continuous subcutaneous **insulin pumps**. Insulin pumps provide the same delivery of basal and bolus insulin as the multiple-injection technique, but it is provided by a computer-driven device that delivers insulin according to instructions programmed by the patient (Fig. 44.6). The use of the subcutaneous insulin pump has been found to provide better glycemic control, especially in patients with higher hemoglobin A1c levels indicating poor glycemic control with traditional methods. Advantages of the pump include convenience and the ability to deliver more precise dosages. Patients state that it allows a better quality of life and more freedom from the strict restrictions inherent in the traditional insulin administration methods. The disadvantages of insulin pumps are the expense, the need for active participation and learning by the patient in response to glucose levels, the need to “wear” the pump continuously, skin issues around the needle insertion site, and potential complications if the pump malfunctions (see Evidence-Based Practice). A newer form of insulin pump combines continuous glucose monitoring (CGM) with the

insulin pump to form a partial closed-loop system in which the pump automatically makes adjustments to the basal rate based on data from the CGM. The patient still counts carbohydrates, checks the glucose level pre-meal, and makes the insulin decision for the meal amount to be delivered.

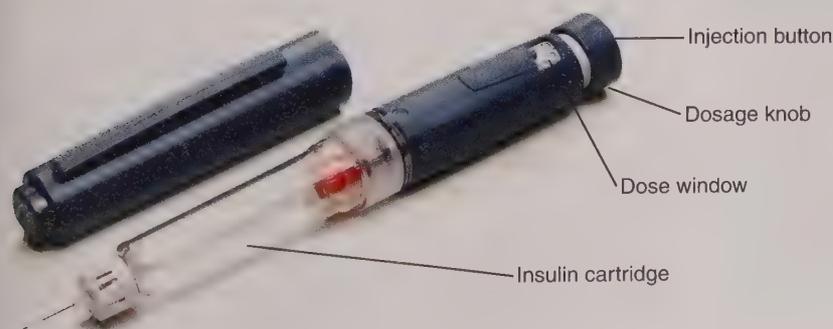

## Evidence-Based Practice

### Psychosocial Factors of Insulin Pump Therapy

Insulin pumps are increasingly being used by patients with type 1 diabetes to manage their disease. This systematic review examined psychosocial facilitators and challenges of insulin pump therapy in patients with type 1 diabetes. An integrative literature review was conducted to evaluate the evidence regarding the psychosocial impact of insulin pumps and included literature from January 2005 to February 2017. The systematic search included the CINAHL, Cochrane, Medline, PsycINFO, and Scopus databases. The psychosocial facilitators identified included flexibility and freedom in daily activities and enhanced social situations. Challenges included the demands of the pump therapy, self-consciousness in wearing the pump, fear of pump failure, and hypoglycemia. The findings of this study can be used by healthcare professionals in teaching and preparing individuals for insulin pump therapy.

Payk, M., Robinson, T., Davis, D., & Atchan, M. (2018). An integrative review of the psychosocial facilitators and challenges of continuous subcutaneous insulin infusion therapy in type 1 diabetes. *Journal of Advanced Nursing*, 74(3), 528–538.

Some patients are unable or unwilling to manage the multiple daily blood glucose evaluations and injections or the insulin pump. An alternative treatment plan is twice-daily finger sticks with twice-daily insulin injections. This does not offer the same possibility of tight glycemic control as the other methods, but it is less complicated and easier to manage. The insulin used is typically a mixture

**FIGURE 44.5** Insulin pen.

**FIGURE 44.6** Insulin pump.

of rapid-acting and long-acting insulin. This insulin can be administered via needle and syringe, or it is also available in an insulin pen. See Table 44.4 for a listing of insulin mixtures.

### Connection Check 44.4

The charge nurse is reviewing orders for a newly admitted patient with type 1 DM. It is a priority for the charge nurse to follow up with the provider about which order?

- NovoLog insulin subcutaneous at bedtime
- NovoLog insulin subcutaneous 15 minutes prior to meals
- Basal insulin subcutaneous at bedtime
- Correctional and nutritional insulin administered immediately after the meal

**Table 44.4** Premixed Insulin

Brand Name	Composition
<b>Humalog 75/25</b>	75% intermediate-acting insulin and 25% rapid-acting (lispro)
<b>Humulin 70/30</b>	70% intermediate-acting insulin and 30% regular insulin
<b>Novolin 70/30</b>	70% intermediate-acting insulin and 30% rapid-acting (aspart) insulin

### Methods for Assessing Glycemic Control

There are three methods of assessing glycemic control. Each method has advantages and drawbacks and should not be used in isolation. The methods are:

- Self-monitoring of blood glucose
- Continuous glucose monitoring
- Monitoring of HgbA1c

#### Self-Monitoring of Blood Glucose

**Self-monitoring of blood glucose** via finger stick (or with some meters, an alternate site) provides a snapshot of blood glucose at a specific instant in time. It can therefore provide timely feedback to the patient about the effect of his or her behavior, health, and eating habits on the blood glucose level. In order for this method to be effective, patients must receive instructions on the accurate testing procedure. The most common patient-related error is an inadequate blood sample size. The patient's technique should be observed by a trained observer on the initiation of the plan of care and also should be reviewed annually or as indicated. Patients should be taught the importance of documenting results. With a record of blood glucose levels, food intake, and medication dosage, a diabetes educator can assist the patient in recognizing and interpreting blood glucose patterns. With this information, the patient can learn to adjust insulin dosing, food intake, or exercise and maximize glycemic control. As patients discover what works and what doesn't, they can gain an important sense of control over their blood glucose levels.

The frequency of self-monitoring of blood glucose in patients using insulin should be individualized on the basis of the frequency of insulin injections, hypoglycemic reactions, level of glycemic control, and patient/provider use of the data to adjust therapy. Generally, patients with type 1 DM are advised to check their blood glucose at a minimum of before meals and at bedtime. Patients on insulin pumps often check more frequently, especially during periods of medication adjustment.

Increased frequency of self-monitoring of blood glucose levels is recommended when:

- Therapy is being initiated or actively adjusted
- There is acute or ongoing illness
- There is hypoglycemia unawareness or an increase in hypoglycemic events
- Fasting and/or postprandial blood glucose levels are not consistent with HgbA1c

#### Continuous Glucose Monitoring

**Continuous glucose monitoring (CGM)** systems use a tiny sensor inserted under the skin to check glucose levels in the interstitial fluid. The sensor stays in place for 7 to 10 days and then is replaced. A transmitter sends information about glucose levels via radio waves from the sensor to a pager-like wireless monitor. Some CGMs require the user to check blood samples with a glucose meter to calibrate the devices. Not every CGM can be used as a replacement for finger-stick blood glucose or used in determining insulin doses. It is

essential that the patient receives education about how to calibrate the device if it is needed and how to interpret the results.

Continuous glucose monitoring devices provide real-time measurements of glucose levels, with levels displayed in 1 to 5 minutes. Users can set alarms to alert them when glucose levels are too low or too high. One form of continuous monitoring is done “on demand” by waving the receiver over the sensor/transmitter and does not have alarms. It is mainly meant to reduce the need for blood glucose sticks. Special software is available to download data from the devices to a computer for tracking and analysis of patterns and trends, and the systems can display trend graphs on the monitor screen. This can provide important information about patterns and trends so that patients can make sense of what is affecting their blood glucose levels. A CGM with alarm functions provides a particular benefit for patients who experience erratic and unpredictable blood glucose drops; the alarm can alert them to take action before the blood glucose drops to dangerous levels.

### Hemoglobin A1c Monitoring

Hemoglobin A1c results should be obtained at least twice a year for patients with diabetes and every 3 months if glycemic targets have not been met or if there are treatment changes.

### Complications

There are many complications related to both type 1 and type 2 DM. The various complications of long-term hyperglycemia are discussed later in the chapter. The focus here is on acute complications, including diabetic ketoacidosis (DKA), hypoglycemia, the dawn phenomenon, and the Somogyi effect.

### Diabetic Ketoacidosis

In **diabetic ketoacidosis (DKA)**, there is inadequate insulin for cells to obtain adequate glucose for normal metabolism. The body attempts to obtain energy by the rapid breakdown of fat stores, releasing fatty acids from adipose tissues. The liver converts the fatty acids into ketone bodies, which can serve as an energy source in the absence of glucose. The ketone bodies, however, have a low pH, resulting in metabolic acidosis. The absence of insulin also results in an increased release of hormones, such as glucagon and cortisol, in response to inadequate glucose transport into the cells. This leads to gluconeogenesis and glycogenolysis, resulting in severe hyperglycemia leading to hyperosmolality and osmotic diuresis, as discussed previously.

The causes of DKA include:

- Intentional or unintentional missed or reduced doses of insulin
- Inadequate insulin due to increased insulin needs secondary to stress or infection
- New onset of type 1 diabetes

**Clinical Manifestations.** Similar to the initial presentation of DM, the initial patient presentation of DKA is

one of polyuria, polydipsia, and polyphagia. The patient becomes dehydrated, and an electrolyte imbalance such as hyperkalemia or hypokalemia may result (see Safety Alert). The increased serum osmolality also results in a shift of fluid from the intracellular to the extracellular space, causing dilutional hyponatremia. The patient is also at risk for hypovolemia secondary to the osmotic diuresis.

Without treatment, the patient abruptly becomes hypotensive and tachycardic because of the volume loss. The patient also develops **Kussmaul respirations**, which are rapid, deep respirations that occur as a compensatory mechanism for the acidosis. There is a fruity, acetone smell to the breath because of the ketone bodies. The patient may complain of nausea and vomiting. Lethargy and coma may ensue without prompt treatment. Figure 44.7 shows the common presenting clinical manifestations of DKA.

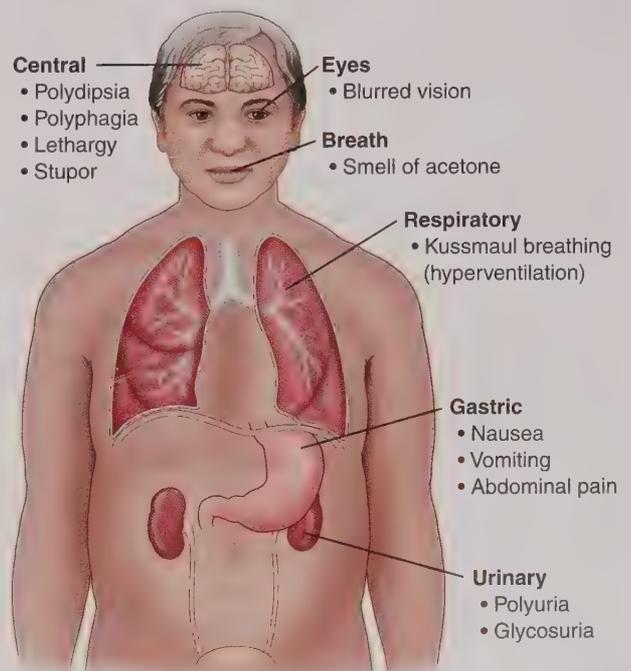

**Diagnosis.** Diagnosis of DKA is based on several factors:

- Blood glucose level greater than 250 mg/dL
- Ketonuria (ketones in the urine)
- Arterial pH of less than or equal to 7.3
- Serum bicarbonate level of less than or equal to 18 mEq/L
- Positive anion gap (Box 44.1)

**Treatment.** Treatment priorities include:

- Fluid replacement with isotonic normal saline
- Correction of electrolyte imbalances, focusing on monitoring and correction of decreased potassium level if necessary, prior to insulin administration
- Insulin administration, usually by intravenous delivery

Fluid replacement with isotonic normal saline is essential to reverse the dehydration that has resulted from the osmotic

**FIGURE 44.7** Clinical manifestations of diabetic ketoacidosis (DKA).

## Box 44.1 Anion Gap

Cations are positively charged ions. The major cations are sodium, potassium, calcium, and magnesium. Anions are negatively charged ions: bicarbonate, chloride, phosphate, and albumin. The anion gap provides an estimation of unmeasured anions in the blood. It is useful in determining the cause of metabolic acidosis. It can also be used as a way of monitoring the response to therapy. The premise of this laboratory analysis is based on the need for electroneutrality in the body; the net positive charge must equal the net negative charge.

The anion gap is calculated using three laboratory values: positively charged sodium, negatively charged chloride, and negatively charged  $\text{HCO}_3^-$ . Positively charged potassium is sometimes added to the calculation, but typically the formula is as follows:

$$\text{Anion gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$$

Serum sodium represents approximately 90% of the extracellular cations. Chloride and  $\text{HCO}_3^-$  represent approximately 85% of the extracellular anions. Because of this, the normal anion gap—the normal amount of unmeasured anions—is positive because the sum of the measured serum anions is smaller than the sum of the measured serum cations or sodium in the formula. The normal value of the anion gap is  $12 \pm 4$ .

If there is an addition of a positively charged acid, the anion gap will be altered. Diabetic ketoacidosis results in an elevated anion gap as a result of the accumulation of acids in the serum. The response to treatment can be monitored through evaluation of the anion gap. As the patient improves, the gap should return to normal.

diuresis. Monitoring and correcting electrolyte imbalances is essential to avoid the dysrhythmias or neurological complications that can occur with potassium and sodium imbalances (see Safety Alert). Insulin administration is necessary to correct the hyperglycemia.

**Safety Alert** Monitoring and correcting potassium imbalances are essential in the treatment of DKA.

Initially, hyperkalemia may be present because of the movement of positively charged potassium ions out of the cell in an effort to maintain homeostasis as positively charged hydrogen ions move into the cell as they accumulate in the extracellular fluid. Hypokalemia then ensues as a result of the loss of extracellular potassium in the urine because of the osmotic diuresis. This results in a severe total body loss of potassium, making the patient susceptible to lethal arrhythmias. Care must be taken to monitor potassium levels prior to treating the hyperglycemia with insulin. As insulin is administered to decrease hyperglycemia, potassium will also move back into the cell, worsening hypokalemia. If hypokalemia is present, potassium replacement is a priority.

## Connection Check 44.5

The nurse correlates which laboratory values with being diagnostic for DKA? (Select all that apply.)

- A. Serum bicarbonate of 18 mEq/L
- B. Negative anion gap
- C. Serum glucose of 350 mg/dL
- D. Positive anion gap
- E. Arterial pH of 7.36

## Hypoglycemia

Hypoglycemia is an important and dangerous complication of the treatment of diabetes. It can present as an acute or even life-threatening emergency due to the potentially devastating effects on the central nervous system. Unlike other tissues of the body that can utilize fatty acids for energy needs, the central nervous system relies solely on glucose for its energy needs. It needs a constant supply to maintain metabolic functioning and avoid cell death.

Hypoglycemia, defined as a blood glucose level of less than 65 mg/dL, results when there is more circulating insulin than is needed to handle the amount of circulating glucose. Surplus insulin can be the result of an overly high dose of insulin administered, overly high dose of the oral agents that stimulate insulin release, or reduced clearance of insulin from the body because of renal insufficiency. Patients are at risk for hypoglycemia when they have a decreased nutritional intake or increased metabolism of glucose through increased exercise. Alcohol can also reduce blood glucose levels by blunting the release of glucose from the liver. Hypoglycemia is more severe when the early signs of low blood glucose are blunted, as in older adults or those who have a change in mental status.

**Clinical Manifestations.** When blood glucose levels drop below normal levels, the body attempts to raise glucose through the stimulation of the sympathetic nervous system and the release of hormones such as epinephrine, norepinephrine, and glucagon. Symptoms include:

- Anxiety
- Hunger
- Palpitations
- Circumoral paresthesia (numbness around lips)
- Sweating
- Shakiness
- Irritability

If blood glucose levels continue to drop, reaching levels where the central nervous system is inadequately supplied with glucose, symptoms include:

- Difficulty thinking
- Dizziness
- Fatigue
- Sleepiness
- Slurred speech
- Weakness/lack of coordination

If untreated and hypoglycemia progresses further, these symptoms can progress to:

- Seizures
- Coma

If hypoglycemia occurs frequently, the body can lose the early warning signals of sympathetic nervous symptoms. If patients have the accompanying “hypoglycemia unawareness,” they will not experience symptoms of low blood glucose until their blood glucose levels fall to the point where the patients are at risk of neurological symptoms. They are then at risk of severe effects such as confusion or loss of consciousness. Individuals with hypoglycemia unawareness should be advised to raise their glycemic targets to strictly avoid further hypoglycemia for at least several weeks to partially reverse hypoglycemia unawareness and reduce the risk of further episodes.

**Management of Hypoglycemia.** The primary management technique consists of the administration of glucose to raise serum glucose levels. Oral glucose (15–20 g) administration is the preferred treatment for the conscious individual with hypoglycemia, although any form of rapidly absorbed carbohydrate may be used. Juice, soda, honey, jelly, bread, or crackers work well. Carbohydrates that contain fat, such as ice cream or chocolate, are not recommended. Pure glucose is the preferred treatment because fat may retard glucose absorption, prolonging the acute hypoglycemic event. After ingestion of carbohydrate, blood glucose levels should be measured within 15 minutes. If blood glucose levels continue to reflect hypoglycemia after treatment, the treatment should be repeated. Once glucose levels return to normal, the individual should consume a meal or snack to prevent the recurrence of hypoglycemia.

In the hospital setting, if a patient is unable to swallow or absorb oral carbohydrates but has IV access, IV dextrose, 25 to 50 mL of 50% dextrose solution (D50), should be administered. If there is no IV access and the patient is unable to swallow or absorb oral carbohydrates, 1 mg of intramuscular glucagon injection should be administered. Glucagon mobilizes glucose release from stores in the liver.

Glucagon administration is not limited to healthcare professionals. Severe hypoglycemia, where the individual requires assistance from another person and cannot be treated with oral carbohydrates because of confusion combined with the inability to swallow or unconsciousness, should be treated with glucagon. It should be prescribed for all individuals at risk of severe hypoglycemia, and caregivers or family members should be instructed in its administration. Instructions should include calling for emergency help if the glucagon injection is administered and turning the patient on his or her side to avoid aspiration because a side effect of glucagon is nausea and vomiting.

## Connection Check 44.6

The nurse should intervene immediately if a patient has which blood glucose level?

- 200 mg/dL
- 150 mg/dL
- 80 mg/dL
- 40 mg/dL

### *Dawn Phenomenon and Somogyi Effect*

The **dawn phenomenon** and **Somogyi effect** are two other complications of DM that result in increased blood glucose levels in the early morning. They occur more commonly in the patient with type 1 diabetes but are also known to occur in patients with type 2 diabetes. The increased blood glucose levels of the dawn phenomenon result from the naturally occurring release of hormones, such as glucagon, cortisol, and growth hormone, in the early morning. Because the body does not have sufficient insulin to control this glucose surge, blood glucose levels rise. This is most likely reflected in higher fasting blood glucose levels in the morning.

The Somogyi effect is much less common than the dawn phenomenon and results in increased blood glucose levels due to an excessive insulin dosage at night. This can occur in a patient who experiences unrecognized low glucose during the night while sleeping. In that circumstance, blood glucose levels drop, and the body responds in the same way as in the dawn phenomenon, releasing growth hormone, cortisol, and catecholamines in an effort to increase blood glucose by releasing glucose stores from the liver. As stated, both complications result in higher-than-normal blood glucose levels in the morning.

In order to determine what is causing the increased blood glucose levels in the morning, the patient needs to check blood glucose levels in the early morning hours, 2 or 3 a.m., for several nights. If the blood glucose level is low at that early morning time, the high glucose levels later in the morning are most likely due to the Somogyi effect. If the blood glucose level is high or normal at that early morning hour, the increased levels later in the morning are most likely due to the dawn phenomenon.

### *Nursing Management of Type 1 DM*

#### **Assessment and Analysis**

The clinical manifestations of type 1 DM are due to the hyperglycemia that results from a lack of insulin secreted by the pancreas. Patients present with polyuria and polydipsia, as well as hemoconcentration in the blood secondary to the increased glucose in the urine, or glucosuria. Both situations create osmotic shifts in fluid, either from the intracellular space to the vascular space or from the renal tubules into the urine. The resultant volume loss triggers the thirst center in the brain, creating polydipsia. Excessive hunger (polyphagia) and fatigue are due to the inability to utilize

glucose for cellular metabolism, resulting in the breakdown of fats and proteins.

### Nursing Diagnoses

- **Impaired tissue perfusion** related to decreased cardiac output secondary to osmotic diuresis
- **Risk for neurological impairment** related to hypoglycemia

### Nursing Interventions

#### Assessments

- **Vital signs**  
*Decreased blood pressure and increased heart rate are secondary to the fluid volume deficit created by the osmotic diuresis related to hyperglycemia. Increased respiratory rate, Kussmaul breathing, or hyperventilation with fruity breath odor may be evident in DKA in an effort to compensate for the metabolic acidosis.*
- **Serum glucose**  
*Increased glucose levels are due to the lack of secretion of insulin from the pancreas. In a patient already diagnosed with and being treated for type 1 diabetes, increased glucose levels indicate:*
  - Inadequate or lack of insulin administration
  - Increased insulin requirements due to stress, such as infection, causing the adrenal release of catecholamines, increasing the hepatic production of glucose*Decreased glucose levels caused by inappropriate insulin administration, such as too much insulin or insulin given while the patient has inadequate PO intake, can lead to lethargy and coma or death. The brain uses only glucose for cellular metabolism, so it is severely affected by decreased glucose levels.*
- **Potassium levels**  
*Potassium levels may be decreased because of the increased volume loss through the kidneys or increased because of the shift of the positively charged potassium out of the cell in an effort to maintain homeostasis when positively charged hydrogen ions move into the cell in the face of acidosis.*
- **Intake and output**  
*Increased urine output may be present because of osmotic diuresis secondary to hyperglycemia.*
- **Carbohydrate intake at meals**  
*Adequate carbohydrate intake at meals is essential to avoid hypoglycemia related to insulin administration.*

#### Actions

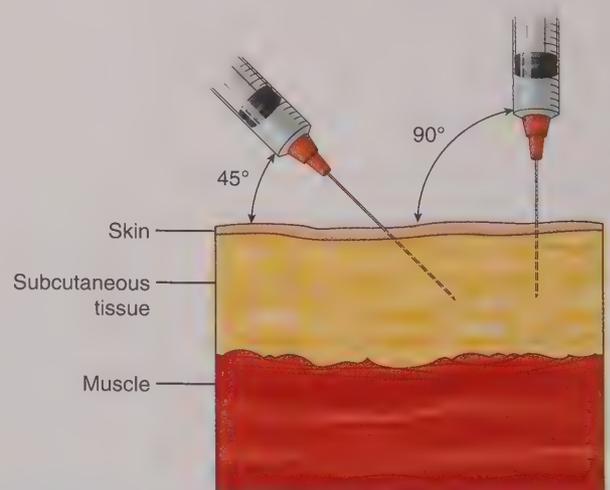

- **Bedside glucose monitoring (finger sticks)** done before meals and at bedtime  
*Regular finger sticks are done to measure the adequacy of glucose control.*
- **Administer insulin as ordered.**
  - Basal
  - Preprandial
  - Correctional*Administering rapid-acting insulin before meals, preparing for ingestion of carbohydrates, and correcting for random high glucose levels as determined by self-monitoring*

*of blood glucose prior to the meal, in combination with longer-acting insulin once a day, will mimic the action of a healthy pancreas, helping to maintain tight glycemic control. In patients with questionable or minimal oral intake, prandial and correctional insulins may be administered together after meals after adequate carbohydrate intake has been confirmed.*

- Administration of isotonic IV fluids as ordered  
*Intravenous fluids may be necessary to replace the volume lost as a result of osmotic diuresis.*

#### Teaching

- **Signs of hypoglycemia and hyperglycemia**  
*It is important that the patient (and family) is able to detect early signs of both hypoglycemia (the underlying disorder that can progress to coma or death) and hyperglycemia secondary to inadequate insulin administration.*
- **Subcutaneous insulin administration:**
  - Common sites that provide good absorption (starting with the area of best absorption) include the abdomen, upper arm, thigh, and buttocks.
  - Subcutaneous injection technique  
*To ensure injection into the subcutaneous tissue, pinch the skin at the injection site and insert the needle straight in at a 90-degree angle. If the patient is very thin with very small amounts of subcutaneous tissue, the needle should be inserted at a 45-degree angle (Fig. 44.8).*
  - Syringe size  
*Choose the syringe size (1 mL, 0.5 mL, 0.3 mL) that best matches your insulin dose. The smaller syringes allow for more accurate measurement of smaller insulin dosages. If available, an insulin pen can be used and instructions given to the patient on accurate use and storage.*
  - Rotating sites  
*Insulin is administered subcutaneously. It is a protein substance. If taken orally, it is broken down in the*

**FIGURE 44.8** Subcutaneous injection angles. Subcutaneous injections are usually inserted at a 90-degree angle. In very thin patients with small amounts of subcutaneous tissue, the needle is inserted at a 45-degree angle.

gastrointestinal tract, rendering it useless. Rotating sites helps decrease lipohypertrophy (fat deposits in the skin) or lipoatrophy (loss of fatty tissue). Rotating sites within one area rather than moving from area to area helps decrease absorption variability from day to day. This can be done by injecting a new shot at least an inch away from the last injection site (Fig. 44.9).

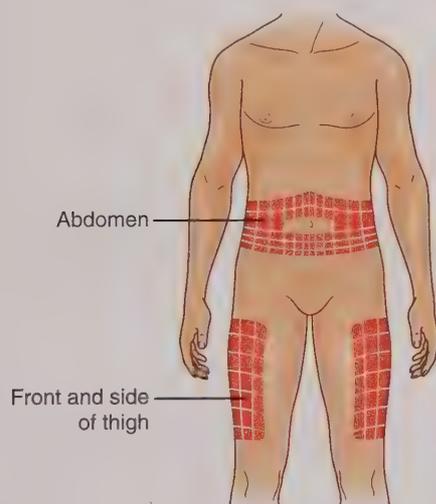

- Infection control  
Immediately discard used syringes and needles; use a new needle for each dose.
- Medication education  
Lifelong insulin administration is required for cellular metabolism. Increased stress, infection, activity level, increased ingestion of carbohydrates, and decreased PO intake all alter insulin requirements.
- Regular blood glucose monitoring via finger sticks or alternate site testing if appropriate  
Regular checks help determine the adequacy of insulin dosage and maintain glycemic targets. Continuous glucose monitoring may be an option for the patient requiring

more glucose information or to reduce the number of finger sticks.

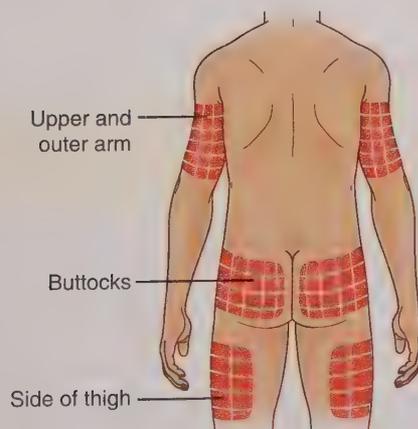

- Healthy lifestyle that includes diet and exercise (see section later in chapter on diet and exercise)  
Healthy lifestyle choices are essential components in the management of DM to help avoid or postpone the development of complications.

### Evaluating Care Outcomes

The patient with type 1 DM can lead a long and healthy life with strict adherence to the treatment regimen and good self-management skills. The tight glycemic control necessary to avoid the complications associated with DM is best achieved through active monitoring of blood glucose levels and treatment with insulin as indicated. Nutrition, patient education, self-management, and detection and prevention of complications are essential components of successful daily management of DM. The involvement of significant people in the patient's life and attention to cultural preferences will help lead to success.

Front

Back

FIGURE 44.9 Subcutaneous insulin injection sites.

### Connection Check 44.7

The nurse recognizes that blood glucose monitoring before meals and at bedtime is done to achieve which outcomes? (Select all that apply.)

- Maintain glycemic control
- Prevent complications of long-term hyperglycemia
- Facilitate insulin administration that mimics the healthy pancreas
- Provide frequent practice with the finger-stick technique
- Prevent acute complications of type 1 diabetes

### CASE STUDY: EPISODE 2

Mrs. Simpson is a 63-year-old African American female with a history of type 2 DM admitted for unstable angina. She is now 4 days postoperative following a triple cardiac bypass. Her laboratory values are an elevated creatinine of 2.2 mg/dL; glomerular filtration rate (GFR) of 27 mL/min/1.73 m<sup>2</sup>; white blood cell (WBC) count elevated at 12.5 10<sup>3</sup>/mm<sup>3</sup>; and a blood glucose of 220 mg/dL, indicating the presence of infection and the beginnings of renal insufficiency. Her vital signs are within normal limits except for an elevated temperature of 100.5°F (38°C). Blood and urine cultures are sent to the laboratory, and she is started on broad-spectrum antibiotics. Her blood glucose level is increased because of the infection, requiring increased insulin coverage. Intravenous fluids are maintained to preserve urine output. Her renal function is closely followed with daily laboratory assessments...

## TYPE 2 DIABETES MELLITUS

### Epidemiology

#### Prevalence

There is a growing epidemic of type 2 diabetes in the United States. In 2000, the overall prevalence of DM was approximately 3% of the population. In 2017, the Centers for Disease Control and Prevention (CDC) estimated that diabetes affects 9.4% of the population in the United States. In adults, type 2 DM accounts for about 90% to 95% of all diagnosed cases; thus, it is far more common than type 1 DM.

Type 2 DM is more common in adults than in juveniles and was called adult-onset diabetes in the past. It is becoming more common in juveniles because of the increased levels of obesity and increased levels of inactivity in young people today. In children, the age of onset of type 2 DM is typically 10 to 19 years old. It is present in all ethnic groups but is more common in nonwhite groups such as American Indians, with a prevalence of 4.5 per 1,000. The prevalence in African Americans and Caucasians is 7.2 per 100,000.

#### Risk Factors

Risk factors for type 2 DM involve both genetics and lifestyle. There is a strong hereditary predisposition to type 2 DM, but there are also many modifiable risk factors.

Modifiable risk factors for type 2 DM include:

- Body mass index (BMI) greater than 26 kg/m<sup>2</sup>; increased risk with BMI greater than 30 kg/m<sup>2</sup>
- Physical inactivity
- High-density lipoprotein (HDL) cholesterol level less than or equal to 35 mg/dL (0.90 mmol/L) and/or a triglyceride level greater than or equal to 250 mg/dL (2.82 mmol/L)
- **Metabolic syndrome** (Box 44.2)

Nonmodifiable risk factors include:

- First-degree relative with diabetes
- Members of a high-risk ethnic population (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
- Women who delivered a baby weighing greater than or equal to 9 lb or who were diagnosed with gestational diabetes
- Hypertension ( $\geq 140/90$  mm Hg or on therapy for hypertension)
- Women with polycystic ovary syndrome
- HgbA1c greater than or equal to 5.7% on previous testing
- History of cardiovascular disease

A condition called **prediabetes** is a warning sign for the development of type 2 DM. This is defined by blood glucose levels higher than normal but not high enough to be considered diabetes. It is an indication that type 2 DM may develop if certain lifestyle changes, the same changes or risk factors related to the development of type 2 diabetes,

## Box 44.2 Metabolic Syndrome

Metabolic syndrome is a cluster of risk factors for both cardiovascular disease and type 2 diabetes. These risk factors include resistance to the action of insulin, hypertension, high cholesterol or low high-density lipoprotein, and hypercoagulability. Most often, patients who meet the criteria for metabolic syndrome are overweight. A patient is considered to have metabolic syndrome if three of the following traits are present:

- Abdominal or central obesity
- Increased serum triglycerides greater than or equal to 150 mg/dL
- Decreased high-density lipoprotein less than or equal to 40 mg/dL in men; less than 50 mg/dL in women
- Hypertension greater than or equal to 130/85 mm Hg
- Fasting blood glucose greater than 100 mg/dL

Patients who meet the criteria for metabolic syndrome need to seriously address these modifiable risk factors in an effort to avoid the debilitating effects of cardiovascular disease or type 2 diabetes; healthy diet and exercise are essential.

are not made. Obesity and sedentary lifestyle play a strong role. Table 44.1 notes the fasting blood glucose, 2-hr postprandial, and HgbA1c values consistent with prediabetes.

### Connection Check 44.8

The nurse is screening patients for the risk of developing type 2 DM. The nurse should consider which patients at risk? (*Select all that apply.*)

- Women with a history of gestational diabetes
- Women with a history of multiple births
- Men with a history of pancreatic cancer
- Men who are overweight or obese
- Men and women with cardiovascular disease

### Pathophysiology

Type 2 DM involves defects at the cell membrane that prevent the normal action of insulin. Even though insulin is present, the cell “resists” its effect in transporting glucose into the cell. Because of this, insulin resistance develops that requires increased levels of insulin in order to drive glucose into the cells. Over time, the pancreas cannot keep up with the increased demand for insulin; beta-cell failure appears and progresses. Toward the later stages of type 2 DM, insulin production declines significantly so that approximately 30% of patients with type 2 DM eventually require exogenous insulin delivery to maintain normal blood glucose levels.

### Connection Check 44.9

The nurse recognizes which of the following statements as correct in relation to the pathophysiology of type 2 DM? (Select all that apply.)

- A. It is due to a relative lack of insulin.
- B. It is due to insulin resistance.
- C. It is due to an absolute lack of insulin.
- D. It remains stable over time.
- E. It is due to an autoimmune process that destroys the beta cells of the pancreas.

### Clinical Manifestations

Type 2 diabetes mellitus typically has a slower onset than type 1 diabetes. In addition to the three “Ps” of type 1 diabetes—polyuria, polydipsia, and polyphagia—other common clinical manifestations include the following:

- Fatigue
- Poor wound healing
- Cardiovascular disease
- Visual disturbances
- Renal insufficiency
- Recurring infection

For example, recurring yeast infections in women with diabetes may indicate poorly controlled blood glucose levels. Yeast cells are normally occurring flora in the vagina. They are kept in check by the acidic environment present in the vagina. In diabetes, vaginal secretions have more glucose, which produces a nourishing environment for yeast, allowing them to grow and multiply, causing an infection.

Many of these manifestations are due to the microvascular and macrovascular complications of long-term hyperglycemia that are discussed later in the chapter under complications.

### Management

#### Medical Management

##### Diagnosis

The diagnosis of type 2 DM is done through evaluation of the same laboratory analyses as type 1 DM: HgbA1c levels, fasting blood glucose levels, 2-hr postprandial blood levels, and random blood glucose levels (see Table 44.1). The differentiation between type 1 and type 2 is based more on the situation present at the time of diagnosis rather than on the specific laboratory values. For example, hyperglycemia noted in a physically inactive, overweight adult (BMI >30 kg/m<sup>2</sup>) whose blood glucose is initially controlled with oral medications is diagnosed as type 2 diabetes even if insulin is eventually required. This is in contrast to the hyperglycemia noted in a physically active child requiring insulin injections at onset to maintain glycemic control (type 1 diabetes) or the

mother diagnosed with gestational diabetes during pregnancy whose blood glucose levels remain high post-delivery and who is diagnosed with type 2 diabetes. If insulin antibodies were checked, a person with type 2 would be negative, but someone with type 1 diabetes has a strong likelihood of being positive.

#### Treatment

The treatment of type 2 DM involves a combination of pharmacological interventions and self-management that includes:

- Education
- Monitoring glycemic control
- Nutrition
- Exercise
- Monitoring for complications

#### Pharmacological Interventions

Pharmacological interventions for type 2 DM include oral medications that increase the production of insulin, lower insulin resistance, slow the absorption of carbohydrates, or help lower blood glucose (Table 44.5). These medications are typically used in combination because of their different mechanisms of action. The combination used depends on the patient’s response, with the goal of achieving and maintaining glycemic targets. Intervention at the time of diagnosis with metformin (Glucophage), in combination with lifestyle changes such as diet and exercise, is common. Continuing, timely augmentation of therapy with additional agents, including early initiation of insulin therapy, as a means of achieving and maintaining levels of glycemic control (i.e., HgbA1c <7% for most patients) is recommended.

Another potential medication combination is the use of an oral medication in conjunction with a glucagon-like peptide-1 (GLP-1) receptor agonist. Glucagon-like peptide-1 agonists are incretin mimetics that are injected subcutaneously either once a week or daily depending on the formulation. They lower glucose levels by slowing glucose absorption from the intestine, increasing insulin secretion when blood glucose levels are high and lowering the high glucagon levels sometimes found in people with diabetes after meals. Another side benefit of GLP-1 agonists is the action of decreasing appetite by attaching to an appetite receptor on the hypothalamus, ultimately helping with weight loss.

Many patients with type 2 DM will eventually require insulin therapy because of the typical progressive loss of beta-cell function with the progression of the disease. Initiation of insulin at the time of diagnosis is recommended for individuals presenting with weight loss or other severe hyperglycemic clinical manifestations. Initiation of insulin is also recommended for any patient with an HgbA1c greater than 10%. Patients with type 2 DM can utilize insulin alone or in combination with noninsulin agents. They may be able to maintain glycemic control with one injection a day of basal insulin in combination with an oral agent(s).

**Table 44.5 Oral Glucose Control Agents**

Medication Class	Mechanism of Action	Dosing	Precautions
<b>Biguanides</b> ( <i>metformin</i> )	Decrease glucose production in the liver; increase insulin sensitivity in skeletal muscle	Taken two times a day	Caution in patients with renal impairment; may cause diarrhea
<b>Sulfonylureas</b>	Stimulate the beta cells to produce more insulin	Typically taken once or twice a day	Risk of hypoglycemia
<b>Meglitinides</b>	Stimulate the beta cells to produce more insulin	Taken three times a day before meals	Risk of hypoglycemia
<b>Thiazolidinediones</b>	Decrease glucose production in the liver; increase insulin sensitivity in skeletal muscle	Taken once daily	May increase risk of heart failure; monitor for liver toxicity.
<b>Alpha-glucosidase inhibitors</b>	Slow the breakdown and absorption of sugars and starches	Taken with the first bite of each meal	May cause diarrhea and flatulence. If the patient experiences hypoglycemia, must correct with dextrose or glucose due to slowed absorption of carbohydrates.
<b>DPP-4 inhibitors</b>	Prevent the breakdown of naturally occurring GLP-1, a compound that stimulates insulin release from the pancreas	Taken once daily	May cause nasopharyngitis
<b>SGLT-2 inhibitors</b>	Lower the renal threshold for glucose excretion with blood glucose lowering and weight loss.	Taken once daily	Indicated for people with type 2 diabetes  Increase risk of urinary tract and genital infections  Reported cases of DKA and acute kidney injury

*DPP-4*, Dipeptidyl peptidase-4 (DPP-4) inhibitors; *GLP-1*, glucagon-like peptide-1.

However, if the hyperglycemia persists or if the pattern of hyperglycemia shows that they have consistent significant hyperglycemia following meals but not overnight, they may require the addition of prandial insulin as well or adjustment of the other diabetes medications. Increasing numbers of patients with type 2 DM who use prandial and basal insulin are beginning to utilize insulin pumps.

### Connection Check 44.10

A nurse is reviewing orders for patients newly diagnosed with type 2 DM. What initial medication orders should be anticipated?

- Metformin PO twice a day
- Nutritional insulin subcutaneously prior to meals
- Basal insulin subcutaneously before bed
- Correctional insulin subcutaneously after meals

### Self-Management

Management of both type 1 and type 2 DM cannot be successful without the individual patient's commitment to

behaviors and lifestyle choices on an ongoing basis. Patient behavior strongly impacts hyperglycemia, with education and self-management being critical to successful outcomes. This involves more than adherence to potentially complicated pharmaceutical regimens. It also involves education, meal planning, exercise, self-monitoring of blood glucose, and adherence to a screening program for complications. The information that follows on monitoring glycemic control, education, nutrition, and exercise applies to type 1 and type 2 DM, as well as the management of diabetes in general.

**Diabetes Self-Management Education.** The goal of diabetes self-management education (DSME) is to empower the person with DM to take responsibility for day-to-day management. It provides the patient with strategies to establish and maintain a healthy lifestyle. According to national standards, all people with diabetes should receive DSME when their diabetes is diagnosed. Education should be individualized and tailored to the patient's needs. Once he or she has completed the initial education, behavioral goals should be set and a follow-up visit schedule planned by the healthcare team and patient. Continuing education may be necessary depending on the patient's needs. Medicare, medical assistance, and most private insurance

reimburse for DSME if it takes place in a program that has been accredited by the American Diabetes Association (ADA) or American Association of Diabetes Educators and is implemented by an interprofessional team. To be accredited, the program must cover:

- Describing the diabetes disease process and treatment options
- Incorporating nutritional management into the lifestyle
- Incorporating physical activity into the lifestyle
- Using medication(s) safely and for maximum therapeutic effectiveness
- Monitoring blood glucose and other parameters and interpreting and using the results for self-management decision making
- Preventing, detecting, and treating acute complications
- Preventing, detecting, and treating chronic complications
- Developing personal strategies to address psychosocial issues and concerns
- Developing personal strategies to promote health and behavior changes

A related objective from *Healthy People 2020* is as follows:

- Increasing the proportion of persons with diagnosed diabetes who receive formal diabetes education

### Monitoring Glycemic Control

As in type 1 diabetes, assessment of glycemic control is important for several reasons. It allows the provider to determine the effectiveness of treatment and to plan adjustments to medication and follow-up. For the diabetes educator, assessment of glycemic control highlights problem areas in patient self-management so that exploration of patient understanding and appropriate education can occur. Perhaps most importantly, if used in the context of appropriate education and follow-up, it provides feedback to the patient about what is and is not working in the overall treatment plan. As noted earlier in the discussion of type 1 diabetes, glycemic control is assessed through:

- Self-monitoring of blood glucose
- Continuous glucose monitoring
- Monitoring of HbA1c

See Table 44.2 for glycemic control targets.

### Medical Nutrition Therapy

The major goal of medical nutritional therapy is to improve metabolic outcomes by modifying nutrient intake. For patients with diabetes mellitus, approaching normal ranges for blood glucose, blood pressure, and lipids slows the development of each of the chronic complications of diabetes. Meal composition affects glycemic control and cardiovascular risk, so assisting the patient in understanding food choices is an essential piece of diabetes self-management. In addition, deciding what to eat is one of the most common questions asked by patients with diabetes and causes anxiety

and misunderstanding in many situations. Working with a professional to understand and feel comfortable with food choices contributes to improving compliance with an overall diabetes care plan. Individual nutritional guidelines are based on a patient assessment that includes food intake, focusing on carbohydrates; medications; metabolic control (glycemia, lipids, and blood pressure); measurements of height, weight, and body composition; and physical activity.

**Carbohydrate Guidelines.** Monitoring carbohydrate intake through carbohydrate counting (Box 44.3), exchanges, or experience-based estimation is a key strategy in achieving glycemic control. In insulin-deficient patients, insulin doses should be adjusted to match carbohydrate intake, the insulin-to-carbohydrate ratio. Basal-bolus insulin therapy in conjunction with carbohydrate counting is the most physiological treatment and provides the greatest flexibility in terms of food choices and timing of meals. Patients on insulin who are unwilling or unable to count carbohydrates should use a consistent carbohydrate meal plan.

### Box 44.3 Carbohydrate Counting

Carbohydrate counting is a technique useful for managing blood glucose levels. Understanding what foods contain carbohydrate, which raises the blood glucose level, and tracking carbohydrate intake help maintain glycemic targets. Carbohydrate intake recommendations are individualized on the basis of patient size, activity, and medication use. The successful use of this technique requires an understanding of what foods contain carbohydrates and how many carbohydrates they contain.

Foods that contain carbohydrates are:

- Starchy foods and vegetables such as bread, cereal, rice, crackers, potatoes, pasta, dried beans, and corn
- Fruit and juice
- Milk and yogurt
- Sweets and sodas, juice drinks, cakes, cookies, candy, and potato chips
- Nonstarchy vegetables such as greens, carrots, green beans, cucumbers, peppers, broccoli, cabbage, asparagus, mushrooms, onions, and eggplant contain carbohydrates but in much smaller quantities than starchy foods. These are great foods for increasing the quantity in a meal without impacting the glucose as much.

The amount of carbohydrate in food can sometimes be determined by reading labels. If estimating, the following are some examples of foods that contain approximately 15 g of carbohydrate:

- 1 small piece of fresh fruit (4 oz)
- 1 slice of bread (1 oz)
- 1/2 cup of oatmeal
- 1/3 cup of pasta or rice
- 4 to 6 crackers
- 1/2 English muffin or hamburger bun
- 1½ cups of green beans

Carbohydrates should be distributed throughout the day in small meals and snacks. If persons with diabetes choose to consume products containing nonnutritive sweeteners, they should be consumed at levels that do not exceed the acceptable daily intakes. Some of these products contain energy and carbohydrates from other sources that need to be accounted for in the total daily carbohydrate intake. For patients managing their diabetes through diet alone or taking glucose-lowering medications or fixed insulin doses, meal and snack carbohydrate intake should be kept consistent on a day-to-day basis. See Table 44.6 for specific dietary guidelines.

### Weight Control

Many individuals with DM are overweight and have insulin resistance. Nutrition therapy often begins with strategies that reduce food intake and increase energy expenditure through physical activity. For patients who are overweight or obese, moderate weight loss (5%–10% of body weight) is associated with significant improvement in insulin resistance, as reflected in metabolic parameters such as blood glucose, blood pressure, and lipid levels. Weight control and diet are essential components of DM management to lower glucose levels and to reduce the risk for cardiovascular disease. Cardiovascular risk is lowest when the BMI is less than 25 kg/m<sup>2</sup>. For weight control, patients must balance lower fat and calorie consumption with regular physical activity of 30 minutes on most days.

### Physical Activity Recommendations

Both aerobic training and resistance training improve glycemic control. Physical activity also improves insulin sensitivity, blood pressure, and the lipid profile and decreases risks for cardiovascular disease and all-cause mortality. It also helps in the management of depressive symptoms and improves sleep quality. People with diabetes should be advised to perform at least 150 minutes per week of moderate-intensity activity (50%–70% of maximum heart rate) and strength training three times per week, unless contraindicated. Before beginning a program of physical activity more vigorous than brisk walking, people with diabetes should be assessed by a healthcare provider for conditions that might be associated with an increased risk of cardiovascular disease. Of concern are uncontrolled hypertension, severe autonomic or peripheral neuropathy, and proliferative or proliferative retinopathy or macular edema. In previously sedentary patients whose 10-year risk of a coronary event is likely to be greater than or equal to 10%, a graded exercise test with electrocardiogram monitoring is recommended. In individuals taking insulin or insulin secretagogues (medications that facilitate the release of insulin), physical activity can cause hypoglycemia if the medication dose or carbohydrate intake is not adjusted. Carbohydrate should be ingested if pre-exercise blood glucose levels are less than 100 mg/dL.

**Table 44.6 Dietary Guidelines**

Food	Guidelines
<b>Carbohydrates</b>	Individualized from a starting point of approximately 45–60 g per meal. Snacks should be <20 g.
<b>Sucrose (table sugar)</b>	If persons with diabetes choose to eat foods containing sucrose, the sucrose-containing foods should be substituted for other carbohydrate foods. Sucrose-containing foods should be eaten in the context of a healthy diet, without excess calorie intake. Labels should be read for “total carbohydrate” content and not just for “sugar” or “sucrose.”
<b>Protein</b>	In persons with diabetes and normal renal function, the recommendation for a usual protein intake of 15%–20% of daily food intake does not need to be changed.  In persons with diabetic nephropathy, referral should be made to dietitians for individualized meal planning.
<b>Fiber</b>	A wide variety of fiber-containing foods, such as legumes, fiber-rich cereals, fruits, vegetables, and whole-grain products, is encouraged. Aim for fiber amounts of 25–50 g per day.
<b>Dietary fat</b>	Total dietary fat should generally comprise less than 30% of daily food intake.  Dietary saturated fat should be limited to less than 7% of daily food intake. Substitution of monosaturated fats for saturated is encouraged.  Trans fats (trans fatty acids) should be eliminated.
<b>Alcohol</b>	If adults with diabetes choose to use alcohol, daily intake should be limited to a moderate amount (one drink per day or less for adult women and two drinks per day or less for adult men). A drink is defined as 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof distilled spirits.  Alcohol depresses the release of carbohydrate from the liver and can lower blood glucose. To reduce the risk of hypoglycemia, alcohol is best consumed with food. Check glucose to determine impact of alcohol on blood glucose levels.

### Psychosocial Assessment and Care

People with diabetes have a depression rate that is more than twice the rate of people without diabetes. Depression has been identified as one of the most common factors involved in nonadherence to a diabetes treatment plan. The psychosocial assessment should be included as an ongoing part of medical management. Consider a referral to a behavioral specialist if psychosocial issues are a concern.

### Monitoring for and Managing Complications

Because the underlying pathophysiology of hyperglycemia involves damage to blood vessels, vascular health and protection are key to avoiding devastating end-organ damage by diabetes. The lifestyle cornerstones of maintaining a healthy weight, healthy eating, and regular exercise improve all diabetes outcomes. In addition to reaching glycemic goals, essential components of vascular health in diabetes include the management of hypertension, hyperlipidemia, and hypercoagulability (antiplatelet treatment) and smoking cessation. In addition to monitoring glycemic control, routine monitoring should also include regular laboratory analysis of coagulation profiles, lipid profiles, renal studies, and dilated eye examinations. Routine monitoring of the skin and feet is essential to avoid wounds and infection, which can potentially lead to amputation.

### Connection Check 44.11

The nurse is providing care for a patient newly diagnosed with type 1 diabetes. Which lifestyle modifications need to be included in the plan of care?

- Limiting exercise, carbohydrate counting, self-monitoring of blood glucose
- Distributing carbohydrate intake throughout the day, controlling weight, limiting alcohol
- Carbohydrate counting, self-monitoring of blood glucose, healthcare provider visits as needed
- Limiting protein intake, distributing carbohydrate intake throughout the day, regular healthcare provider visits

### Complications

#### Hyperosmolar Hyperglycemic State

**Hyperosmolar hyperglycemic state (HHS)** is a serious metabolic derangement that occurs in patients with DM. The condition is characterized by hyperglycemia, hyperosmolality, and dehydration without significant ketoacidosis. It occurs when there is sufficient insulin to prevent rapid fat breakdown and ketone release. However, there is not enough insulin to prevent severe hyperglycemia. Blood glucose levels can rise to extremes above 600 mg/dL. The resulting extreme hyperosmolality leads to osmotic diuresis. Dehydration can be profound and electrolyte

imbalances severe. Along with dehydration, most patients present with global neurological defects.

It is less common than the other acute complication of DM, diabetic ketoacidosis (DKA), and differs in the magnitude of dehydration, ketosis, and acidosis. Hyperosmolar hyperglycemic state usually presents in older patients with type 2 DM and carries a higher mortality rate than DKA, estimated at approximately 10% to 20%. Hyperosmolar hyperglycemic state most commonly occurs in patients who have some concomitant illness that leads to reduced fluid intake. Infection is the most common preceding illness. Once HHS has developed, it may be difficult to differentiate it from the preceding illness. The diagnosis of HHS is based on the following:

- Blood glucose level of 600 mg/dL or greater
- Serum osmolality of 320 mOsm/kg or greater
- Profound dehydration
- Serum pH greater than 7.4
- Bicarbonate concentration greater than 15 mEq/L
- Low ketonuria and absent to low ketonemia
- Alteration in level of consciousness

Treatment priorities include standard care for dehydration with IV fluid and treatment for altered mental status, including airway management as appropriate. Patients may respond to fluids alone, but IV insulin may be necessary to correct hyperglycemia. See Table 44.7 for the differences between DKA and HHS.

#### Acute and Long-Term Complications of Hyperglycemia in Both Type 1 and Type 2 DM

**Depressed Immune Response.** A depressed immune response can lead to infection and poor wound healing, and both are considered acute complications of hyperglycemia. Neutrophil and macrophage phagocytosis of bacteria is impaired, prolonging the inflammatory phase. The proliferative phase is also prolonged as RBCs become less pliable and less able to deliver oxygen to the wound for tissue metabolism and collagen synthesis. Interference with normal wound healing can be particularly important in the surgical, home-health, and long-term care settings. Effects include prolonged hospitalization, increased risk for sepsis, and increased morbidity from the extension of tissue damage. Hyperglycemia is associated with increased rates of:

- Skin and soft tissue infection
- Pneumonia
- Influenza
- Bacteremia/sepsis
- Tuberculosis

**Prolonged Hyperglycemia.** Prolonged hyperglycemia adversely affects blood vessels and nerves. Because the entire body relies on these networks, the long-term effects are extremely widespread.

**Vascular Effects.** Diabetes can be primarily thought of as a vascular disease, in that the damage done to the lining of blood vessels accounts for much of the damage throughout

**Table 44.7 DKA Versus HHS**

	<b>DKA</b>	<b>HHS</b>
<b>Occurrence</b>	Most often seen in type 1 DM but can also occur in type 2, especially with severe stress such as infection	Occurs more commonly in older adults in response to stress or infection
<b>Onset</b>	Rapid	Gradual
<b>Laboratory work</b>		
● Blood glucose levels	Greater than 250 mg/dL	Greater than 600 mg/dL
● Arterial pH levels	Less than or equal to 7.3	Greater than 7.4
● Serum bicarbonate levels	Less than 18 mEq/L	Greater than 15 mEq/L
● Urine or serum ketones	+	-
● Effective serum osmolality	Greater than 300 mOsm/kg	Greater than 320 mOsm/kg
● Anion gap	+	-

DKA, Diabetic ketoacidosis; DM, diabetes mellitus; HHS, hyperosmolar hyperglycemic state.

the body. Complications from diabetes are classified as macrovascular and microvascular. **Macrovascular complications involve damage to the large arteries that supply the heart and brain.** The leading cause of diabetes-related death is cardiovascular disease, with four of five people with diabetes dying from cardiovascular disease. Adults with diabetes die from myocardial infarction about two to four times more often than adults without diabetes. The risk for stroke is two to four times higher among people with diabetes.

**Microvascular complications** involve damage done to the small blood vessels and result in damage as follows:

- **Eyes:** The delicate blood vessels that supply the retina are susceptible to damage from prolonged hyperglycemia, resulting in retinal hypoxia. Diabetes is the leading cause of new cases of blindness among adults aged 20 to 74 years. Diabetic retinopathy causes 12,000 to 24,000 new cases of blindness each year.
- **Gums:** Periodontal disease is more common with diabetes because of the decreased circulation to the gums and increased susceptibility to periodontal bacteria and dental caries. Early tooth loss is a common outcome.
- **Kidneys:** The vasculature to the kidneys is affected by hyperglycemia. Diabetes is the single leading cause of renal failure requiring dialysis in the United States.
- **Peripheral vascular disease (PVD):** As many as 36% of patients with diabetes have lower extremity peripheral artery disease based on lower extremity blood pressure readings. In combination with peripheral neuropathy, PVD increases the risk of nontraumatic amputations of the lower extremities. Diabetes is the leading cause of nontraumatic amputation in the United States, with the risk of amputation being

between 15 and 40 times higher for people with diabetes than without.

**Neurological Effects.** Through mechanisms that currently are incompletely understood, prolonged hyperglycemia damages nerve cells. The results can affect several areas of the body. Typical problems include:

- Diabetic peripheral neuropathy
- Autonomic neuropathy

**Diabetic Peripheral Neuropathy.** Diabetic peripheral neuropathy results when the nerves to the feet and hands are damaged, but it can also impact other peripheral nerves in the body. Clinical manifestations include numbness, tingling, or pain. Approximately one-third of people with diabetes over the age of 40 have some impaired sensation to their feet. Loss of protective sensation can lead to injury that may not be felt. Infection and amputation are more likely in this setting. The greatest risk is from improperly fitting shoes.

**Autonomic Neuropathy.** Autonomic neuropathy results when there is damage to the nerves of the autonomic nervous system. Common manifestations are:

- **Diabetic gastroparesis,** which results when the nerves that innervate the stomach are damaged, leading to delayed or erratic emptying of stomach contents into the intestine. Clinical manifestations include symptoms such as bloating, early satiety, nausea, and vomiting. Blood glucose can drop or spike unpredictably if the food reaches the intestine at an unexpected rate.
- Erectile dysfunction
- Orthostatic hypertension
- Urinary problems, such as difficulty starting urination and inability to completely empty the bladder, can result in urinary tract infections.

## Nursing Management

### Assessment and Analysis

The clinical manifestations of type 2 DM are related to acute changes secondary to hyperglycemia, such as dehydration and electrolyte imbalance. Other manifestations are due to the more long-term effects of hyperglycemia resulting in vessel damage and organ hypoxia, such as fatigue, poor wound healing, recurring infection, cardiovascular disease, visual disturbances, and renal insufficiency.

### Nursing Diagnoses

- **Risk for ineffective tissue perfusion** related to macrovascular vessel changes secondary to hyperglycemia
- **Risk for ineffective renal perfusion** related to microvascular changes secondary to hyperglycemia
- **Risk for infection** related to decreased perfusion and sensation in distal extremities

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Decreased blood pressure and increased heart rate are secondary to the fluid volume deficit created by osmotic diuresis related to hyperglycemia. Temperature may be elevated if infection is present.*
- **Serum glucose**  
*Increased glucose levels are due to insulin resistance or relative lack of insulin related to body size. In a patient already diagnosed with and being treated for type 2 DM, increased glucose levels indicate:*
  - Inadequate self-management, such as poor diet, weight gain, and limited exercise
  - Increased insulin or oral glucose control medication requirements due to stresses, such as infection, causing adrenal release of catecholamines, increasing the hepatic production of glucose  
*Decreased glucose levels can be caused by inappropriate administration of insulin or medications that stimulate the release of insulin from the pancreas while the patient has inadequate oral intake or increased activity requiring more circulating glucose.*
- **Capillary refill in lower extremities**  
*Decreased perfusion secondary to microvascular changes may manifest as delayed capillary refill.*
- **Skin assessment, especially lower extremities and feet, looking for breaks in the skin, erythema, trauma, pallor on elevation, dependent rubor, changes in foot size/shape, nail deformities, and extensive callus**  
*Skin breakdown or wounds may occur unnoticed by the patient because of peripheral neuropathy. Resulting wounds are slow to heal as a result of impaired inflammatory response and tissue hypoxia secondary to vessel damage that occurs secondary to hyperglycemia.*
- **Intake and output**  
*Increased urine output may be present because of osmotic diuresis secondary to hyperglycemia.*

- **WBC count**  
*An increased WBC count may indicate the presence of infection.*
- **Serum blood urea nitrogen (BUN) and creatinine levels**  
*Elevations in serum BUN and creatinine levels are indicative of decreased renal function associated with the microvascular changes that develop in the kidneys secondary to sustained hyperglycemia.*
- **Spot urine for microalbuminuria**  
*Elevations of microalbumin are an early indication of microvascular damage to the kidneys from hyperglycemia and/or hypertension.*
- **Carbohydrate intake at meals**  
*Adequate carbohydrate intake at meals is essential to avoid hypoglycemia related to insulin administration.*

#### ■ Actions

- **Blood glucose monitoring (finger sticks) completed before meals and at bedtime**  
*Regular finger sticks are done to measure the adequacy of glucose control.*
- **Administer oral diabetes medications as ordered.**  
*Oral diabetes medications are administered to increase the production of insulin, lower insulin resistance, or slow the absorption of carbohydrates or in order to lower blood glucose levels.*
- **Administer insulin as ordered.**
  - Basal
  - Preprandial
  - Correctional  
*Administering rapid-acting insulin before meals, preparing for ingestion of carbohydrates, and correcting for random high glucose levels as determined by self-monitoring of blood glucose levels prior to the meal, in combination with longer-acting insulin once a day, will mimic the action of a healthy pancreas, helping to maintain tight glycemic control. In patients with questionable or minimal oral intake, prandial and correctional insulins may be administered together after meals after adequate carbohydrate intake has been confirmed.*
- **Administer isotonic IV fluids as ordered.**  
*Intravenous fluids may be necessary to replace volume lost due to diuresis.*
- **Administer antibiotics as ordered.**  
*Antibiotics may be indicated if infection is present.*

#### ■ Teaching

- **Medication education**  
*Lifelong medication administration is required for cellular metabolism. Increased stress, infection, activity level, increased ingestion of carbohydrates, and decreased PO intake all alter medication requirements. Over time, insulin administration may become necessary. Regular blood glucose checks help determine the adequacy of the medication regimen and maintain glycemic targets.*
- **Regular blood glucose checks via finger sticks, alternate site testing, and CGM**  
*Regular checks help determine the adequacy of the medication regimen and maintain glycemic targets.*

- Healthy lifestyle that includes meal planning and exercise  
*Healthy lifestyle choices are essential components in the management of diabetes to help avoid or prolong the development of complications associated with uncontrolled and/or sustained hyperglycemia. Lowering BMI and weight may delay the onset and severity of the long-term complications of DM.*
- Signs of hypoglycemia and hyperglycemia  
*It is important that the patient and family are able to detect early signs of both hypoglycemia (the underlying disorder that could progress to coma or death) and hyperglycemia secondary to inadequate medication administration.*
- Foot care (Box 44.4)  
*Meticulous foot care is essential to avoid wounds and infections that could result in amputation due to poor wound healing related to hyperglycemia. The use of therapeutic shoes and evaluation by podiatry can minimize risks.*
- Monitoring for complications  
*Regular healthcare provider visits are essential to monitor for cardiovascular, renal, visual, and skin complications related to hyperglycemia. Regular healthcare provider visits with routine blood work to monitor cardiovascular and renal functioning, along with annual dilated eye examinations and inspection of the feet and lower extremities, are essential to avoid the complications of long-term hyperglycemia.*

### Connection Check 44.12

The nurse prioritizes which nursing diagnosis in the plan of care for the patient with type 2 DM?

- Risk for infection
- Risk for falls
- Risk for impaired gas exchange
- Risk for injury: hyperkalemia

### Box 44.4 Foot Care

Foot care education should cover the following:

- Wash feet daily and dry thoroughly, including between the toes.
- Do not soak feet unless specified by a healthcare provider; soaking can unduly break down the skin and make it prone to damage.
- Be careful of hot water.
- Use creams, lotions, or moisturizer but not between the toes to avoid a fungal infection from too much moisture.
- To avoid injury, do not walk barefoot.
- Use caution in cutting nails. Ingrown toenails or other nail problems may require podiatry consultation.

Properly fitting footwear is essential. Check shoes each day for objects that may have fallen inside, excessive wetness, or areas that may cause irritation.

### Evaluating Care Outcomes

The patient with type 2 DM can lead a long and healthy life with strict adherence to the treatment regimen. The tight glycemic control necessary to avoid the complications associated with DM is best achieved through active monitoring of blood glucose levels and treatment with glucose control medications and insulin as indicated. Nutrition, patient education, self-management, and detection and prevention of complications are essential components of the successful daily management of diabetes.

## Making Connections

### CASE STUDY: WRAP-UP

Mrs. Simpson is now 6 days postoperative following her triple cardiac bypass. Her cultures reveal a urinary tract infection, and she is started on Bactrim. Her vital signs are stable, her temperature is within normal limits, and her WBC count is back to normal. During her hospital stay, her diabetes is being treated with subcutaneous insulin. She is given nutritional, correctional as necessary, and basal insulins. Her blood glucose is back within tight glycemic control after an initial increase with the infection. Her urine output is stable, and renal function tests appear to be normal. The plan is to discharge her to home tomorrow.

### Case Study Questions

- The nurse includes which information in the teaching plan for Mrs. Simpson?
  - Daily insulin administration
  - Once-a-day blood glucose monitoring
  - Eliminating fat in her diet
  - Monitoring for infection
- Which statement by Mrs. Simpson about her home medication regimen indicates the need for further teaching?
  - “My kidney problem will not affect my metformin prescription.”
  - “I may need to change from my metformin/glyburide medication therapy because of the problem with my kidneys.”
  - “I will need to be especially careful about low blood glucose.”
  - “I need to be diligent with my self-blood glucose monitoring.”
- Which statement by Mrs. Simpson indicates that teaching has been effective?
  - “I don’t have to worry about my blood pressure now that I’ve had heart surgery.”
  - “My diabetes is separate from my heart problems.”
  - “My blood glucose may go up if I get another infection.”
  - “I can take two of my glucose pills to make up for a missed dose as long as I check my blood glucose.”

4. The nurse recognizes that the management of diabetes is most successful with which action?
  - A. A priority focus on medications
  - B. A focus on regular healthcare provider follow-up
  - C. Patient commitment to self-management
  - D. A priority focus on appropriate diet
5. The nurse understands that HHS differs from DKA in which of the following ways? (*Select all that apply.*)
  - A. Hyperosmolar hyperglycemic state (HHS) has a more gradual onset.
  - B. Diabetic ketoacidosis (DKA) presents with higher serum glucose.
  - C. Potassium depletion is a potential complication with HHS.
  - D. A positive anion gap is not diagnostic for HHS.
  - E. Ketosis is typically not present in HHS.

## CHAPTER SUMMARY

Type 1 DM is typically triggered by an autoimmune process in which the insulin-producing beta cells of the pancreas are destroyed, resulting in an absolute lack of insulin. Predominate features include polyuria, polydipsia, polyphagia, fatigue, and weight loss. Diagnosis of type 1 DM is done by one of three methods: fasting blood glucose levels greater than or equal to 100 mg/dL, 2-hr postprandial greater than or equal to 200 mg/dL, and random blood glucose levels greater than or equal to 200 mg/dL in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis.

The primary pharmacological intervention used in the treatment of type 1 DM is insulin administered subcutaneously. An approach using a combination of long-acting or intermediate-acting insulin to provide “basal” insulin; rapid-acting or short-acting insulin subcutaneous or inhaled short-acting taken at mealtimes to cover the incoming carbohydrates, “prandial” insulin; and “correctional” insulin to compensate for blood glucose elevations is most effective

in maintaining tight glycemic control. Three methods of assessing glycemic control are:

- Self-monitoring of blood glucose
- Continuous glucose monitoring
- Monitoring of HgbA1c

Complications of type 1 DM include diabetic ketoacidosis (DKA), hypoglycemia, the dawn phenomenon, and the Somogyi effect.

In adults, type 2 DM accounts for about 90% to 95% of all diagnosed cases; thus, it is far more common than type 1 DM. It is caused by defects at the cell membrane that prevent the normal action of insulin, or insulin resistance. Type 2 DM typically has a slower onset than type 1 DM. In addition to the three “Ps” of type 1 DM—polyuria, polydipsia, and polyphagia—other common clinical manifestations include fatigue, poor wound healing, recurring infection, cardiovascular disease, visual disturbances, and renal insufficiency. Diagnosis of type 2 DM is as in type 1 diabetes. Type 1 DM diagnosis may also include a test for insulin antibodies and c-peptide to determine insulin production.

Pharmacological interventions for type 2 DM include oral and injectable medications that increase the production of insulin, lower insulin resistance, or slow the absorption of carbohydrates or medications that help lower blood glucose. These medications are typically used in combination because of their different mechanisms of action.

Management of both type 1 and type 2 DM cannot be successful without the individual patient’s commitment to healthy behaviors and lifestyle choices. Education and self-management are critical to successful outcomes. This involves more than adherence to potentially complicated pharmacological regimens. It also involves education, nutrition, exercise, self-monitoring of blood glucose levels, and adherence to a screening program for complications.

Acute complications include hyperosmolar hyperglycemic state (HHS), hypoglycemia in response to medication, and depressed immune response leading to infection and poor wound healing. Prolonged hyperglycemia adversely affects blood vessels and nerves, which can result in the long-term complications of autonomic neuropathy, diabetic peripheral neuropathy, renal failure, blindness, myocardial infarction, or stroke.

## Promoting Health in Patients With Sensory System Disorders

### Chapter 45

## Assessment of Visual Function

*Kelley Miller Wilson*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the visual system
2. Discussing the function of the visual system
3. Describing the procedure for completing a history and physical assessment of visual function
4. Correlating relevant diagnostic examinations with visual function
5. Explaining nursing considerations for diagnostic studies relevant to the visual system
6. Describing methods to prevent eye trauma and pathology
7. Discussing changes in visual function associated with aging

#### CONCEPTS

- Assessment
- Inflammation
- Perioperative
- Promoting Health
- Safety
- Sensory Perception

#### ESSENTIAL TERMS

Accommodation  
Amblyopia  
Anisocoria  
Astigmatism  
Convergence  
Emmetropia  
Enophthalmos  
Exophthalmos  
Fundus  
Hyperopia  
Intraocular pressure  
Keratomalacia  
Miosis  
Mydriasis  
Myopia  
Nystagmus  
Orbit  
Presbyopia  
Ptosis  
Pupillary constriction  
Red reflex  
Refraction  
Retina  
Sclera  
Strabismus  
Uvea  
Visual acuity

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Melanie McCormick, who is 48 years old, is seeing her nurse practitioner for a routine checkup. Melanie believes she is in excellent health, with “no known chronic diseases.” She works full-time as a middle school English teacher, takes no medications, is careful to eat at least four servings of fruits/vegetables daily, and has no significant family history of medical problems. Melanie has been noticing some changes with her vision over the past 5 years that she plans to discuss with her practitioner. Her most common complaints are dry eyes, difficulty reading unless objects are held at arm’s length, and “spots” that move in and out of her visual fields on occasion. Melanie contacts her primary healthcare provider for an appointment to have her vision evaluated...

## INTRODUCTION

Vision is an important sense, and ensuring eye health is critical to visual acuity. Perhaps one of the most sophisticated systems in the human body, the eye is responsible for taking light, converting it into electrical signals, and then sending it to the brain for processing. One of the five major senses in the body, vision allows awareness and assessment of surroundings, awareness of potential danger, and an appreciation for beauty as well as the ability to work, play, and interact with others.

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

Often considered the “window to the brain,” the eye is a fascinating structure that encompasses both internal and external frameworks. The adult eyeball is often compared to a Ping-Pong ball in size and shape; it sits in a hollow area of the facial skull called the **orbit** and consists of three layers. The external layer is known as the **sclera**, providing the tough protective outer coating; the middle layer is called the **uvea**, containing such structures as the choroid, the ciliary body, and the iris. The innermost layer is known as the **retina**, which converts light waves into nerve impulses resulting in visual reception. Within the eyeball itself, **intraocular pressure** is needed to keep the eyeball inflated. The following discussion illustrates how the fluid-like substances present in the aqueous and vitreous humors maintain this pressure. The major structures of the eye are diagrammed in Figures 45.1 and 45.2 and consist of internal and external structures.

### Internal Structures

*Aqueous humor* is the clear fluid, similar to water, found in the anterior chamber of the eye. Helping to maintain pressure and nourishing the cornea and lens with oxygen and nutrients, this fluid drains back into the circulation through the canals of Schlemm.

The *canals of Schlemm* are located around the perimeter of the iris, and they allow aqueous fluid to drain back into the bloodstream. The meshwork located along the canals of Schlemm regulates the eye’s internal pressure, and blockage of these canals is seen with the eye disease known as glaucoma, which causes an increase in intraocular pressure. This increase in intraocular pressure slowly destroys the

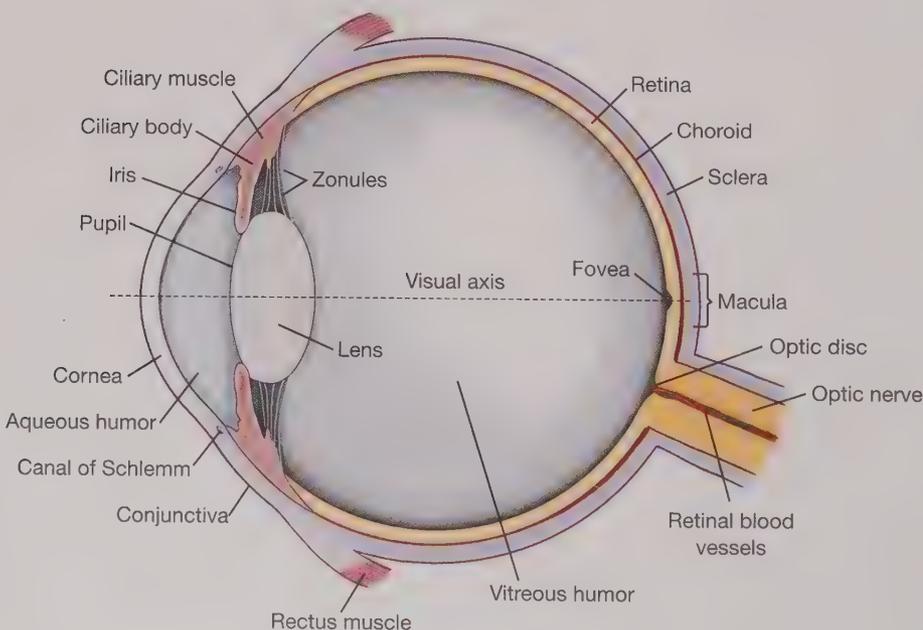

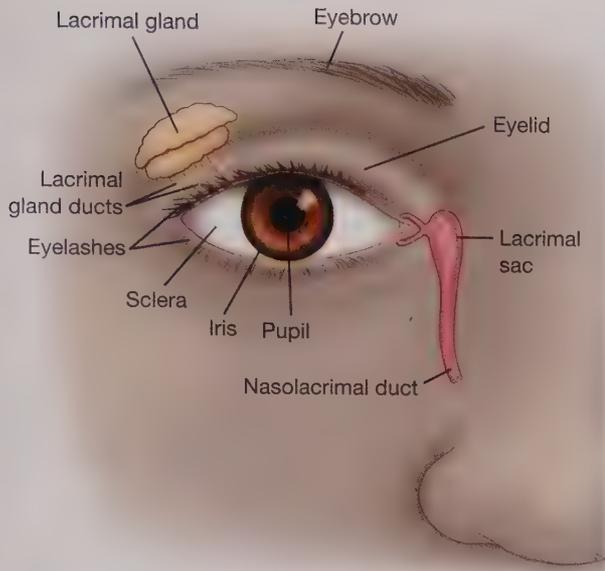

FIGURE 45.1 Internal structures of the eye.

**FIGURE 45.2** External structures of the eye.

optic nerve, thus severely restricting or destroying vision. This disorder is discussed in more detail in Chapter 46.

*Choroid* describes the layer of blood vessels located between the retina and sclera that supplies blood to the retina. The growth of abnormal blood vessels between the retina and the choroid can damage the macula, causing macular degeneration and yielding profound vision loss.

The *ciliary body* is the structure located just behind the iris. It has three main functions, including **pupillary constriction** (allowing change of the lens for eye focus), aqueous humor production (clear fluid that fills the front of the eye), and maintenance of the *lens zonules* (fibers that suspend the lens in place).

*Ciliary muscles* are the involuntary muscles that change the lens shape to allow the eye to focus on images at different distances. The ciliary muscles change the shape of the lens; they relax and flatten the lens for distance vision. Everyone eventually develops an eye condition called **presbyopia**. With age, this condition involves the ciliary muscles and lens losing their elasticity, causing people over the age of 40 to need “reading glasses” at some point in time.

*Conjunctivae* function to lubricate the front portion of the eye as well as the eyelids. This clear, thin membrane is the first line of protection for the eye against infection. Inflammation of this layer manifests itself as conjunctivitis, often called “pinkeye.”

The *cornea* is the transparent dome that sits on top of the colored portion of the eye that is known as the *iris*. This structure contains no blood vessels and is the first and most powerful lens in the optical system of the eye.

The *fovea* is the central part of the macula that provides the sharpest vision.

The *iris*, or the colored portion of the eye, is actually a ring of muscle fibers located behind the cornea and in front of the lens. The iris contracts and expands, opening and

closing the pupil in response to the amount of light present, thus helping to protect the sensitive retina.

*Lenses* are circular and convex and are located behind the cornea. The lens is responsible for keeping images in focus on the retina. This structure bulges for focus on near objects and flattens for far objects.

The *macula* is the spot seen on an ophthalmic examination and is the most sensitive part of the retina. Located in the central portion of the retina, the macula provides vision for fine work and reading. Degeneration of the macula causes vast decreases in eyesight, often in the 20/200 to 20/800 range.

The *optic disk* is the spot on the retina where the optic nerve leaves the eye; lack of sensory cells here creates a blind spot. Working together, the two eyes cover the blind spot for each other, and the brain is able to fill in the missing information.

The *optic nerve*, cranial nerve II, is often described as the cable connecting the eye to the brain. This substantial nerve carries visual signals from the eye to the brain.

The *orbital muscles* include the six muscles that control eye movements. Four muscles control the movement of the eye when the head is twisted. Weakness or dysfunction of these muscles can lead to conditions such as **nystagmus** (abnormal twitching of the eyes) and **amblyopia** (lazy eye).

The *pupil* is the hole in the center of the iris that allows light to pass. Muscles in the iris control the size of the pupil.

The *retina* is the portion of the eye that converts light rays into electrical signals and then sends them to the brain via the optic nerve. The sides of the retina are responsible for peripheral vision, and the center area of the retina is called the macula.

*Retinal blood vessels* are visible with an ophthalmoscope upon eye examination and are in the choroid, just beneath the retina. They function to provide nourishment and oxygen to the eye. Abnormalities in these vessels can lead to vision loss in conditions such as diabetic neuropathy and macular degeneration.

The *sclera* is the tough white covering that functions as the outer layer of the eyeball. The sclera is also covered by a clear mucous membrane consisting of cells and an underlying basement membrane of conjunctival tissue. Tiny red lines (blood vessels) are often visible; these blood vessels transport blood to the sclera. Discoloration of the sclera can provide clues to the patient’s current health status. For example, yellowing of the sclera can indicate the presence of pathology of the liver or biliary system.

*Vitreous humor* is the clear, jellylike fluid found in the back portion of the eye that helps maintain the shape of the eye. With age, the vitreous humor changes from a gel-type substance to a liquid and gradually shrinks, separating from the retina. This normal sign of aging can cause people to start seeing “floaters” and dark spots in their vision.

## External Structures

*Eyelashes* and *eyebrows* are protective in nature and help to prevent dust or particulates from falling into the eye. The eyelashes form a screen to keep dust and insects out.

Specialized hairs protect the eyes from foreign particles that could cause injury. Touching the eyelashes triggers the eyelids to blink.

*Eyelids* function to protect and lubricate the eyes. Oil-producing glands line the inner edge of the eyelid; these oils mix with tears upon blinking, keeping the eyes moist and clean.

*Lacrimal glands* function to lubricate and prevent dehydration of the cornea. This gland continuously releases tears and other protective enzymes onto the surface of the eye.

*Lacrimal sacs* are the channels that drain tears and other debris from the eye. The fluid flows down the nasolacrimal duct into the nose, where it functions to help keep the nasal linings moist.

## Cranial Nerves

There are four cranial nerves (Table 45.1) that are involved with vision and eye function. These cranial nerves provide the framework for accurate vision to take place. The nerves and their function are listed in the following section.

### Connection Check 45.1

In assessing a patient's vision, the nurse recognizes which structures as key to the visual system?

- A. Uvea, lacrimal gland, macula
- B. Eyeball, cochlea, retina
- C. Fovea, retina, macula
- D. Rods, ciliary body, aqueous humor

## OVERVIEW OF VISUAL FUNCTION

Vision is controlled by the interaction of light and nerve impulses transmitted to the nervous system. As light enters the pupil, it hits the lens. The lens then focuses light rays on the back of the eyeball that is known as the retina. The ciliary muscles attached to the lens change the shape of the

lens depending on whether the focus is near or far away. The presence of light on the retina causes it to change the light into nerve signals for the brain to interpret.

The retina uses special cells called *rods* and *cones* to process the light. Each eye contains approximately 120 million rods and 6 to 7 million cones. Rods allow differentiation between black, white, and gray and are responsible for the interpretation of the form or shape of an object. They are not color sensitive, but they do allow for vision in very dark conditions. Cones require more light than rods, and they allow the processing of objects in color. There are three types of cones in the retina. Each cone group is sensitive to one of three different colors—red, green, or blue. Together, these cones can sense combinations of light waves, allowing vision of the millions of colors of the spectrum.

The optic nerve (cranial nerve II) is the structure in the back of the eye that carries the messages from the eye to the brain. The optic nerve serves as the “high-speed Internet” line connecting the eye to the brain that makes the vision process possible.

The four functions of the eye that allow for clear images of objects no matter what the distance are **refraction**, pupillary constriction, **accommodation**, and **convergence**. Refraction refers to the bending of light and is critical to image formation. Refraction errors occur when the bending of light rays by the cornea and lens does not focus the image correctly onto the retina. Whereas **emmetropia** is considered perfect refraction, an eyeball that is too long or too short for the optics of the lens and cornea causes refractive errors (Fig. 45.3).

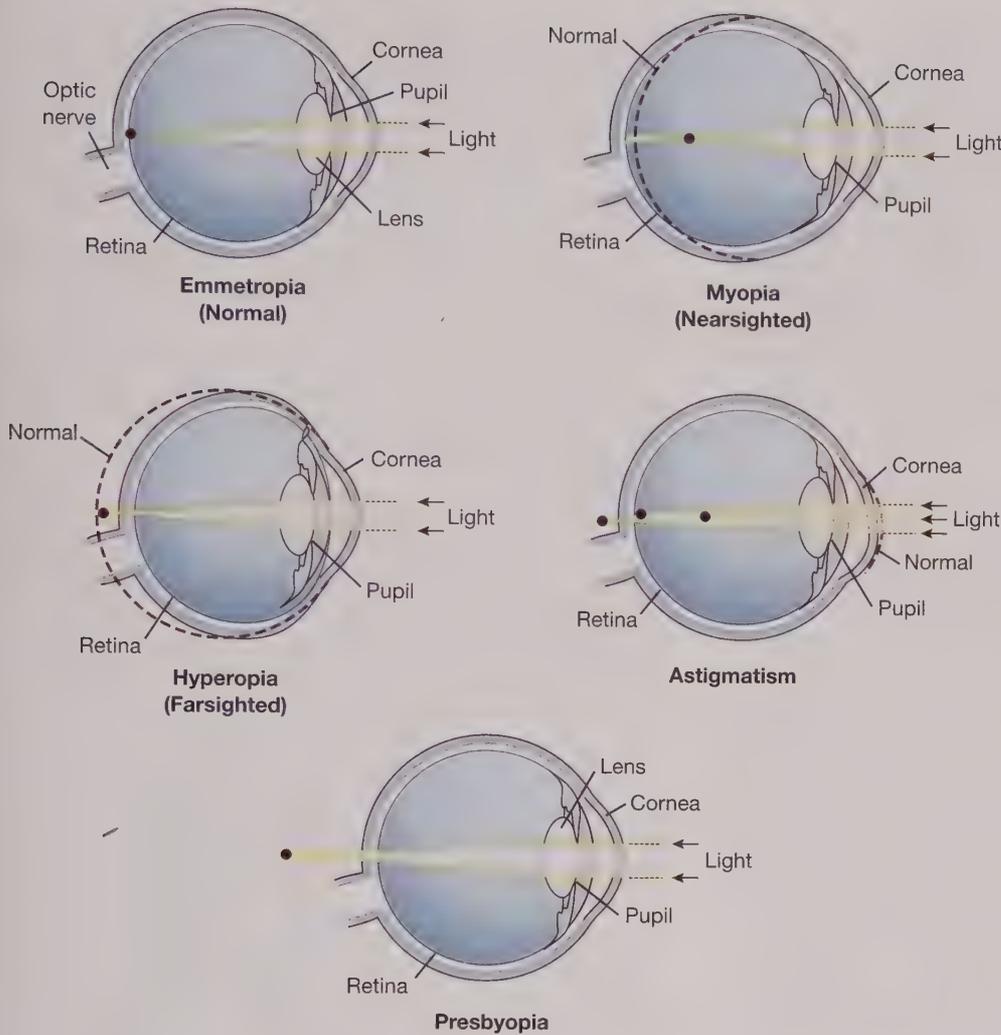

An irregularly shaped cornea can also have the same effect. Errors in refraction include **myopia** (nearsightedness), **hyperopia** (farsightedness), and **astigmatism**. Myopia results from an eyeball that is too long or when the cornea has too much curve present, thus causing the focused image to fall in front of the retina. Patients with myopic vision have blurred vision of distant objects and therefore have difficulty seeing faraway objects. Hyperopia is the opposite, causing the image to fall behind the retina. These patients have trouble seeing near objects. Astigmatism results from a misshaped cornea. Patients with astigmatism have difficulty seeing fine details either close-up or from a distance. Refractive errors are usually easily corrected with corrective lenses.

The amount of light that is allowed to enter the eye is controlled by pupillary constriction and dilation. The amount of light present and the ability of the retina to adapt to the change affect the degree of dilation. Constriction of the pupil is termed **miosis**, and dilation of the pupil is known as **mydriasis**. In addition to changes in light, medications and eye drops can also alter pupillary dilation and constriction.

Accommodation is the eye's ability to maintain clear vision of an image when an object shifts from distant to near. The changing of the curve of the lens allows this transition to take place. Convergence is the simultaneous inward movement of both eyes toward the center (usually focused

**Table 45.1** Cranial Nerves That Control Eye Function

Cranial Nerve	Function
<b>II: Optic</b>	Transports visual information from the retina to the brain and is therefore responsible for vision
<b>III: Oculomotor</b>	Controls pupil constriction as well as eyelid and eyeball movement
<b>IV: Trochlear</b>	Innervates the superior oblique muscles and allows eye movement in a downward and lateral motion
<b>VI: Abducens</b>	Controls lateral movement of the eye

**FIGURE 45.3** Refraction and visual disorders.

on the nose) in an effort to ensure the visibility of a single object at close range.

### Connection Check 45.2

The nurse recognizes which action as the major function of the visual system?

- Differentiate colors
- Convert light into nerve signals for the brain to interpret
- Focus light onto the choroid
- Accommodate vision from light to dark

## ASSESSMENT

### History

#### Personal History

Obtaining a comprehensive history of the patient's health is essential prior to examination of the eye. Historical information to be gathered includes the patient's living conditions and level of independence; type of occupation; current medications, both prescription and over the counter; allergies

to foods and environmental factors; known injury or trauma to the eye; present illnesses; and any past surgical procedures.

#### Family History

Assessment of the eye also includes questioning the patient about the personal and family history of eye problems. Careful history-taking helps to determine the immediate presence of illness as well as the identification of potential risks for genetic-related illnesses of the eye. Questions such as "Does anyone in your family have vision problems?" and "Does anyone have night blindness, color blindness, or glaucoma?" are important inquiries to make.

#### Nutritional History

Nutrition plays a role in healthy eyes because vitamins and nutrients impact certain eye conditions. Nutrients such as lutein and beta-carotene are reported to help maintain retinal function. Deficiencies in vitamin A are noted to cause dry eyes, **keratomalacia** (drying of the cornea, which can progress to clouding of the structure), and even blindness. Vitamin C and vitamin E are also known as strong antioxidants that protect the eye against free-radical damage. Free radicals are unbalanced cells in the body that are known to

be destructive and are linked to macular degeneration as well as cataract formation; they naturally increase in numbers with advanced age but can also be caused by lifestyle choices. Excessive sun exposure, poor diet, and smoking all increase free-radical production. Research continues on the effects of vitamins and minerals, especially as to their potential use in treating different eye diseases. Replenishment of antioxidants fortified with lutein has proven to decrease the cell destruction caused by free radicals. Obtaining a dietary history from a patient provides clues as to current health issues being encountered with vision or predicts possible difficulties later in the advancing years of a patient.

### History of Eye Trauma

Obtaining a complete history of eye trauma also provides clues to the presence of actual and potential pathologies. Assessing the patient's use of protective eye equipment is also important in helping to prevent a potential injury. The use of protective goggles at home and for sports/activities that may cause injury to the eye itself and the use of sunglasses are assessed. Included in the history are questions regarding possible occupational hazards. For example, people employed in steel mills or factories where metals are being shredded are at risk for having tiny, sometimes microscopic pieces of metal embedded in their eyes, particularly if protective goggles are not consistently worn. This leads to the formation of a "rust ring" because the surface of the eyeball is wet, and impaled metallic foreign bodies can quickly begin to rust. Left embedded in the cornea, these metal fragments may result in recurrent corneal erosion. This condition causes substantial pain for patients and occurs as the cornea becomes scratched at random times as the rust penetrates and moves through the cells on the top portion of the cornea.

#### Safety Eye Protection Alert

- Protective eye equipment, including goggles and prescription protective glasses, should be used for selected contact sports and occupations.
- Ultraviolet protective eyewear should be worn with outdoor sun exposure and with occupations that occur in the outdoors.
- A face shield should be used to protect eyes and face as needed; it should also be used with safety goggles.
- Eye goggles should be worn for grass cutting/trimming/weed whacking as well as chopping wood and using caustic substances that could potentially splash.

### Inspection

Prior to any assessment, adequate explanation to the patient regarding the examination that is about to be performed is essential. Instruction on the type of examination and what

to expect is important. Hand washing and use of gloves are also necessary prior to the start of the examination.

The visual inspection first begins by noting the symmetry of the eyes on the face, noting any abnormal protrusion of the eyeball itself (**exophthalmos**) or a sunken-in appearance of the eyes (**enophthalmos**). Alignment of the eyebrows with the top of the ears is also assessed.

The following provides a comprehensive list of structures that are inspected during an examination of the structures of the eyes:

**Eyebrows:** Note hair distribution and symmetry. Also note that the eyebrow is even in alignment with the tops of the ears.

**Eyelashes:** Note the distribution of eyelashes present as well as the presence of a slight curl and slightly outward projection.

**Eyelids:** Note the surface characteristics, ability to blink, and frequency of blinking. Assess the eyelids for the presence of drooping (**ptosis**) as well as any swelling, discoloration, or lesions (Fig. 45.4). To comprehensively examine the eyelids, elevate the eyebrows with the right thumb and index fingers. Ask the patient to close his or her eyes and inspect the eyelids while the lids are in this closed position.

**Conjunctiva:** Assess the color and texture by retracting the eyelids in an upward motion, asking the patient to look up, down, and side to side. Evert the upper eyelids, pull down the lower lids, and inspect. The color of the conjunctiva provides important clues regarding the health of the patient. For example, the presence of very pale conjunctiva is a clue that a patient has a low red blood cell count.

**Iris:** Note the color, symmetry, size, and shape of the pupil. About 5% of people normally have a noticeable difference in the size of their pupils, which is known as **anisocoria**. The normal pupil size is between 3 and 5 mm.

### Connection Check 45.3

What assessment data are most important in completing a history and physical examination of the eye?

- Family history, current state of health
- Record of daily food intake, obtaining an accurate weight of the patient
- Medications taken daily and occupation
- Use of sun protective glasses on a daily basis and immunization history

FIGURE 45.4 Ptosis.

## Vision Testing

Several relatively simple tests are administered to evaluate the functioning of the eye. Patients who normally wear corrective lenses are tested both with and without their lenses in place.

The Snellen chart (Fig. 45.5), commonly known as the “eye chart,” is used to evaluate distance vision. This test is easily completed in a provider’s office, clinic, school, or other facility. To complete this test, the chart is usually mounted on a wall or other object 20 feet away from where the patient is standing. There are many variations of this chart, but in general, it includes 11 rows of capital letters. The top row consists of one letter (usually an “E”). The subsequent rows contain letters that get progressively smaller in size. With the patient standing 20 feet from the chart and covering one eye, the provider assists by pointing to the letters. When the last possible letter is completely read, the patient then covers the other eye and is asked to read the chart with the uncovered eye. The patient is asked to continue reading the chart until unable to determine the letter in the row to which the provider is pointing. The

provider is then able to determine the patient’s “visual acuity” by noting the number assignments in the margin of the chart. A common definition of **visual acuity** is the sharpness or clearness of images perceived; “20/20” vision is considered “normal” vision, meaning the patient at 20 feet reads a letter that most people are expected to be able to read at 20 feet. As an example, a person with 20/40 vision standing 20 feet from a vision chart sees what a normal person sees standing 40 feet from the chart. A person is considered legally blind if the best corrected visual acuity, meaning the best distance vision with eyeglasses or contacts in place, is 20/200 or worse. The Snellen chart vision examination is usually done first with corrective lenses in place and then without corrective lenses being used. Charts are adapted with pictures and other lettering options for pediatric patients and patients unable to read the English language.

Another routine assessment of vision is the Rosenbaum Pocket Vision Screener or Jaeger card. This test assesses for “near” vision and is used with patients who are unable to read without magnification. The card is pocket-size and held 14 inches away from the eyes. The eyes should be tested separately and then together. The value of the lowest line on which the patient can identify at least half of the letters/characters is recorded; “14/14” is considered a normal result, meaning the patient can read at 14 inches what a normal person is expected to be able to read at 14 inches.

An Ishihara chart (Fig. 45.6) is used to assess color vision. People who are color-blind are not able to distinguish red from green or blue from yellow. This chart shows a number figure composed of dots of a single color encircled in a group of dots of a different color. The eyes are tested separately for this test. Failure to determine the number figure present in the inner circle of the chart represents the need for further testing for possible color blindness. The

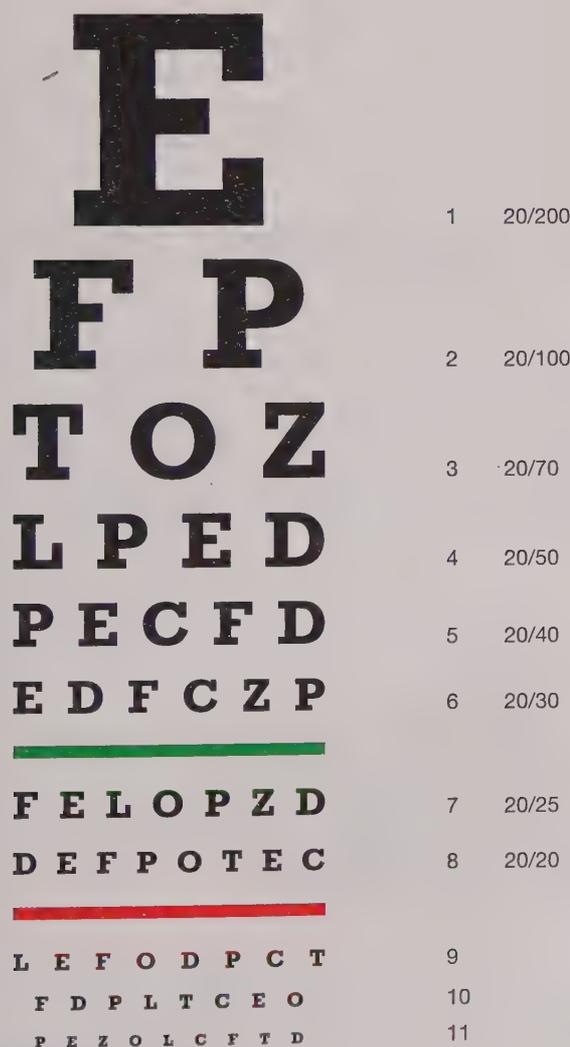

FIGURE 45.5 Snellen chart.

FIGURE 45.6 Ishihara chart.

majority of color blindness occurs in males. Females are carriers of the gene but are not normally affected. Approximately 8% of males and 1% of females are afflicted with this disorder.

The confrontation test is another commonly performed assessment of the eye and is a test of the visual fields that determines the degree of peripheral vision. This test is completed manually or with a computerized machine, similar to what is often seen in departments of motor vehicles when people are briefly eye-tested prior to being issued a driver's license. To complete this test manually, the provider sits facing the patient and asks the patient to look directly into the provider's eyes. The provider covers his or her right eye while asking the patient to cover his or her left. With an extended arm, the provider moves a finger from a nonvisible area to the patient's line of vision. The patient with normal peripheral vision should be able to notice the finger at about the same time the provider does. Repeat this same process having the provider cover the left eye and the patient cover his or her right eye.

The corneal light reflex and the six cardinal positions of gaze (Fig. 45.7) tests are used to assess extraocular muscle function. Cranial nerves III, IV, and VI are also assessed when completing these tests.

The corneal light reflex provides information about the alignment of the eyes. When there are no alignment problems with the eyes, the light reflex is in approximately the same position in both pupils. If, for example, the patient has an irregularity such as **strabismus** (a disorder where the eyes appear to be looking in different directions), the light will appear off-center in the crossed eye. To complete this test, the provider asks the patient to stare straight ahead, often directing the patient to stare at the nose of the provider. As the patient stares at the light object, the provider shines a penlight from a distance of 12 to 15 inches on both corneas. The light should reflect on the shiny surface of the cornea in a symmetric position in both eyes. Asymmetry with this test indicates probable muscle imbalance, and further investigation is warranted.

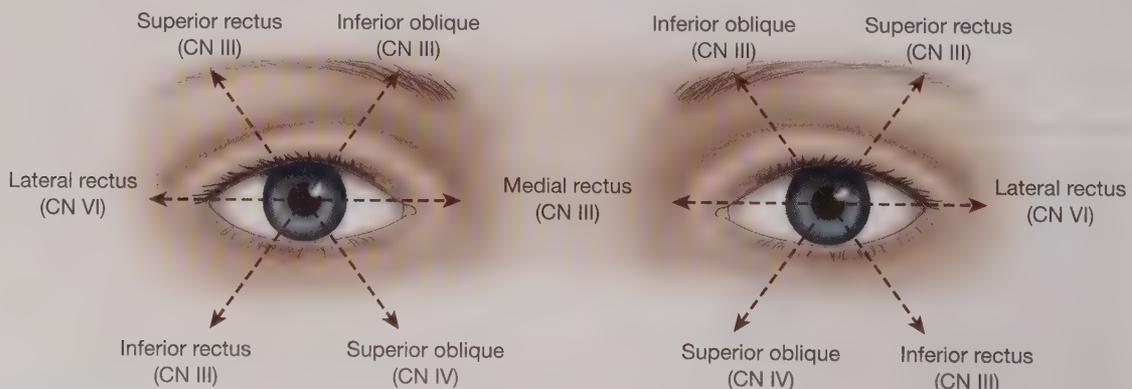

Assessment of the six ocular movements is done to check eye alignment and coordination. The test is performed on patients older than 6 years of age. To complete this test, the patient is instructed to stand directly in front of the provider with the head held in a fixed position. With a penlight held approximately 12 inches (30 cm) in front of the patient's eyes, the patient is asked to follow the movement of the penlight with his or her eyes only. The penlight should be moved slowly and in an orderly fashion both laterally and medially as is described in Figure 45.7. The penlight movement should be stopped periodically to detect nystagmus.

Pupillary light reflex is the normal, expected constriction of the pupil observed when exposed to bright light. This response is considered a "subcortical reflex arc," meaning the patient has no conscious control over it. Cranial nerve II, the optic nerve, is responsible for the part of the pupillary reflex that senses the incoming light. Cranial nerve III, the oculomotor nerve, is responsible for the pupillary reflex by constriction of the pupil. A direct light reflex (pupillary constriction) occurs when the eye is exposed to bright light. Normally, a consensual light reflex is also seen, meaning there is a simultaneous constriction of the other pupil. To test this reflex, the room should be darkened, and the patient should be instructed to stare straight ahead. The provider then advances the light slowly from the side. The normal response will elicit a constriction of the same-side pupil (ipsilateral; direct light reflex) as well as a simultaneous constriction of the opposite pupil (contralateral; a consensual light reflex).

### Connection Check 45.4

The nurse prepares the patient for which common diagnostic evaluations during a visit to an eye care provider?

- Pupillary light test, ultrasound of the eye
- Test of peripheral vision, otoscope examination
- Test for presence of bacteria in the conjunctiva, pupillary light test
- Snellen eye chart examination, peripheral vision check

**FIGURE 45.7** Six cardinal positions of gaze. This test assesses extraocular muscle function and cranial nerves III, IV, and VI.

## CASE STUDY: EPISODE 2

Upon arrival to the clinic, Melanie provides a detailed health, family, and medication history to her healthcare provider, and there are no concerns raised about her history. During the appointment, the registered nurse completes a visual acuity test to assess Melanie's current visual status. The advanced practice nurse practitioner (APRN) then completes a full eye examination using an ophthalmoscope and a Rosenbaum Pocket Vision Screener to assess the internal health of the eye as well as Melanie's near vision. The findings of the examination include expected changes, such as the presence of dry eyes and "floaters" in her vision field caused by opacities present in the vitreous humor. The need for reading glasses (eye magnification), as determined by the results of the Rosenbaum test, reflects the expected loss of lens elasticity that is an anticipated change seen with healthy aging eyes...

## DIAGNOSTIC STUDIES

An ophthalmic examination is most commonly completed in the provider's office or clinic setting by a medical doctor (MD) or APRN. Providers who specialize in the evaluation of the eye are ophthalmologists or optometrists. The ophthalmologist is a medical doctor and is trained in all aspects of medical and surgical diagnosis as well as the treatment of eye disorders. An optometrist is a doctor of optometry, allowing for examination and treatment of certain types of visual and eye disorders. Ophthalmic examinations provide very important information about the health of the patient's eyes and also about general health status. Examination of the eye using the ophthalmoscope allows the provider to view the retina as well as other vessels and structures of the eye. The examination usually takes place in a darkened room to allow for pupil dilation, which assists in the examination of the **fundus** (the internal surface of the retina). The patient is asked to stare straight ahead and fix eyes on an object behind the provider. The provider usually places a hand on the shoulder or eyebrow of the patient to assist in determining the distance from the ophthalmoscope. With the ophthalmoscope pressed firmly against the provider's face and starting from 12 to 15 inches away, the provider looks through the hole and moves slowly and steadily toward the patient while slowly advancing the dial on the lens selector dial of the ophthalmoscope to increase the acuity of the visual examination. The provider uses the same eye as the patient is having examined (i.e., the provider places the ophthalmoscope on the right eye and examines the patient's right eye). As the ophthalmoscope is directed inward toward the pupil, a red glow known as the **red reflex** should be visible. The red reflex

is a reflection of light on the retina. The absence of the red reflex could indicate opacity of the lens or cloudiness of the vitreous humor. Cloudiness of the vitreous humor may be the result of the presence of inflammatory cells, cellular debris, and/or blood. Once the retina is visible, the optic disk, optic vessels, fovea centralis, and macula should be visible (Fig. 45.8).

Prior to beginning the ophthalmic examination, the provider explains to the patient the reason for the examination and what to expect. If the patient is in a combative state or unwilling to complete the examination, it is suspended and completed at another time to decrease the potential for injury to the patient and the provider. The nurse is available for questions or postprocedural teaching depending on the results.

## Computed Tomography

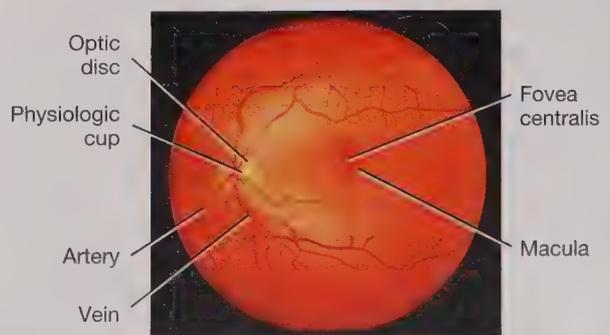

Computed tomography (CT) scans may be ordered to help diagnose diseases of the eye in the following areas: blood vessels, eye muscles, optic nerve, the presence of an abscess in or around the eye, fractures of the eye socket, and presence of a foreign body in the eye or the eye socket. These scans may be ordered with or without contrast.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) gives the provider an image that provides detailed views of the soft tissue with no bone or air contrast. An MRI scan is used most frequently to discover tumors, infection, chronic disease, fractures, changes in the optic nerve, and enlarged eye muscles.

## Ultrasonography

Ultrasonography of the eye is done by projecting high-frequency sound waves to produce an image of soft tissue when conditions make it difficult for the provider to see in the eye. (Cataracts and retinal detachment are common conditions that warrant an ultrasound examination by the provider.) This test is often able to be completed in the provider's office. Vitreous hemorrhage and tumors are often discovered using this test.

**FIGURE 45.8** View of the retina through an ophthalmoscope.

## Radioisotope Scanning

Radioisotope scanning is a scan that involves a small amount of various radioactive substances injected into the body with different uptakes to differentiate between normal and malignant tissues. This test is often done to identify tumors and ocular melanomas that are difficult to visualize with some of the less-invasive testing modalities.

## Slit-Lamp Testing

Examination of the patient using a slit lamp is often included in a routine ophthalmic examination. This comprehensive test may be conducted to view structures in the posterior portion of the eye as well as for viewing structures such as the optic nerve and retina. Other uses of the slit lamp include diagnosis of cataracts, conjunctivitis, glaucoma, and macular degeneration or to verify the presence of a foreign body. This examination uses an instrument that provides a high-intensity light magnification, making three-dimensional (3D) imaging possible. Eye drops may be used to temporarily anesthetize the eye for this examination, and the patient is required to remove eyeglasses or contact lenses prior to the start of the examination.

## Intraocular Pressure Testing

The tonometer is used to measure the pressure inside the eyeball itself. This pressure is known as the intraocular pressure, and the normal range is 10 to 21 mm Hg. Elevation of intraocular pressure decreases the blood flow to the eye structure and can result in catastrophic visual effects. The accumulating pressure within the eye can be caused by an overproduction of aqueous humor or, most commonly, inadequate drainage of the canals of Schlemm in the eye. Often a tonometer is also mounted on the slit lamp so that exact intraocular pressures may be obtained. In order to complete this test, most providers use anesthetizing drops and a yellow-orange dye solution called *fluorescein* (described in the following section) to stain the eye and allow for greater visualization of abnormalities. The test is completed as the patient rests the chin on a support bar and stares straight into an instrument (slit lamp, tonometer, etc.). The provider sits in front of the patient, shines a bright light into the patient's eye, and gently touches the probe to the eye. The tension dial on the instrument thus provides the provider with an accurate reading of the patient's intraocular pressure. In order to complete this test, the patient must remove eyeglasses or contact lenses. The patient is instructed that the test is most accurate when no more than 2 cups of liquid are consumed 4 hours before the test and no alcoholic beverages are consumed for at least 12 hours prior to testing. It is also important to instruct patients receiving eye anesthetizing medication to refrain from rubbing their eyes for at least 30 minutes after the test or until eye sensation has returned to normal. Rubbing an eye that is anesthetized can result in injury or scratching of the cornea because the patient is unable to feel objects that would normally cause pain.

## Corneal Staining Test

The corneal staining test is an assessment that uses a yellow-orange dye (fluorescein) placed directly into the eye in the form of a drop or instilled by a piece of blotting paper with dye impregnated on it. After the dye has been inserted into the eye, the patient is asked to blink to help distribute the dye evenly throughout the eye cavity. With the room lights off, a blue light is then held over the open stained eye to detect foreign bodies or scratches that might be present on the cornea. Oftentimes, an anesthetizing medication is also placed in the eye to assist with patient comfort and allow for a more comprehensive examination. Prior to this examination, it is important to instruct the patient on the type of examination being performed, as well as the fact that some of the fluorescein eye stain will remain in the eye and cause a temporary discoloration. If anesthetizing drops are used, instructions to the patient to refrain from rubbing the eye for at least 30 minutes are important to prevent possible eye injury. Table 45.2 outlines important patient teaching related to post-eye examination care. Contact lenses should not be reinserted into the eye until feeling has returned to the eye and the yellow-orange eye color has dissipated, usually 2 to 4 hours after the examination.

## Fluorescein Angiography

Performed by a provider or an advanced practice registered nurse, this diagnostic procedure provides detailed images about the internal eye circulation. An IV dye (usually 5 mL of a 10% fluorescein solution) is injected, and photographs are taken in rapid sequence. This test is useful in determining retinal circulation because it identifies problems such as diabetic retinopathy, retinal hemorrhage, macular degeneration, and tumors.

Preparation of a patient for this examination includes patient teaching, safety considerations, placement of a peripheral IV catheter, and administration of eye drops. Patient teaching includes an explanation of the procedure, assessment of any patient allergies, and information that the patient may have slightly yellow skin for a couple hours after the procedure, as well as a green color to his or her urine as the dye is excreted from the body. Instructions to increase the intake of water are also paramount in helping to flush the infused dye out of the body. Ensuring that the patient has a family member or friend to assist with vision needs and transportation home are safety concerns.

## Connection Check 45.5

The nurse must consider all of these assessments prior to preparing a patient for diagnostic studies of the eye. Which intervention can be delegated to the technician on the team?

- Assessing the patient's past medical history
- Administering preprocedure medications
- Obtaining an accurate height and weight of the patient
- Reviewing current medications the patient is taking daily

**Table 45.2 Patient Education Related to Eye Examination**

Instruction	Rationale
Use eye protection (such as eyeglasses or sunglasses) after the examination is complete.	The anesthetic property of the eye drops blocks the ability to feel foreign objects (which would normally cause pain) entering or touching the eye. (Dust and wind-blown articles are common threats.)
Do not rub the eyes.	The anesthetic property of the eye drops prevents the ability to feel if a foreign substance is present and is being rubbed in the eye. It also makes it difficult for the patient to realize the amount of pressure being exerted with rubbing action, and damage to the eye can result.
Contact lenses should not be reinserted until all feeling has returned to the eye, usually 2 to 4 hours.	Insertion of contact lenses when the eye is anesthetized can result in scratches or damage to the eye because there is no feeling to guide the patient.
No swimming or showering until feeling has returned to the eye, usually 2 to 4 hours	The inability to feel any pain in the eye can result in injury from foreign substances potentially present in swimming pools as well as water forcefully hitting an open eye. The reflex to close the eye to the offending agent is not present.

## EYE PROTECTION

The numerous sensitive internal and external structures within the eye itself make eye protection critical for preventing injury or loss of vision. The use of protective goggles at work and at home with high-risk activities is vital. People are often unaware of injuries that can be sustained with everyday activities such as cutting grass, playing sports, unintentional exposure to caustic or corrosive substances, and other everyday at-risk activities. Sunglasses are an important piece of equipment and are often overlooked. Exposure to ultraviolet-B (UV-B) light over time can have damaging effects on the eye. It is now known that there is an association between excessive exposure to UV-B light and the early formation of cataracts. Hand washing is another simple way to prevent injury to the eye by preventing the transfer of toxic or injurious substances directly to the eye. Eye examinations are an important protective measure and are recommended at different intervals depending on the patient's age and health status. In general, it is recommended that patients aged 20 to 39 have a comprehensive eye examination every 3 to 5 years, patients aged 40 to 64 every 2 to 4 years, and patients 65 or older every 1 to 2 years. Prompt treatment for eye concerns should always be acted on to decrease the possibility of permanent damage to these sensitive structures. Patients with chronic diseases such as hypertension and diabetes are also encouraged to keep their diseases well controlled to minimize the possibility of complications.

### Safety Alert Eye Symptoms Needing Further Assessment

- Sudden loss of vision in any part of the visual field
- Sudden onset of pain in the eye
- Flashing lights present
- Physical trauma/injury to the eye
- Constant tearing of the eye with or without photophobia

## Connection Check 45.6

The nurse recognizes which action as most important to preventing eye trauma?

- A. Wearing protective goggles at home or work as indicated
- B. Keeping hands clean
- C. Refraining from looking directly into light sources
- D. Eating a well-balanced diet

## AGE-RELATED CHANGES

Anatomical changes to the eye occur as a natural process as people age. Not all decreases in visual ability are of pathological origin. The most significant age-related changes occur in the lens and the pupil and account for the majority of the visual limitations experienced with advancing age.

As a person advances in age, the pupil becomes smaller and less responsive to light. It is common for people to need more time adjusting from changes in light levels as they age. Loss of lens elasticity is another expected change in the eye that occurs around the age of 45. The loss of elasticity of the lens makes it harder for the lens to bend in order to focus on closely held objects. This loss of lens accommodation is known as presbyopia and makes “reading glasses” necessary for people in this age group and older. Another common expected change that occurs in the eye with aging is the gradual yellowing of the lens. This yellowing tends to absorb and scatter blue light, making it difficult to see differences in shades of blue, green, and violet. Dullness in color perception may become evident. This change in vision may also make it more difficult to navigate where an object ends and the background begins.

Deposits in the vitreous humor, often referred to as “floaters,” may become evident in advancing years. These spots may occur as the vitreous humor develops opacities that become visual to the patient as “floaters” and bounce

in the visual field. Shrinkage of the vitreous humor may also cause the same clinical manifestations; shrinking is also attributed to advancing age and is considered a normal, expected process.

Some of the other expected changes that occur in the eyes are found in the conjunctiva, the retina, and the eyelids. The conjunctiva becomes more susceptible to chronic inflammation secondary to an increase in eye dryness. The increased dryness can be secondary to hormonal decreases within the body with advancing age in adulthood. The tear glands and conjunctiva may lose the ability to efficiently lubricate the eye and therefore produce “dry eye.” The arteries and veins of the retina become narrower with age, thus reducing blood flow and yielding a less responsive light reflex. The eyelids lose elasticity and tone, causing ptosis (drooping), thereby decreasing visual fields.

### Connection Check 45.7

The nurse recognizes which findings as expected changes in visual function associated with aging?

- Presbyopia, decrease in general color perception
- More narrowed field of vision, otosclerosis
- Decrease in general color perception, increased tear production
- Pupillary miosis, presbyopia

## Making Connections

### CASE STUDY: WRAP-UP

The APRN refers Melanie to an optometrist for further evaluation for glasses or contacts. Melanie will also need to use moisturizing eye drops to ensure that her eyes stay lubricated, obtain and use reading glasses for near vision, and schedule yearly eye examinations to ensure optimal eye health. She is also provided with instructions on vitamins to support eye health.

#### Case Study Questions

- Which changes in Melanie’s vision are expected age-related clinical manifestations?
  - Frequent tearing and “spots” in her vision fields
  - Difficulty reading objects when held at arm’s length
  - Dry eyes and difficulty reading unless objects are held at arm’s length
  - Itching of both eyes and blurry vision
- Which tests will Melanie’s provider order based on her presenting clinical manifestations and history?
  - Visual acuity test with ophthalmic examination
  - A CT scan to rule out the presence of tumors or other pathology
  - Ophthalmic examination using fluorescein to check for foreign bodies
  - Ophthalmic ultrasound to rule out the presence of cataracts
- In addition to focused examinations of the eyes, what other data should Melanie’s provider assess?
  - Immunization history
  - Dietary history
  - Travel history
  - Obstetrical history
- Based on her clinical presentation, Melanie’s provider is most likely to offer which suggestion?
  - Increase the intake of carrots in her diet to help stimulate her visual acuity.
  - Use lubricating eye drops for 2 weeks, and then return for a follow-up examination.
  - Get at least 8 hours of sleep at night.
  - Schedule a follow-up examination with an eye care specialist.
- What is the rationale for Melanie’s provider to perform the Rosenbaum test?
  - Assesses Melanie’s near vision
  - Assesses Melanie’s far vision
  - Assesses Melanie’s peripheral vision
  - Assesses Melanie’s CN IV function

## CHAPTER SUMMARY

The visual function of the human body is a spectacular system that contains countless different components. Disruption of any of these key components can result in a loss or interruption of vision. Completing an accurate and comprehensive medical history and eye examination of the patient’s visual system, including family history details, is essential for the maintenance of a healthy visual system. Diagnostic testing of the visual system also determines the current level of visual function and provides important baseline information for the future. Predictable changes

occur within the eye throughout the life span; these changes are readily visible during physical examination and during certain diagnostic tests related to the eye. The nurse must be keenly aware of the expected changes so that proper patient teaching and instruction can take place. Injury prevention education is another teaching area

in which it is essential for the nurse to take an active role with patients, even during routine physical examinations. Providing patients with yearly eye examinations, comprehensive and accurate education, and instruction for injury prevention all help to provide for a lifetime of good vision.

# Chapter 46

## Coordinating Care for Patients With Visual Disorders

*Kelley Miller Wilson*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of visual disorders
2. Explaining the pathophysiological processes of visual disorders
3. Correlating clinical manifestations with pathophysiological processes of
  - a. Visual acuity disorders
  - b. Endogenous endophthalmitis (related to opioid overuse)
  - c. Conjunctivitis
  - d. Corneal abrasions
  - e. Cataracts
  - f. Glaucoma
  - g. Macular degeneration
  - h. Retinal detachment
  - i. Eye trauma
4. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the eye
5. Discussing the medical management of selected disorders of the eye
6. Describing complications associated with selected disorders of the eye
7. Developing a comprehensive plan of nursing care for patients with eye disorders
8. Developing a teaching plan for a patient with eye disorders

### CONCEPTS

- Assessment
- Comfort
- Infection
- Inflammation
- Medication
- Perioperative
- Sensory Perception

### ESSENTIAL TERMS

Amsler grid  
Astigmatism  
Blunt eye trauma  
Cataract  
Conjunctivitis  
Corneal abrasion  
Drusen bodies  
Glaucoma  
Hyperopia  
Hyphema  
Keratotomy  
Keratoplasty  
Keratotomy  
Laser-assisted in situ  
keratomileusis (LASIK)  
Macula  
Macular degeneration  
Myopia  
Orthokeratology  
Penetrating eye trauma  
Phacoemulsification  
Presbyopia  
Refraction  
Retinal detachment  
Tonometry

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mike Peterson is a 64-year-old African American architect working in a busy urban architectural firm. Mike has always enjoyed excellent visual acuity, which has been vital to his career reviewing intricate architectural drawings on a daily basis. Lately, Mike has noticed his peripheral vision is decreasing; he is “missing” objects on the left side of his visual field. He plans to visit his provider this week for a physical examination and to discuss this new change in his vision...

## INTRODUCTION

The eyes are complex organs that work in conjunction with the brain to provide vision. There are many disorders of the eyes that impact vision, from visual disturbances that are treated with corrective lenses to degenerative disorders that potentially lead to total blindness. Understanding the pathophysiological changes associated with the various disorders provides the basis for the rationales for medical and nursing interventions.

## VISUAL ACUITY DISORDERS

**Refraction** is one of the four functions of the eye that controls clarity of vision no matter what the distance, and there are four refractive errors that occur when the bending of light rays by the cornea and lens does not focus the image correctly on the retina. **Myopia**, nearsightedness, results

from an eyeball that is too long or when the cornea has too much curve present, thus allowing the focused image to fall in front of the retina. **Hyperopia**, farsightedness, is the opposite issue, causing the image to fall behind the retina. **Astigmatism** results from a misshaped cornea. Another abnormality known as **presbyopia** occurs almost exclusively with aging and results from the loss of lens elasticity and occurs around age 45. The diagnosis of a visual acuity disorder may be made in a general provider’s office or clinic by using a Snellen chart as a general guide. Abnormalities in a visual acuity examination are referred to an eye care professional (ophthalmologist or optometrist) for further assessment and exact diagnosis. The provider also discusses the most appropriate care options available to the patient. All four of these disorders may be successfully treated with prescriptive lenses (eyeglasses or contact lenses).

## Epidemiology

Refraction errors affect approximately one-third of persons 40 years or older in the United States. The risk factors and prevalence for each specific refraction error are listed in Table 46.1.

## Pathophysiology

The shape of the eye and the role of the cornea provide most of the ability of the eye to focus clearly on objects near and far. The primary disorders of visual acuity are myopia, hyperopia, astigmatism, and presbyopia.

Myopia is a common condition caused by a larger-than-normal eyeball that causes light rays from distant objects to focus before they reach the retina. It may be inherited and is often detected in schoolchildren during routine vision examinations completed at school. Hyperopia commonly occurs when the eyeball is smaller than normal. This size

**Table 46.1** Specific Refraction Disorders

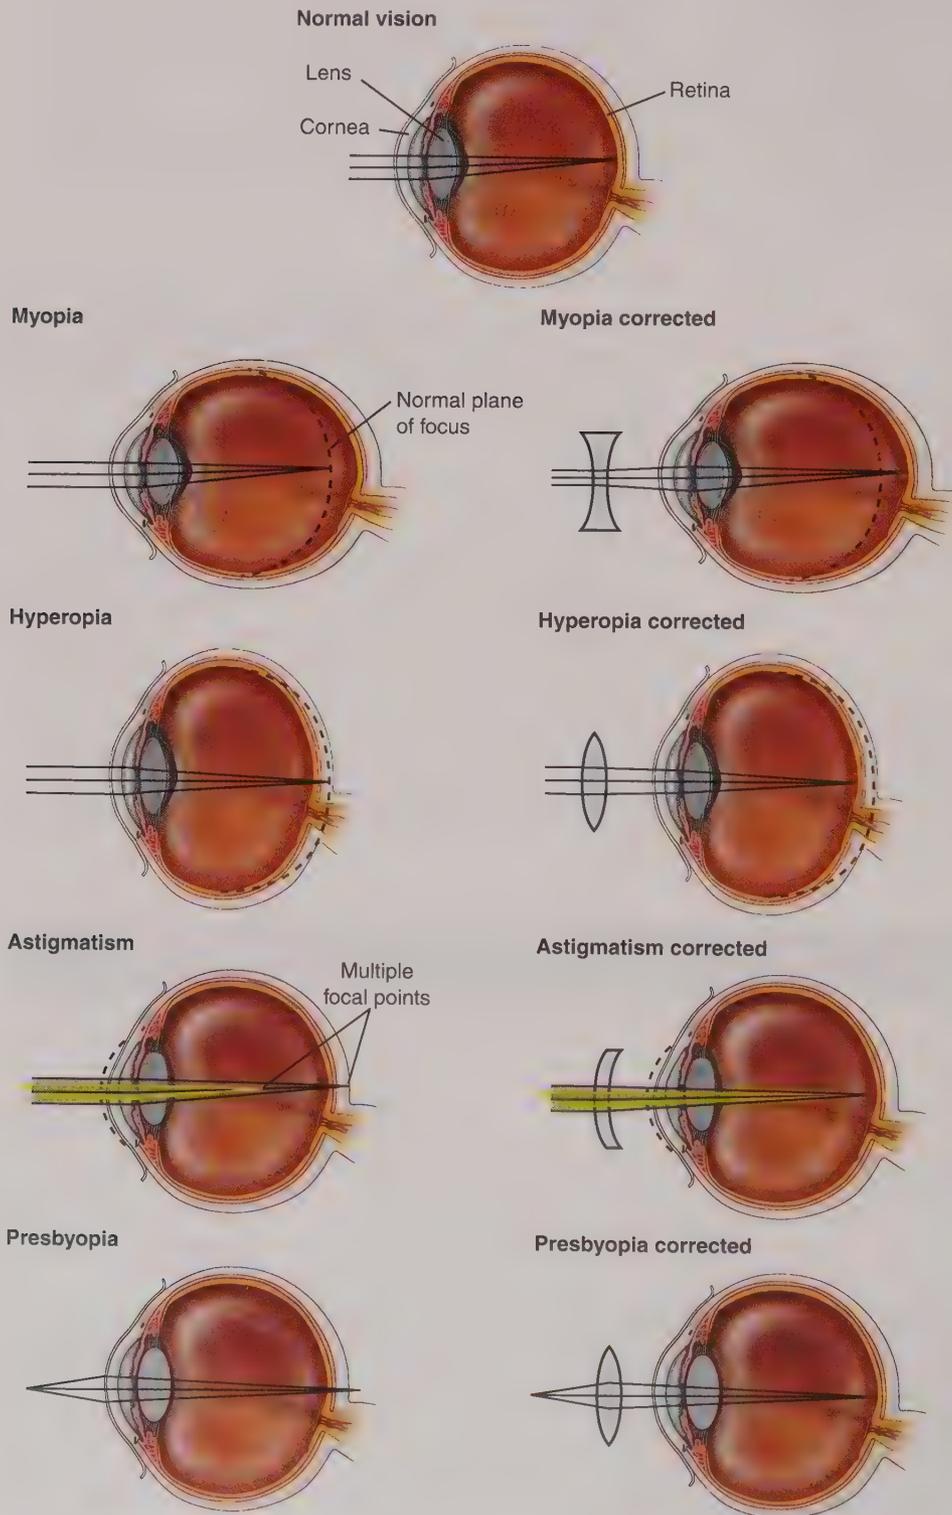

Refraction Error	Risk Factors	Prevalence
<b>Myopia</b>	Heredity; environmental factors such as reading in dim light and doing excessive amounts of close work may also contribute	Approximately 25% of the U.S. population is known to have myopia, affecting men and women equally.
<b>Hyperopia</b>	Heredity and increased age	Approximately 25% of the U.S. population is hyperopic, with men and women affected equally.
<b>Presbyopia</b>	A normal part of aging	Almost all people experience some degree of presbyopia when they reach their mid-40s.
<b>Astigmatism</b>	Heredity; injury that causes the lens or cornea to become distorted (including trauma, scarring, and surgical procedures involving the structures); persons with keratoconus (a condition where the cornea becomes thin and cone shaped; may be inherited or result from chronic eye rubbing); diabetes	Occurs often with myopia and hyperopia; it is believed that most people have some degree of astigmatism.

distortion causes light rays from near objects to focus improperly on the retina in the back of the eye. Often, babies and young children are slightly hyperopic, a condition that tends to improve as the eye grows.

Astigmatism is a condition that occurs when the lens or cornea (or both) is curved more steeply in an oval instead of a round shape. This distortion often occurs in combination with myopia or hyperopia. The uneven curvature

prevents light rays entering the eye from focusing to a single point on the retina.

Presbyopia results from a loss of lens elasticity that occurs in almost all adults around the age of 45. The loss of elasticity of the lens makes it more difficult for the lens to bend in order to focus on closely held objects. "Reading glasses" or handheld magnification is required to visualize properly. Figure 46.1 provides a visual representation of these disorders.

**FIGURE 46.1** Refraction and correction of visual disorders.

## Clinical Manifestations

The clinical presentations of disorders of visual acuity are directly related to the underlying pathophysiology.

- Myopia causes a person to see near objects more clearly than objects at a distance. The result of this distortion is blurred vision for distant objects.
- Hyperopia occurs when a person can see distant objects more clearly than near objects. Blurred vision of near objects is the symptom associated with this disorder.
- Astigmatism results in visual changes where objects that are near and distant are blurry. Other clinical manifestations include squinting, headaches, and blurry vision.
- Presbyopia, an expected change in vision around midlife, results in the inability to focus on objects held close to the face.

## Management

### Medical Management

The goals of medical management of disorders of visual acuity focus on maximizing sight through interventions such as corrective lenses. Table 46.2 provides the specific types of correction associated with each disorder. **Orthokeratology** is a nonsurgical option to reshape the cornea that requires the patient to wear a special contact lens that slowly reshapes the cornea and corrects the myopia over time.

### Surgical Management

Common surgical treatments for visual acuity disorders include the following (Table 46.3), including different approaches to **keratotomy** (surgical approach involving cutting into the cornea), **keratectomy** (surgical removal of a section or layer of the cornea), and **keratoplasty** (surgical procedure replacement of damaged/diseased corneal tissue with healthy tissue from a donor):

- **Radial keratotomy** is a surgical procedure in which tiny incisions are made in the cornea that cause it to flatten and reduce the refraction disorder (Fig. 46.2A).
- **Photorefractive keratectomy (PRK)** involves removing a portion of the cornea with a laser to change its shape and therefore modify the refractive error (Fig. 46.2B).

**Table 46.2 Treatments for Visual Disorders**

Condition	Medical Treatment Available
<b>Myopia</b>	Corrective lenses such as glasses or contact lenses
<b>Hyperopia</b>	Convex corrective lenses in eyeglasses or contact lenses
<b>Presbyopia</b>	“Reading glasses” or magnification
<b>Astigmatism</b>	Eyeglasses, contact lenses, or orthokeratology

**Table 46.3 Surgical Treatments for Visual Disorders**

Condition	Most Commonly Used Surgical Treatment Available
<b>Myopia</b>	Radical keratotomy, photorefractive keratotomy, and LASIK  Implantable lens known as Phakic Intraocular Lens is another form of treatment to correct myopia.  This treatment is usually reserved for patients who are unsuitable for LASIK or other vision corrective surgeries.
<b>Hyperopia</b>	Refractive surgery such as LASIK, photorefractive keratectomy, thermal keratoplasty, conductive keratoplasty, and intraocular implants
<b>Presbyopia</b>	Refractive surgery and implanted intraocular lenses (several other therapies are also currently under investigation)
<b>Astigmatism</b>	Refractive surgery, LASIK, photorefractive keratectomy

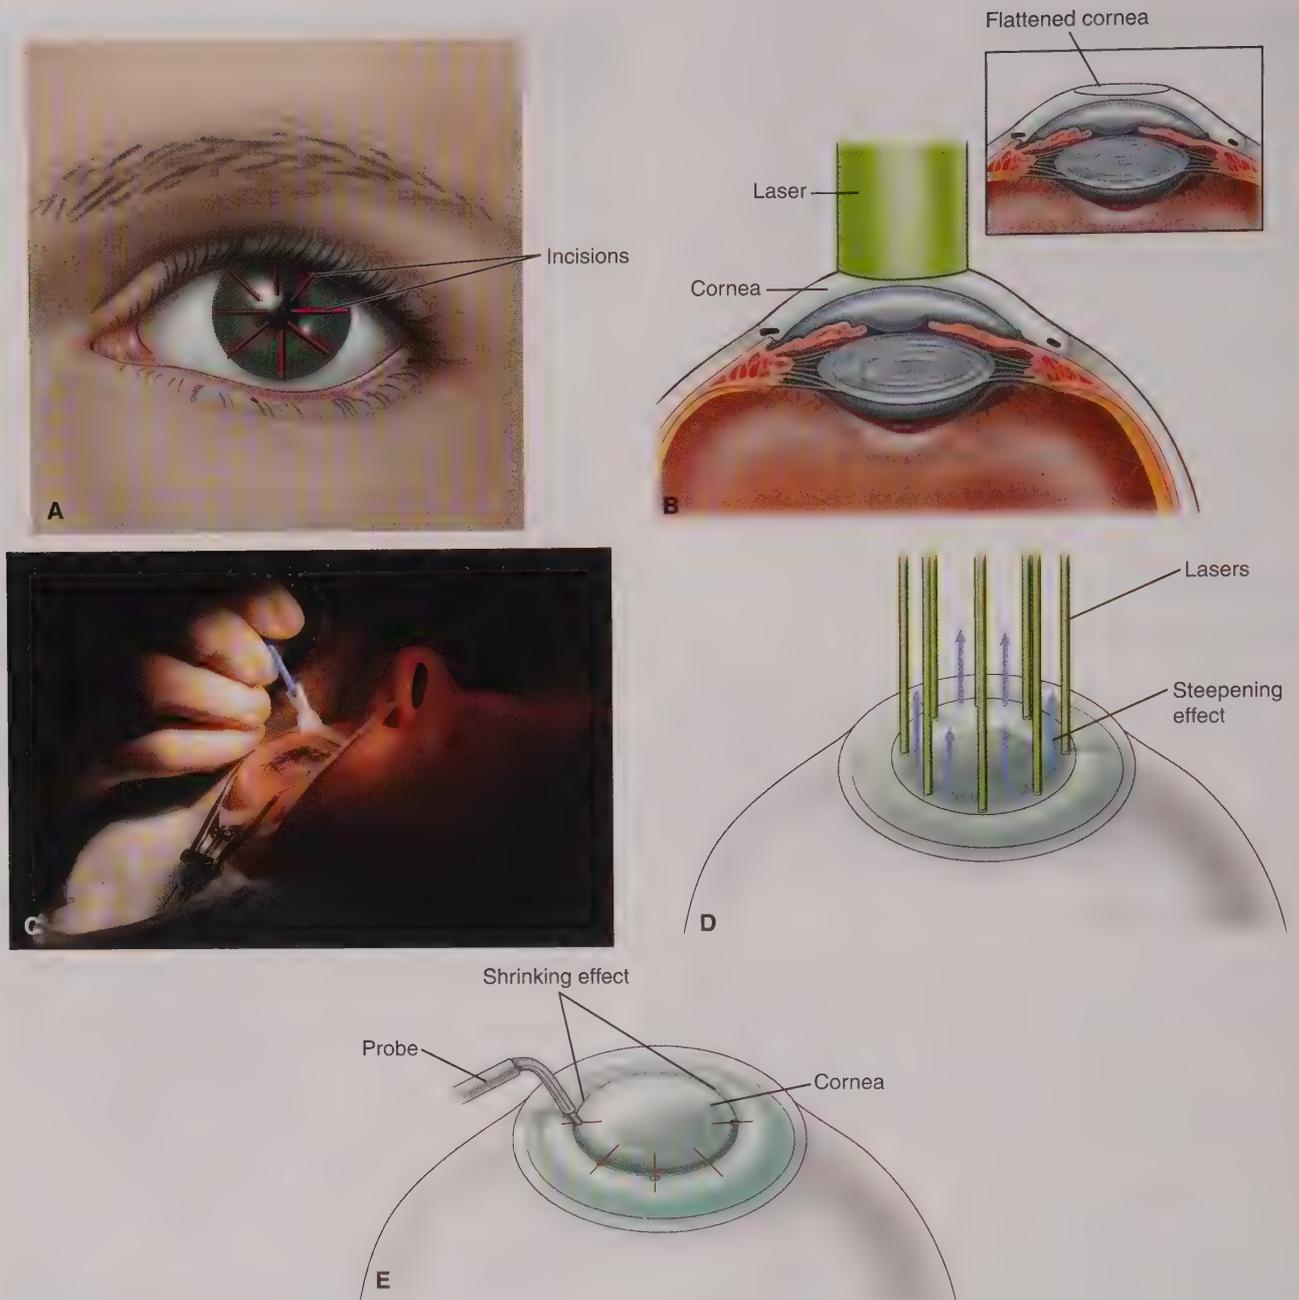

LASIK, Laser-assisted in-situ keratomileusis.

- **Laser-assisted in situ keratomileusis (LASIK)** involves the use of a laser or a special instrument called a *microkeratome* to create a thin circular flap in the cornea (Fig. 46.2C). The flap is then folded back out of the way, and the surgeon uses the laser to remove some of the corneal tissue. The laser is directed and then uses a cool ultraviolet (UV) light beam to precisely ablate (remove) very tiny bits of tissue from the cornea to reshape it.
- **Laser thermal keratoplasty (LTK)** uses a Holmium laser to reshape the cornea (Fig. 46.2D). The Holmium laser is an infrared or thermal laser that uses heat to shrink the corneal tissue.
- **Conductive keratoplasty** uses radiofrequency energy and does not remove any corneal tissue (Fig. 46.2E). An instrument with a tiny probe on the end is placed at specific points around the peripheral portion of the cornea. These points then emit energy that causes collagen to contract, shrinking the circumference of the cornea and changing the shape of the curve.

## Nursing Management

### Assessment and Analysis

Treatment of visual acuity disorders varies greatly depending on the diagnosis (Table 46.4). All four visual acuity disorders may be treated medically with corrective eyeglasses or contact lenses. Surgical options are also available for each disorder. Depending on expected results, patient age, and personal circumstances, treatment plans are individualized for the patient.

**FIGURE 46.2** Common surgical treatments for visual acuity disorders. A, Radial keratotomy is a surgical procedure in which tiny incisions are made in the cornea that cause it to flatten and reduce the refraction disorder. B, Photorefractive keratectomy involves the removal of a portion of the cornea with a laser to change its shape and therefore modify the refractive error. C, Laser in situ keratomileusis (LASIK) uses a laser to create a thin circular flap in the cornea. D, Laser thermal keratoplasty uses a laser to reshape the cornea. E, Conductive keratoplasty uses an instrument with a tiny probe on the end that is placed at specific points around the peripheral portion of the cornea. These points then emit radiofrequency energy that causes collagen to contract, shrinking the circumference of the cornea and changing the shape of the curve.

### Nursing Diagnoses

- **Disturbed visual sensory perception** related to refractive disorders of the eye
- **Risk for injury** related to inability to correctly focus
- **Anxiety** related to visual impairment and inability to correctly focus on objects

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Vital sign changes or fluctuations are not usually directly related to visual acuity disorders. Elevations in pulse and blood pressure are mostly related to pain or anxiety.*

**Table 46.4 Assessment and Analysis of Visual Disorders**

Assessment Data	Analysis/Explanation
<b>Myopia (nearsightedness)</b>	Blurred vision when looking at distant objects, headaches, feeling of eye strain, squinting when looking at objects more than a few feet away
<b>Hyperopia (farsightedness)</b>	Blurred vision when looking at close-up objects, aching eyes or feeling of eye strain, headache during reading
<b>Presbyopia</b>	Holding reading material far away so that letters are clear, blurred vision at normal reading distance, feeling of eye strain or headaches after reading or doing close work (may also occur with myopia and hyperopia)
<b>Astigmatism</b>	Headache, blurred vision at all distances, feeling of fatigue or eye strain

- Eye changes associated with visual acuity changes  
*Physical assessment changes center around changes in the corneal shape in myopia, hyperopia, and astigmatism. Presbyopia yields changes in lens elasticity and therefore produces a more elongated lens instead of the expected round shape.*
- Diagnostic results  
*Diagnostic results for visual acuity disorders center on eye examination and visual acuity changes that are noted on Snellen vision charts or more comprehensive examinations completed by eye care professionals in their office.*
- Age-related considerations  
*Advanced age increases the risk for all four visual acuity disturbances because the eye begins to undergo predictable changes. Presbyopia, yielding a loss in lens elasticity specifically, is considered a normal process of aging and occurs in midlife around age 45. Routine eye examinations after age 45 are recommended to monitor for any eye changes.*

#### ■ Actions

- Ensure the patient correctly wears corrective lenses (eyeglasses and contact lenses).  
*Corrective lenses, both eyeglasses and contact lenses, provide necessary treatment to correct refraction errors.*
- Provide adequate lighting to maximize visual acuity.  
*Insufficient lighting may place additional strain on the eyes and adversely impact visual acuity.*

#### ■ Teaching

- Importance of wearing corrective lenses, including eyeglasses and contact lenses  
*Review with the patient proper care for eyeglasses and proper disinfection, insertion, and storage of contact lenses. Patients wearing contact lenses also need to be instructed to remove lenses at night to prevent eye damage (an exception is contact lenses approved for long-term use).*
- Report visual changes or chronic headaches to health-care provider.  
*Patients need to be instructed to notify a healthcare provider for visual disturbances or continued headaches indicating that lens correction may not be sufficient. Yearly follow-up with a provider is recommended for all patients with corrective lenses.*

- Postoperative considerations

*Patients should be instructed to notify providers of increased pain, temperature, or other unusual feelings because these could indicate a structural complication or an infection. Follow-up appointments are also very important to ensure that proper healing is taking place. Restrictions on lifting, bending, and Valsalva maneuvers are important instructions for some surgeries to prevent increased intraocular pressure (IOP) from occurring.*

#### Evaluating Care Outcomes

Patients with visual acuity disorders can lead a productive, normal life. The patient requires continued follow-up and monitoring by a healthcare provider to ensure optimal vision as magnification requirements change over time. Knowledge of possible complications and specific postoperative instructions must also be followed for successful treatment.

#### Connection Check 46.1

The clinic nurse is preparing to check a patient's vision. The nurse knows that nearsightedness or myopia causes light rays

- from distant objects to focus before they reach the retina.
- to focus improperly on the retina in the front of the eye.
- to diverge to focus on the retina.
- to reflect off the macula.

## VISION LOSS RELATED TO OPIOID USE

### Epidemiology and Pathophysiology

Opioid use and deaths associated with opioid abuse in the United States have dramatically increased since 2000. An unexpected and devastating result related to IV opioid drug use is endogenous endophthalmitis, an infection

transmitted via the bloodstream that multiplies in the choroid, leading to infiltration of the retina and spreading to the vitreous humor. Drug use via injection with non-sterile equipment can result in microbial bloodstream infections that can seed ocular infection, and these infections may be bacterial, fungal, or viral in nature. Despite treatment, nearly 50% of those affected will have no light perception, and the condition can lead to partial or complete blindness.

## Clinical Manifestations

Patients with suspected endogenous endophthalmitis present with minimal clinical manifestations, including a red and painful eye, photophobia, floaters, and reduced vision. Most often, patients present with unilateral clinical manifestations, although up to one-third of cases have bilateral involvement. Upon examination, symptomatic patients may have reduced visual acuity, conjunctival injection, corneal edema, and inflammation of the iris and vitreous parts of the eye.

## Management

### Medical and Surgical Management

A key diagnostic finding associated with endogenous endophthalmitis is the presence of a white infiltrate originating in the choroid and sometimes erupting into the vitreous cavity. Specialized equipment and providers with specialization in eye diseases examine the patient more extensively to make this diagnosis.

Treatment should be initiated as soon as endophthalmitis is suspected and is often started even before a definitive diagnosis is made. Most commonly, treatment begins with prompt intravitreal antibiotic administration, combined with hospitalization, infectious disease consultation, and IV antibiotics.

In determining the best therapeutic approach, the causative organism and the extent of ocular involvement should direct the aggressiveness of therapy. If the ocular lesion is confined to the choroid, systemic therapy with antibiotics or antifungals and close observation may be suitable; if the infection has spread beyond the choroid into the vitreous, then more aggressive intravitreal antibiotic therapy should be considered.

### Nursing Management

#### Assessment and Analysis

Patients often present with local clinical manifestations of an eye infectious process associated with IV opioid use. Treatment plans are individualized for the patient based on the circumstances related to the infectious process.

Clinical manifestations of this disorder include:

- Red, painful eyes
- Photophobia
- Floaters

- Decreased visual acuity
- Corneal edema

## Nursing Diagnoses

- **Disturbed visual sensory perception** related to infectious process in the eye secondary to IV opioid use
- **Risk for injury** related to decrease in visual acuity
- **Pain** related to inflammation and infection

## Nursing Interventions

### Assessments

- Vital signs  
*Slight elevation in body temperature may be noted with endogenous endophthalmitis secondary to the presence of infection/inflammation. Elevations in heart rate and blood pressure may be associated with anxiety or recent IV drug use.*
- Visual changes reported by the patient  
*Active infectious processes may cause visual changes. The presence of floaters may also impair visual acuity.*
- Eye appearance: Eye assessment changes noted on physical exam  
*Redness, tearing, and swelling are objective assessments caused by the infectious process in the eye.*
- Diagnostic results for visual acuity changes  
*The presence of a white infiltrate originating in the choroid and sometimes erupting into the vitreous cavity*

### Actions

- Administer antibiotics, antifungals, and/or antivirals as prescribed.  
*Intravitreal and IV medications treat the infectious process.*
- Provide comfort care.  
*Cool compresses applied to the affected eye help decrease inflammation of the eye. Sunglasses may offer comfort in bright light conditions.*
- Assist with healthcare provider examination by providing adequate lighting and equipment.  
*A definitive diagnosis and identification of bacteria or fungus are key to effective treatment.*
- Safety considerations if vision is impaired  
*Decreased visual acuity increases the risk of falls and other injuries.*

### Teaching

- Activity level  
*Instruct patient about any required changes in activity levels based on the provider's instructions and diagnostic findings.*
- Hand hygiene  
*Clean hands are essential to prevent the transmission of conditions from one eye to another.*
- Medication therapy  
*It is important that the patient and family understand the importance of taking medications as prescribed and completing all medications to prevent reoccurrence or incomplete treatment. Incomplete treatment can lead to even more serious or complicated infections.*

- Relationship between IV opioid use and development of endogenous endophthalmitis  
*Drug use via injection with nonsterile equipment can result in microbial bloodstream infections that can seed ocular infection.*
- Follow-up treatment  
*It is essential that patients follow up with providers with scheduled appointments in order to closely monitor the healing process and any further changes in visual acuity.*

### Evaluating Care Outcomes

The outcomes of endogenous endophthalmitis are variable and are generally dictated by the aggressiveness of the causative organism. In general, yeasts are associated with the best visual outcomes, bacteria with moderate outcomes, and molds with the worst. Patient compliance with prescribed treatments, especially antibiotic, antifungal, or antiviral therapies, is key to the treatment of this disorder. It is also important that the patient and family understand the connection between IV drug use (opioids) and the development of endogenous endophthalmitis.

## CONJUNCTIVITIS

### Epidemiology

**Conjunctivitis** is a nonspecific term used to describe an inflammation of the conjunctivae of the eye. Most commonly known as pinkeye, this condition is usually caused by a wide range of conditions and is present throughout the world. It affects all ages, races, genders, and socioeconomic status groups.

Risk factors for this condition are sporadic or related to epidemic outbreaks. According to a National Health Survey, the prevalence of conjunctivitis in the United States in patients aged 1 to 74 is approximately 13 in 1,000. This study also noted that there are no reliable figures documenting the incidence of conjunctivitis, although it is estimated to be one of the common disorders of the eye. It is estimated that 3% of all emergency department visits are related to eye disorders, and approximately 30% of these are conjunctivitis. In primary care clinics, 2% of visits are related to ocular complaints, with 54% being related to conjunctivitis or corneal abrasions. Following diligent and frequent hygiene practices decreases the chances of transmission of conjunctivitis.

### Pathophysiology

The condition termed *conjunctivitis* is described as an inflammation of the conjunctivae of the eye. Although viral conjunctivitis is more common than bacterial, *Streptococcus*, *Staphylococcus*, and *Haemophilus aegyptius* are the most common bacterial causes of conjunctivitis. There are different types of conjunctivitis, and most people in their lifetime will have the unpleasant experience of at least one of them. Diagnosis of conjunctivitis is made based on history, clinical presentation, and physical findings.

### Clinical Manifestations

The most common forms of conjunctivitis include the following clinical presentations:

- **Allergic conjunctivitis** is a condition involving inflammation of the conjunctivae secondary to an allergy-causing substance such as pollen or dander. The patient has clinical manifestations including red/pink sclera, intense itching, burning, tearing, and puffy eyelids.
- **Bacterial conjunctivitis** is an infection of the conjunctivae caused by a microbe or bacteria. The microbe often causes a gritty sensation in the eye; patients often describe it as feeling like sand is in the eye. There is also often a purulent eye discharge and matting of the eyelashes upon awakening in the morning.
- **Viral conjunctivitis** is a common condition involving inflammation of the conjunctivae secondary to the presence of a virus. Often seen with common colds, a virus affecting the upper respiratory tract, and sore throats, the eye usually exhibits a watery discharge, and the condition easily spreads from one eye to another.
- **Chlamydial conjunctivitis** is a sexually transmitted infection that is most commonly transmitted through the hand-to-eye spread of infected genital secretions. Chlamydial conjunctivitis may be transmitted during birth from an infected mother to the newborn. The organism causing the infection is *Chlamydia trachomatis*, and the patient usually has clinical manifestations for weeks or months. This specific type of conjunctivitis is known worldwide and in the past was considered to be a leading cause of blindness.
- **Contact lens–related conjunctivitis** is caused by hypersensitivity to one or more of the chemicals used to make the contact lens itself. Contact lens soaking solutions can also cause a hypersensitive reaction, thus yielding conjunctivitis. In addition, this condition is also caused by dirty lenses or debris under the lens in the eye.
- **Mechanical conjunctivitis** involves an irritation of the conjunctival surface caused by mechanical means such as an eyelash, foreign body, or other object of irritation.
- **Traumatic conjunctivitis** results from a direct injury such as a laceration, abrasion, or chemical injury (it is considered a secondary response).
- **Toxic conjunctivitis** typically develops following administration of a medication or direct contact with a corrosive or noxious chemical.

### Management

#### Medical Management

The treatment of conjunctivitis depends on the causative agent. Comprehensive history-taking is essential for determining the type and guides effective patient treatment. The provider may use a slit lamp or other instrument to verify that there is no foreign body present in the eye. In conditions such as chlamydia or other suspected infection, the

provider may also take a culture of the conjunctivae for microscopic examination. Visual acuity checks are always performed before treatment and after treatment in the patient with conjunctivitis. Table 46.5 lists the most common treatments for specific types of conjunctivitis.

### Nursing Management

#### Assessment and Analysis

Many clinical manifestations of conjunctivitis (Table 46.6) are similar, and comprehensive history-taking is essential to making the correct diagnosis (Table 46.7). Tearing, itching, and inflammation of the conjunctiva are commonly observed. Incorrect diagnosis can lead to improper treatment.

#### Nursing Diagnoses

- **Risk for infectious transmission** related to inflammation/infection of the conjunctivae
- **Pain** related to inflammation of the conjunctivae

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*A slight elevation in body temperature may be noted with some conjunctival infections of the eye secondary to the presence of infection/inflammation. No other changes in vital signs are expected.*
- Appearance of eye  
*The sclera is expected to be pink/red/inflamed-looking secondary to the presence of infection/virus or allergen.*

*Tearing is present secondary to inflammation; purulent discharge may or may not be present depending on whether a bacterial infection is present.*

- Diagnostic results  
*Diagnosis is based primarily on the physical examination and history. Suspicious bacterial infections may also suggest that the provider swab the eye with a culture swab and send it to the laboratory for microscopic evaluation and incubation.*
- Age-related considerations  
*This condition affects all age groups, making no one group more at risk than another.*
- **Actions**
  - Pharmacological therapy  
*Specific medications are prescribed on the basis of the etiology and clinical manifestations (see Table 46.5).*
  - Provide comfort care.  
*Cool compresses applied to the affected eye help decrease inflammation of the eye. Sunglasses may offer comfort in bright light conditions. Administration of antihistamine eye drops as prescribed offers some relief from itching of the eye.*
  - Collaborative care  
*Referral to an eye care specialist for visual disturbances or difficult-to-treat clinical manifestations*

##### ■ Teaching

- Hand hygiene  
*Clean hands are essential to preventing the transmission of conditions from one eye to another or from one person*

**Table 46.5 Treatment of Conjunctivitis**

Etiology	Treatment
<b>Allergic conjunctivitis</b>	Most common are topical steroid and mast cell stabilizing drops instilled directly into the eye to decrease inflammation and block the release of histamine; topically instilled vasoconstrictor/antihistamine drops to the eye to decrease itching; removal of the allergen if known or if possible; good hand-washing practices
<b>Bacterial conjunctivitis</b>	Administration of antibiotic ointment or drops directly into the eye (rare cases may require systemic antibiotics); good hand-washing practices
<b>Viral conjunctivitis</b>	Cold compresses to the eye for pain relief and decrease in swelling/irritation; eye lubricants and ocular decongestants to help reduce swelling and inflammation; good hand-washing practices
<b>Chlamydial conjunctivitis</b>	Systemic antibiotics in most cases for up to 1 month; good hand-washing practices; medical treatment of the infected partner
<b>Contact lens conjunctivitis</b>	Discontinue wearing of lenses and determine underlying causes (solution allergies, age of lenses, bacterial contamination, trauma); good hand-washing practices
<b>Mechanical conjunctivitis</b>	Removal of trauma-inducing agent; may need antibiotic ointment or drops if significant epithelial disruption is present; good hand-washing practices
<b>Traumatic conjunctivitis</b>	Depends on the cause; usually need corneal staining to determine extent of trauma; may require antibiotic drops/ointment and pressure patch
<b>Chemical-induced conjunctivitis</b>	May require continuous irrigation with normal saline solution; corneal staining examination and antibiotic therapy depending on condition

**Table 46.6 Clinical Manifestations of Conjunctivitis**

Etiology	Condition	Clinical Manifestations
<b>Bacterial</b>	Acute/chronic bacterial	Tearing, lid crusting, feeling that something gritty is in the eye, purulent discharge, sclera pink/inflamed, eyes may be itchy
<b>Viral</b>	Adenovirus	Tearing, lid crusting, pink and inflamed sclera and conjunctiva, puffy eyelids, itchy
<b>Allergic</b>	Seasonal/dander	Itching, tearing, pink or red inflamed sclera/conjunctiva
<b>Chlamydial</b>	<i>Chlamydia trachomatis</i>	Tearing, red/pink conjunctiva and sclera, sticky eye mucous discharge, tearing, photophobia, foreign-body sensation

**Table 46.7 Assessment and Analysis of Conjunctivitis**

Assessment Data	Analysis/Explanation
<b>Tearing</b>	Initial response that occurs when a foreign substance is present in the eye
<b>Red/Pink sclera</b>	Change in scleral color is secondary to inflammation present on the sclera (mucosal) covering of the eye. This inflammatory process may be caused by bacterial or viral organisms.
<b>Inflamed conjunctivae</b>	Inflammation of the conjunctivae occurs, causing redness or swelling of the conjunctivae secondary to the presence of bacteria or viral organisms in the eye.
<b>Itchy eye</b>	Irritation of the sclera and mucosal linings of the eyelids produces an immune reaction that causes an itching sensation.
<b>Purulent discharge from the eye</b>	Presence of bacteria and the immune system response cause the formation of a purulent drainage to be present in the eye.

to another; conjunctivitis is considered extremely contagious.

- **Hygiene at home**  
*Towels and pillowcases should be changed frequently and isolated from other family members to prevent possible transmission to another person.*
- **Completion of all prescribed medications**  
*Completion of all prescribed medication as ordered to prevent reoccurrence or incomplete healing. Incomplete treatments can lead to an even deeper infection in the eye.*
- **Follow-up care**  
*It is essential that patients keep follow-up appointments with their provider to verify the healing process and to monitor for any possible visual loss.*

### Evaluating Care Outcomes

Conjunctivitis is a nuisance for most patients who suffer from this condition. Early diagnosis and definitive treatment offer relief and prevent possible transfer of infection from one eye to another or one person to another. Clinical manifestations of the condition are directly related to the type of conjunctivitis. Most treatments are very effective, and the condition is easily resolved in 10 to 14 days.

### Connection Check 46.2

The nurse correlates which clinical manifestations with a diagnosis of viral conjunctivitis? (Select all that apply.)

- Pink or red sclera
- Presence of upper respiratory symptoms or sore throat
- Sensation of a foreign body in the eye
- Watery discharge from the eye
- Loss of peripheral vision

## CORNEAL ABRASION

### Epidemiology

One of the most common ophthalmological conditions leading to visits to emergency departments is **corneal abrasion**, and it is estimated to account for more than 10% of eye-related visits to healthcare providers. Contact lens wearers present with this condition more frequently than those who do not wear contact lenses. Two types of abrasions can occur; these are known as superficial and deep. A superficial corneal abrasion is a painful scratch or scrape to the cornea of the eye in which epithelial cells are removed.

Deep corneal abrasions penetrate the Bowman's membrane (the smooth layer of the eye located just under the epithelium) and usually take longer to heal (Fig. 46.3).

The most common risk factors associated with corneal abrasion include:

1. Contact lens wearers
2. Participation in contact sports
3. Presence outdoors in windy conditions without protective eyewear
4. Any abrasive eye injury
5. Dry eye syndrome
6. Abuse of topical eye anesthetics and steroids
7. Autoimmune disorders
8. Recent eye surgeries

There are four common causes of corneal abrasions: trauma, foreign bodies, contact lenses, and spontaneous defect.

### Traumatic Corneal Abrasion

A traumatic corneal abrasion is caused by mechanical trauma to the eye resulting in disruption of the epithelial surface. Common causes of this type of abrasion are fingernail scrapes/pokes; animal paws inadvertently hitting the eye surface; pieces of paper or cardboard coming in contact with the eye surface; and makeup applicators (a mascara wand is a common source), hand tools, and branches and leaves coming in contact with the eye surface. Traumatic abrasions are also commonly caused by a foreign body, such as a piece of dust, eyelash, or other small particulate that lodges under the lid, resulting in a scratch to the eye surface.

### Foreign Bodies

These disruptions in the corneal epithelium are caused by the removal or spontaneous dislodgment of a foreign substance/object. Common foreign-body abrasions are caused by pieces of rust, wood, glass, plastic, and fiberglass.

### Contact Lenses

Removal/insertion of contact lenses and overworn or improperly fitting lenses can cause an abrasion to occur. Improperly cleaned/disinfected lenses can also be the culprit in some corneal abrasions because the dirt/bacteria present can cause an abrasion to develop.

FIGURE 46.3 Corneal abrasion.

### Spontaneous Defects

Previous eye abrasions, trauma, or underlying defects make a person more prone to spontaneous abrasions. Dry eyes and underlying chronic illness (e.g., diabetes and autoimmune illness) can make the epithelial cells more prone to a scratch. Persons who have had previous eye trauma, including tears, can develop a spontaneous injury.

### Pathophysiology

Corneal abrasions are defined as a disruption of the cornea resulting from physical or chemical trauma. The abrasion is a disruption in the integrity of the cornea that is limited to only the epithelial layers. These abrasions can be very small or very large in size and usually heal within 24 to 48 hours of injury.

### Clinical Manifestations

The most common clinical manifestations of corneal abrasions include eye pain (sometimes severe), photophobia (inability to be in the presence of bright light), spasm causing squinting, tearing, blurred vision, and the sensation of a foreign body in the eye.

### Management

#### Medical Management

The medical management of a corneal abrasion includes a comprehensive examination by a healthcare provider. This examination includes a visual acuity test, anesthetizing the eye with an anesthetic agent (commonly tetracaine 1%), corneal staining with fluorescein stain, and visualization under a Wood lamp to confirm the diagnosis of the abrasion. Upon confirmation of the diagnosis, antibiotic eye drops and eye drops to help decrease muscle spasms of the eye may be prescribed. Eye patching is considered controversial and may or may not be used. Tetanus vaccination should be verified and administered if the patient is not considered up to date because any open surface of the body can provide a port of entry for *Clostridium tetani*. Discharge instructions include wearing sunglasses for pain relief and following up with an eye care professional within 24 to 48 hours.

#### Surgical Management

Most corneal abrasions are treated medically, and unless the patient received an extensive corneal abrasion, treatment is as outlined previously. Extreme corneal abrasions are often diagnosed as deep corneal lacerations and may require surgical exploration and suture placement for repair.

#### Nursing Management

##### Assessment and Analysis

The removal of epithelium from the covering of the eye in most cases is extremely painful. The corneal area of the eye has an abundance of nerve cells present that make it almost immediately obvious that an injury has occurred (Table 46.8).

**Table 46.8 Assessment and Analysis of Corneal Abrasions**

Assessment Data	Analysis/Explanation
<b>Eye pain (can be severe)</b>	Disruption of the epithelial surface of the cornea also disrupts the numerous sensory nerves, resulting in pain.
<b>Tearing</b>	Initial response to eye injury or foreign substance being present in the eye.
<b>Photophobia</b>	This is present because too much light is able to enter the eye with the disruption of the corneal cells.
<b>Redness of the sclera</b>	New blood vessels form, and those present enlarge, to increase blood flow to the eye so that healing can occur.

Most corneal abrasions will heal within 24 to 48 hours after injury and without complication. Clinical manifestations include pain, redness, tearing, the sensation of something in the eye, squinting, and photophobia.

### Nursing Diagnoses

- **Pain** related to disruption of epithelial cells on the cornea
- **Disturbed visual sensory perception** related to corneal disruption
- **Risk for infection** related to a tear in epithelial cells of the cornea

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*There is no disturbance in vital signs from this injury, although elevations may be noted in heart rate and blood pressure if pain is present.*
- Preparation for examination/physical assessment changes  
*Prepare the patient for an eye examination. Visual acuity is assessed to verify initial acuity; worsening of these numbers on follow-up examination could indicate the severity of injury. Instillation of tetracaine 1% provides instant pain relief in most instances; instillation of fluorescein eye stain helps to highlight the presence of injury when a UV light (Wood lamp) is shone over the injured eye. This helps the provider verify the presence and extent of injury.*
- Diagnostic results  
*Diagnostic results are as noted previously and guide treatment.*
- Age-related considerations  
*This condition affects all ages, and there are no special considerations for age; treatment modalities are considered the same.*

#### ■ Actions

- Pharmacological therapy  
*Patients identified as having a corneal abrasion are prescribed medications on the basis of the severity of the abrasion and the amount of pain the patient is experiencing. Pain medication may be over-the-counter preparations, such as acetaminophen, or a stronger prescription-strength medication may be selected by the provider. Antibiotic eye drops are selected*

*according to the degree of abrasion present and the amount of contamination present in the injury. Cycloplegic eye drops such as atropine are sometimes prescribed. These drops dilate the pupil and help decrease the amount of painful muscle spasms in the ciliary body of the eye that can develop after such an injury. Antibiotics are indicated with corneal abrasions that are infected.*

- Comfort measures  
*Comfort measures are provided to assist the patient in recovery from this injury. Medications taken as prescribed help promote healing and decrease pain from exposed nerve cells and painful muscle spasms of the eye. An eye patch is sometimes recommended and often provides some relief because light is no longer able to reach the eye. Sunglasses are suggested for patients in the presence of bright light to help reduce the photophobic effect of the injury.*
- Collaborative care  
*Referral to an eye care specialist for severe or difficult-to-heal injuries*
- **Teaching**
- Discharge instructions for care at home  
*The patient is instructed to follow all discharge instructions provided by the provider, including antibiotic eye-drop instillation to heal/prevent infection, pain medication as ordered to prevent severe pain and to provide comfort, and an eye patch (if ordered) to remain in place with specific time parameters. Eye patches can provide comfort and, in some cases, can add a compression effect to prevent possible bleeding. (Eye-patch placement is controversial, and some providers believe that eye patches can delay healing and therefore do not prescribe patches.) Additionally, the patient is to practice good hand hygiene and keep hands away from the eye to lessen the chance of infection or the possibility of a tear or injury secondary to rubbing the eye. The nurse emphasizes the importance of follow-up appointments so that the chance for permanent injury, including loss of vision, is lessened.*

### Evaluating Care Outcomes

Patients who suffer a corneal abrasion usually notice significant relief of symptoms within 24 to 48 hours of injury depending on the severity of the abrasion. Medical evaluation, treatment with antibiotic eye drops, pain medication (if indicated), an eye patch (if prescribed by the provider),

and verification of tetanus vaccination are all key factors in treating corneal abrasions. Follow-up care appointments with providers are also vital so that assessment of progress and verification of visual acuity may be obtained. Collaborative care with specific eye care professionals is essential for large or complicated abrasions.

### Connection Check 46.3

The nurse is developing a teaching plan for the patient with a corneal abrasion and includes which information? (Select all that apply.)

- A. Hand-washing techniques
- B. Steroid eye drops
- C. Bilateral eye patches
- D. Comfort measures
- E. Anesthetic eye drops

## CATARACTS

**Cataracts** are a common phenomenon that can occur at any time in a person's life but are most commonly seen with advanced age. A cataract is clouding of the eye's crystalline lens. The lens works to focus light onto the retina at the back of the eye, allowing for clear vision both up close and far away. The clouding of this structure decreases vision and leaves patients at risk for injury (Fig. 46.4).

### Epidemiology

Cataracts affect nearly 22 million Americans aged 40 and older. By age 80, more than half of all Americans have cataracts, and they are slightly more likely to affect women than men.

Risk factors for cataracts include:

- **Exposure to UV light:** Risk may be higher for those who have had significant sun exposure at a young age. People working in outdoor capacities where sunlight exposure is frequent and intense for long periods of time, such as lifeguards, landscape workers, and sports players, are commonly seen to be at increased risk.
- **Advanced age:** Cataracts are most common after age 60 but can occur at any time.

FIGURE 46.4 Cataract.

- **Family history:** Tends to follow family genetic history; those with family members who had cataracts are therefore more likely to develop them at some point in their life.
- **Race and ethnicity:** African Americans have twice the risk of Caucasians. Hispanic Americans are also noted to have a higher risk than Caucasians.
- **Diabetes mellitus and other chronic medical conditions:** Patients with diabetes, both type 1 and type 2, are at a higher risk for developing cataracts and are more likely to develop them at a younger age. It is thought that these cataracts are due to elevated blood glucose levels. Patients with autoimmune diseases are also thought to have a higher risk of developing cataracts because of their chronic steroid use. Patients with certain eye conditions, such as myopia, or patients with previous eye injuries or surgeries are also considered to be at higher risk for cataract development.
- **Obesity:** Being obese may predispose an individual to the development of cataracts.
- **Elevated blood pressure:** High blood pressure may also increase a patient's risk for developing a cataract.
- **Smoking and alcohol use:** Smoking a pack of cigarettes a day may double the risk of developing cataracts.
- **Environmental factors:** Long-term lead exposure is known to cause an increased risk for cataract development similar to an increased exposure to sunlight.

### Pathophysiology

The lens is the clear part of the eye that focuses light on the retina for precise, accurate vision. In the normal eye, the light passes through the crystal-clear lens to the retina. The clarity of the lens is necessary for the retina to receive a sharp image. The lens is composed of mostly water and proteins. The specific proteins within the lens produce a chemical reaction to maintain the clarity of the lens. Alteration in the lens proteins occurs over the years as a person ages, yielding a gradual clouding of the lens secondary to the chemical change. Other factors resulting in cataract formation include direct blunt trauma to the eye and glaucoma from diabetes mellitus.

### Clinical Manifestations

Clinical manifestations of cataracts include clouded, blurred, or dim vision; increasing night vision difficulty; sensitivity to light and glare; halo vision around light sources; fading or yellowing of colors; and double vision in a single eye. The manifestations change and become more dramatic as the cataract grows larger and distorts more of the patient's vision.

### Management

#### Medical Management

The diagnosis of cataracts is generally completed on physical examination of the patient and includes a visual acuity test and direct ophthalmoscope examination with a slit lamp to

observe the eye closely. Opaqueness is often readily seen by the provider during an examination. The most effective treatment of cataracts is surgical removal of the opaque lens. If surgery is not an option for the patient, regular follow-up with the provider is recommended so that progression of the condition may be followed and changes to eyeglass/contact lens prescription may be made as needed to maximize visual acuity.

### Surgical Management

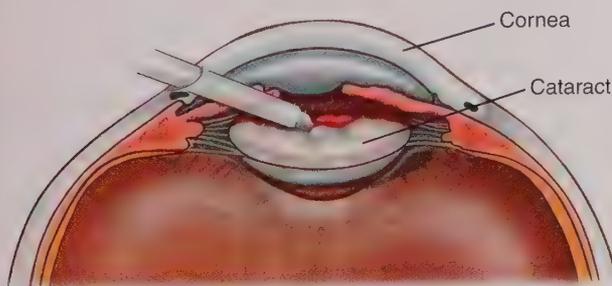

One of the most common types of eye surgeries performed in the United States for people over age 65 is for cataract removal. This surgery involves the removal of the clouded lens and its replacement with a plastic lens implant. If a patient is unable to have a replacement lens implanted, then once the cataract is removed, vision correction is achieved with corrective eyeglasses or contact lenses. Surgery is usually done on one eye and scheduled for the other eye, if needed, several weeks later. The procedure is usually done under a local anesthetic in an outpatient setting. Cataract removal also increases the risk of **retinal detachment** (separation of the retina from underlying layer of blood vessels that provide oxygen and nutrition to the eye). Cataract surgery improves vision in up to 95% of patients and prevents blindness.

### Surgical Procedures

The two most common surgeries for cataract removal are **phacoemulsification** and extracapsular or intracapsular cataract extraction. The most common procedure in the United States is phacoemulsification (Fig. 46.5).

The procedure is as follows:

1. A local anesthetic is introduced directly into the eye.
2. An incision is then made directly into the eye near the lens by the surgeon.
3. A thin probe is inserted directly into the eye that transmits ultrasound to break up the clouded lens into small fragments.
4. Debris from the procedure is then aspirated out with a suction device.
5. The replacement lens is inserted where the natural lens previously resided.

**FIGURE 46.5** Phacoemulsification procedure. An incision is made near the lens, and a thin probe is placed that uses ultrasound to break up clouded fragments, which are aspirated out. A replacement lens is then placed.

6. Most incisions are small and seal simultaneously post-operatively and do not require sutures.

The second most common surgical repair for cataracts is the extracapsular or intracapsular procedure (Fig. 46.6). This procedure is generally used in patients with an extremely hard lens and involves:

1. The surgeon makes a small incision under microscopic visualization directly into the eye.
2. The surgeon extracts the clouded lens through the incision.
3. The capsule is left in place to add strength to the structure of the eye and to enhance the healing process.
4. The surgeon then adds a replacement lens, and the incision is sutured closed.

### Nursing Management

#### Assessment and Analysis

Because cataracts affect vision, the clinical presentation of the patient includes specific alterations in the ability to see (Table 46.9). A comprehensive assessment is important to follow the progress of interventions.

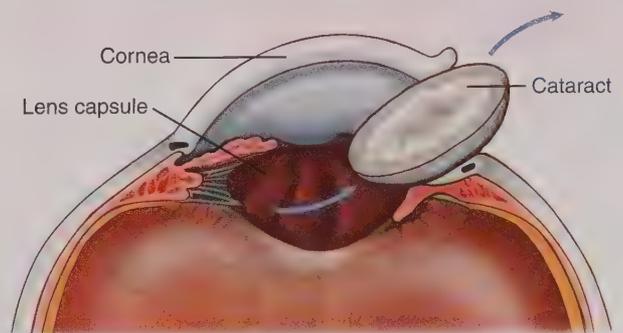

#### Nursing Diagnoses

- **Disturbed visual sensory perception** secondary to opacity of the eye lens
- **Risk for injury** due to clouding of visual fields
- **Anxiety** related to inability to clearly see objects in visual fields

#### Nursing Interventions

##### Assessments

- Visual acuity  
*Visual acuity test and slit-lamp evaluation are the most common assessments used to diagnose cataracts.*
- Diagnostic results  
*Visual acuity abnormalities are noted to be present because of increased opacity of the lens. Slit-lamp evaluation provides the provider with direct visualization of the lens and more specific detail about the extent of the opacity present.*

**FIGURE 46.6** Extracapsular cataract extraction. A small incision is made, the clouded lens is removed, a replacement lens is placed, and the incision is sutured.

**Table 46.9 Assessment and Analysis of Cataracts**

Assessment Data	Analysis/Explanation
<b>Visual acuity</b>	Decrease in visual acuity is noted when performing this test secondary to the clouding of the lens distorting the amount of light being able to enter the eye and therefore not allowing an accurate image to form on the retina.
<b>Blurred vision</b>	Clouding of the lens distorts the amount of light that is able to be projected on the retina and causes visual blurring.
<b>Increased difficulty with night vision</b>	Night vision is especially affected because a decreased amount of light is already a factor at night, and with increased clouding of the lens, light entering the eye is further decreased.
<b>Double vision in a single eye</b>	Clouding of the lens may also cause visual distortions to appear, yielding double vision in some cases.

- **Age-related considerations**

*Yearly eye examinations for patients over age 45 to monitor/treat any abnormalities discovered. Changes in the eye lens occur with advancing age, which increases the risk of opacity or cataract formation.*

- **Actions**

- **Implement safety measures**

*Awareness of loss of vision so that proper safety measures can be implemented. Driving and other activities that require keen eyesight need to be evaluated to prevent possible risk to patient safety.*

- **Administer eye drops.**

*Mydriatic (dilating) and cycloplegic (paralyze ciliary muscles to keep the eye dilated) eye drops are often prescribed in preparation for surgery.*

- **Elevate the head of the bed 30 to 45 degrees postoperatively.**

*Promotes drainage and prevents any increase in IOP*

- **Position patient on back or nonoperative side.**

*Promotes drainage and decreases IOP*

- **Maintain eye patch as prescribed by the provider.**

*The eye patch offers protection, minimizes eye movement, and decreases discomfort.*

- **Administer stool softeners, as prescribed; increase fiber and fluid intake.**

*Straining with bowel movements increases IOP and can cause damage to the operative site.*

- **Teaching**

- **Pre- and postoperative teaching for patients having surgical intervention**

*Exact preoperative instructions to be obtained from the provider, including NPO status, administration of preoperative eye drops, arrangements for a friend or family member to drive the patient home postprocedure, position changes postoperatively*

- **Decrease risk factors.**

*Protective eyeglasses worn in the presence of sunlight decrease UV ray damage, a known factor in promoting cataract formation.*

- **Safety concerns**

*Talk with the patient and family members regarding current visual impairment and ability to drive. Cataracts decrease visual acuity, creating a safety risk. Discuss safety around the home on stairs and when using kitchen equipment and other objects that could cause injury with impaired vision.*

- **Follow-up appointments**

*Discussion with patient regarding importance of follow-up appointments with provider so that condition may be closely monitored for changes*

- **Accessibility to community agencies**

*Referral to local community agencies that can help patients with rides, information, and other services when visual impairment is present (i.e., Prevent Blindness America, EyeCare America)*

### **Safety Postoperative (24–48 Hours) Alert Teaching for Patients Having Cataract Surgery**

During the first 24 to 48 hours following cataract surgery, patients should take the following precautions:

- Do not rub or apply pressure to eye.
- Avoid sneezing, coughing, bending over, vomiting, or lifting objects heavier than 5 lb.
- Prevent constipation (straining to have a bowel movement increases IOP and can cause bleeding).
- Contact the physician immediately for severe pain, visual change, or increase in eye discharge.
- Avoid eye straining.
- Follow provider's instructions for eye dressing and use of eye shield at bedtime.
- Wipe excess tearing from inner to outer canthus with a clean soft tissue.
- Glasses must be worn if lens implant not inserted by the surgeon.

## Evaluating Care Outcomes

Patients with cataracts can lead a normal life. Surgical removal of the cloudy lens in conjunction with prescription eyeglasses can vastly improve preoperative vision. Cloudy vision and inability to see objects clearly pose a great safety risk to patients who are often advanced in age. Detailed postoperative instructions are essential for optimal recovery from this surgery. Continued follow-up with eye care professional is paramount for any patient suffering from this condition regardless if surgery is performed.

### Connection Check 46.4

The nurse suspects a cataract in a 68-year-old Caucasian male patient with lupus based on which information?

- The patient's history of angina and gender
- The patient's use of high-dose steroids to treat the lupus
- The patient's race status and history of high blood pressure
- The patient's history of long-term exposure to zinc and obesity

## GLAUCOMA

**Glaucoma** is not just a single eye disease but a group of eye conditions that present with increased IOP and result in damage to the optic nerve, leading to loss of vision. High IOP, greater than 21 mm Hg, is most often the culprit. Increased IOP can be the result of inadequate draining of aqueous humor from the canal of Schlemm, or it can be caused by an overproduction of aqueous humor. Early diagnosis is a key factor in minimizing or preventing visual loss.

### Epidemiology

Anyone can develop glaucoma, and according to the World Health Organization, it is noted as a leading cause of blindness in the world. According to the National Eye Institute (NEI) at the National Institutes of Health (NIH), it is estimated that as many as 2.2 million Americans have been diagnosed with glaucoma, and approximately another 2 million people have the disease without knowing it.

There are many risk factors known to place patients at increased risk for glaucoma, and it is important to identify those with the highest chance for developing this disease.

Risk factors that increase the chance of developing glaucoma include:

- African American individuals over age 40
- People with a family history of glaucoma
- Everyone over age 60, especially Mexican Americans
- Medical conditions such as diabetes and hypothyroidism
- Patients with myopia
- Prolonged corticosteroid use

Risk factors specific to normal-tension glaucoma include:

- People with family history of this type of glaucoma
- Persons of Japanese ancestry
- Persons with heart disease such as irregular heart rhythm
- More common in women than men

### Pathophysiology

Glaucoma causes damage to the optic nerve, resulting in loss of vision and blindness in severe cases. There are five major types of glaucoma: primary open-angle glaucoma, angle-closure glaucoma, normal-tension glaucoma, secondary glaucoma, and pediatric glaucoma.

Primary open-angle glaucoma is the most common form of the disease, affecting approximately 3 million Americans. Most patients have no symptoms or early warning signs. Angle-closure glaucoma is also known as acute glaucoma or narrow-angle glaucoma. In this relatively rare form of glaucoma, the eye pressure rises very quickly.

The clinical manifestations of angle-closure glaucoma include headaches, eye pain, nausea, rainbows around lights at night, and very blurred vision. This form of glaucoma is a medical emergency and requires prompt medical intervention. Eye drops are usually instilled immediately to try to reduce the rising IOP.

Normal-tension glaucoma is also known as low-tension glaucoma or normal-pressure glaucoma. Patients with this type of glaucoma have damage to the optic nerve even though the IOP is not very high. It is not understood why some patients suffer optic nerve damage with IOPs in the "normal" range of 12 to 22 mm Hg, but it is believed to occur either because of a fragile optic nerve (a condition that might be inherited) or a decrease in blood flow to the optic nerve itself (vascular disease including vasospasm and ischemia).

Secondary glaucoma usually results from an eye injury, inflammation, tumor or advanced cases of cataracts, or diabetes. Medications such as steroids, when used chronically, are also noted to cause this type of glaucoma.

Pediatric glaucoma consists of congenital glaucoma (diagnosed during the first year of life), infantile glaucoma (occurring in the first 3 years of life), and juvenile glaucoma (occurring at age 3 through the young adult years). Left untreated, glaucoma continues to progress in a predictable manner. Initially, blind spots occur in the patient's peripheral vision, leading to tunnel vision that may deteriorate to total blindness.

### Connection Check 46.5

A 76-year-old patient was recently diagnosed with primary open-angle glaucoma. What part of the past medical history places the patient at risk for developing glaucoma?

- History of a recent facial trauma
- Prolonged antibiotic therapy
- Prolonged corticosteroid usage
- History of angina

## Clinical Manifestations

Clinical manifestations vary by type of glaucoma. In primary open-angle glaucoma, clinical manifestations include gradual loss of peripheral vision, usually in both eyes, and tunnel vision in advanced stages. Acute-angle glaucoma is characterized by severe eye pain, nausea and vomiting, sudden onset of visual disturbance (often in low light), blurred vision, halo vision, and reddening of the eye. Normal-tension glaucoma (also referred to as low-tension glaucoma) is a condition where optic nerve damage and vision loss occur despite having a normal IOP between 12 and 22 mm Hg.

## Management

### Medical Management

The best prevention for glaucoma is regularly scheduled eye examinations by a qualified provider. (Frequency depends on age, state of health, and presence of known eye pathology.) Medical treatments for glaucoma include medications (early stages) that cause the eye to make less aqueous humor, as well as medications to help drain fluid in the eye, thereby decreasing the pressure in the eye. Commonly used eye-drop medications are included in Table 46.10.

Oral medications may also be prescribed, such as a carbonic anhydrase inhibitor, to help further reduce IOP. These medications work by reducing the production of aqueous humor, leading to a decrease in IOP.

### Connection Check 46.6

The medical management of glaucoma includes which interventions? (*Select all that apply.*)

- A. Beta-blocker eye drops
- B. Steroid eye drops
- C. Strict bedrest
- D. Routine appointments with healthcare provider
- E. Antibiotic eye drops

### Surgical Management

Surgery is used to treat glaucoma if medications are not effective in treating the disease. The surgeries most commonly used to treat glaucoma include laser trabeculoplasty, filtering surgery, or placements of drainage implants.

Laser trabeculoplasty is used in treating open-angle glaucoma. The patient is given an anesthetic eye drop, and a high-energy laser beam is used to open clogged drainage canals, thereby allowing the aqueous humor to drain more easily from the eye. This procedure is usually performed in the provider's office or eye clinic, and only one eye is treated at a time if both eyes are involved (Fig. 46.7).

Filtering surgery or trabeculectomy is usually done in a hospital or outpatient surgery center under local sedation. The surgeon uses specialized instruments and places an opening in the sclera of the patient, removing a small piece of the trabecular meshwork. This opening allows for the aqueous humor to freely exit the eye and lowers the IOP (Fig. 46.8).

Drainage implants, used most commonly with secondary glaucoma or pediatric glaucoma, commonly take place in a hospital or outpatient clinic. The surgeon inserts a small silicone tube in the eye to help drain the aqueous humor (Fig. 46.9).

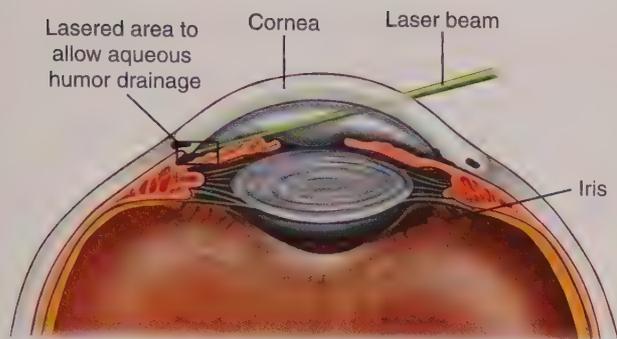

## Genetic Connections

### Glaucoma

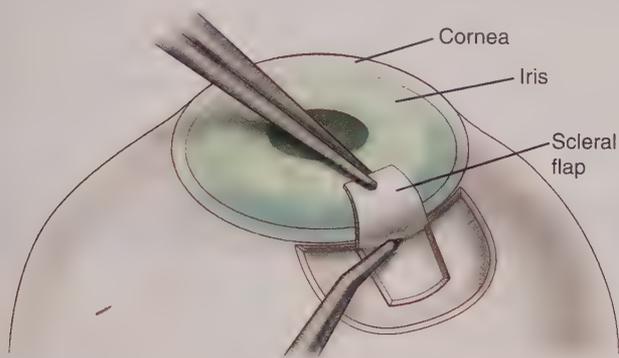

Heredity plays a key role in the development of glaucoma, and genetic factors are believed to account for between 13% and 25% of cases of primary open-angle glaucoma in adults. There are both autosomal-dominant and recessive patterns noted.

**Table 46.10 Medications Used in the Treatment of Glaucoma**

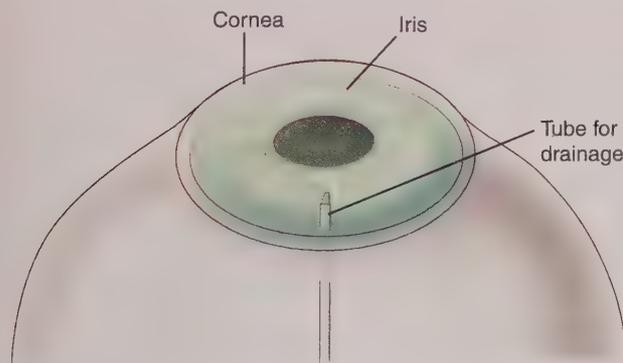

Type of Compound	Common Medication Names	Desired Effect
<b>Prostaglandin-type medications</b>	Latanoprost (Xalatan), bimatoprost (Lumigan)	Increases the outflow of aqueous humor and thus decreases volume, therefore decreasing intraocular pressures
<b>Beta-blocker medications</b>	Timolol (Betimol, Timoptic), betaxolol (Betoptic), and metipranolol (OptiPranolol)	Reduces the production of aqueous humor, therefore decreasing intraocular pressure
<b>Alpha antagonists</b>	Apraclonidine (Iopidine) and brimonidine (Alphagan)	Reduces the production of aqueous humor and increases drainage
<b>Carbonic anhydrase inhibitors</b>	Dorzolamide (Trusopt) and brinzolamide (Azopt)	Decreases the production of aqueous humor
<b>Miotic or cholinergic agents</b>	Pilocarpine (Isopto Carpine) and carbachol (Isopto Carbachol)	Increases the outflow of aqueous humor
<b>Epinephrine compounds</b>	Dipivefrin (Propine)	Increases the outflow of aqueous humor

**FIGURE 46.7** Laser trabeculoplasty. A high-energy laser beam is used to open clogged drainage canals, allowing the aqueous humor to drain more easily from the eye.

**FIGURE 46.8** Filtering surgery or trabeculectomy. The surgeon uses specialized instruments and places an opening in the sclera of the patient, removing a small piece of the trabecular meshwork to allow for the aqueous humor to freely exit the eye.

**FIGURE 46.9** Drainage implants. The surgeon inserts a small silicone tube in the eye to help drain the aqueous humor.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of glaucoma are closely related to the damage and complications associated with increased IOP (Table 46.11). Common complaints include decreased visual acuity, nausea and vomiting, and headache. Other clinical manifestations include eye pain and multicolored halos around lights.

**Table 46.11** Assessment and Analysis of Glaucoma

Assessment Data	Analysis/Explanation
<b>Vision loss</b>	Can be sudden or gradual and may not be noted until vision loss is more pronounced. Vision loss is associated with pressure on the optic nerve caused by increased IOP, thereby preventing transfer of nerve signals to the brain.
<b>Nausea/vomiting</b>	Increased pressure building in the eye often causes nausea/vomiting in patients.
<b>Headache</b>	Abupt increase in IOP often causes eye pain, which can be severe.

IOP, Intraocular pressure.

#### Nursing Diagnoses

- **Disturbed visual sensory perception** related to disturbance in optic nerve function secondary to increased intraocular pressure
- **Anxiety** related to decreasing visual field presence
- **Knowledge deficit** regarding the progressive nature of glaucoma
- **Impaired home maintenance** related to activity restrictions and impaired vision

#### Nursing Interventions

##### Assessments

- Physical assessment via ophthalmoscope and use of a tonometer  
*Physical examination of patients with glaucoma demonstrates increased ocular pressures in most patients that are verified with a tonometer. Bulging vessels in the internal eye can also be seen on examination with an ophthalmoscope.*
- Diagnostic results  
*Intraocular pressures registering above the expected 10 to 22 mm Hg are a common finding. Visual acuity tests yield decreases in visual acuity.*
- Visual acuity  
*Visual acuity tests yield decreases in visual acuity. The patient may describe fogginess of vision.*
- Age-related considerations  
*Proper screening and routine visual examinations of patients of advanced age can help in the early detection of glaucoma before significant damage is done.*

##### Actions

- Administer medications to decrease IOP.  
*Medications are ordered to decrease the production of or increase the outflow of aqueous humor. Table 46.10 describes the actions of and rationales for medications used in the treatment of glaucoma.*
- Follow proper procedure for the instillation of eye drops.  
*Maintaining aseptic technique is important to proper eye-drop instillation. (The Safety Alert provides a guide for eye-drop instillation.)*

- Elevate the head of the bed 35 to 40 degrees.  
*Promotes intraocular (aqueous humor) drainage and decreases IOP.*
- Avoid bending at the waist for the first 48 hours postoperatively.  
*Bending at waist may increase IOP.*
- Administer stool softeners, and include fluid and fiber intake.  
*Constipation or straining to have a bowel movement can increase intraocular pressure.*

### ■ Teaching

- Progressive nature of disease process  
*Education of patients and family members/significant others regarding the disease process is essential. Education regarding signs/symptoms or when to notify the provider and the importance of follow-up care on a routine basis is essential.*
- Medication instructions  
*Instructions on the name and type of eye drops are essential for successful treatment and compliance. Provide simple, understandable explanations to prevent the patient from feeling overwhelmed. Instruct the patient not to take any over-the-counter or prescription medications without contacting the eye care provider first (i.e., anticholinergic medications can cause worsening of glaucoma by constricting the drainage of aqueous humor). Due to the frequency of eye-drop administration, a chart of times, eye, and number of drops/dose may be helpful to the patient and family.*
- Specific postoperative instructions  
*Specific instructions from the patient's eye care provider must be followed precisely. Common instructions that are given include restrictions on strenuous activities, bending at the waist, and lifting of heavy objects (greater than 25 lb) and avoiding constipation for at least the first 2 weeks postoperatively. Lifting heavy objects, bending at the waist, and strenuous activities can increase IOP and cause damage to the newly repaired eye. Constipation or straining to have a bowel movement can increase the chance of postoperative bleeding within the eye. Reporting increased pain or drainage is also an important instruction for postoperative patients.*

### Safety Eye-Drop Instillation

#### Alert

When instilling eye drops, the following

precautions should be taken:

- Wash hands thoroughly and don nonsterile gloves.
- Verify correct medication/time and number of drops.
- Instruct patient to tilt head back with eyes open and looking upward.
- Retract lower lid downward.
- Invert the medication bottle and gently rest wrist on patient's cheek.
- Gently squeeze bottle and instill prescribed number of eye drops into conjunctival sac, taking care not to

contaminate the medication dropper/bottle by touching the eye sac or other foreign objects.

- Instruct patient to gently close eyes.
- Additional eye drops may be administered after 3 to 5 minutes to allow for absorption.
- Application of gentle pressure with a clean tissue on the patient's nasolacrimal duct for 30 to 60 seconds decreases systemic absorption.

### Evaluating Care Outcomes

Given the sometimes-insidious disease process of glaucoma, routine examinations and careful, comprehensive patient education are essential to minimize eye damage and promote eye health. The treatment of glaucoma requires a lifelong commitment from the time of diagnosis (see Evidence-Based Practice). Daily medication and routine medical follow-up provide the best possible chance for maintaining vision.

### Evidence-Based Practice

#### Adherence With Treatment for Glaucoma

Because patients with chronic disease requiring lifelong treatment, like glaucoma, may have issues with adherence, this study focused on an evidence-based approach to addressing patient adherence to treatment for glaucoma. The three specific aims included evaluation of risk factors for poor adherence, assessment of whether improved adherence impacted outcomes, and identification of steps to improve adherence. Based on previous studies, four categories of factors were identified that impacted adherence:

- Environmental related—primarily cost of treatments
- Patient related—severity of glaucoma and understanding the relationship between adherence and outcomes
- Treatment related—complexity of the eye-drop regimen and side effects of the medications
- Provider related—poor adherence and outcomes associated with inadequate support from glaucoma provider

The Cochrane review completed included 16 trials that evaluated interventions with adherence. The primary outcome in the review was adherence with prescribed medical management, and secondary outcomes included intraocular pressure (IOP) reduction related to treatment, visual field loss, and quality of life.

The findings of the review revealed that no specific strategy or intervention led to increased compliance. Further studies are needed to evaluate approaches to facilitate better adherence with prescribed medical treatments.

There is also a growing body of research related to other strategies for managing glaucoma, including smartphone technology, minimally invasive surgical interventions (whose outcomes could be compared with more traditional medical management), and different approaches to intraocular medication delivery.

Joseph, A., & Pasquale, L. R. (2017). Attributes associated with adherence to glaucoma medical therapy and its effects on glaucoma outcomes: An evidence-based review and potential strategies to improve adherence. *Seminars in Ophthalmology*, 32(1), 86–90.

## CASE STUDY: EPISODE 2

At the appointment with the advanced practice registered nurse, Mike discusses his history, which includes being diagnosed with type 1 diabetes mellitus at age 16. He has no other known chronic illnesses, and his blood glucose is considered in “good control.” Mike is diligent about checking his blood glucose before all meals and before bedtime. He does not take any medication on a daily basis other than his insulin injections. Mike does not wear corrective eye lenses except when he is reading. Mike’s father died at age 52 of heart failure and complications from diabetes. His mother is 86 years old and without any significant past medical history...

## MACULAR DEGENERATION

**Macular degeneration** is most commonly age related and is a disease that gradually destroys sharp, central vision. Affecting the **macula** (the part of the eye that is responsible for central vision and allows for vision in fine detail), it causes no pain. Macular degeneration is slow to develop in some patients, often causing the patient to be unaware of any changes in vision. In others, it develops at a much faster pace. Patients who have advanced macular degeneration in one eye are at high risk for developing the same condition in the other eye.

### Epidemiology

The greatest risk factor for macular degeneration is related to advancing age. According to the study by the NEI at the NIH, middle-aged people have about a 2% risk of developing macular degeneration, but the risk increases to nearly 30% in those patients over age 75. There are also modifiable and nonmodifiable risk factors for this disorder.

Modifiable risk factors include:

- High blood pressure
- High cholesterol
- Obesity

- Smoking
- Decrease in zinc blood levels

Nonmodifiable risk factors include:

- Age (patients over age 60 are at greatest risk)
- Family history of macular degeneration
- Gender (women are more likely than men)
- Race (more common in Caucasians)

### Pathophysiology

The macula is a structure in the eye that is located in the center of the retina. The retina converts light and images instantly into electrical impulses and then sends these impulses or nerve signals to the brain via the optic nerve. There are two primary types of macular degeneration: dry macular degeneration and wet macular degeneration (Table 46.12).

#### Dry Macular Degeneration

Dry macular degeneration, the most common form of macular degeneration, occurs when the light-sensitive cells in the macula slowly start to break down. The dry form of macular degeneration can turn into wet macular degeneration. All people who have wet macular degeneration initially had dry macular degeneration. One of the most common early indications of dry macular degeneration is **drusen bodies**, which are yellow deposits that are located under the retina and are usually found in people over age 60 (Fig. 46.10). Eye examinations that include a comprehensive dilation evaluation usually detect drusen bodies.

There are three phases of dry macular degeneration: early dry macular degeneration, intermediate dry macular degeneration, and advanced dry macular degeneration. In

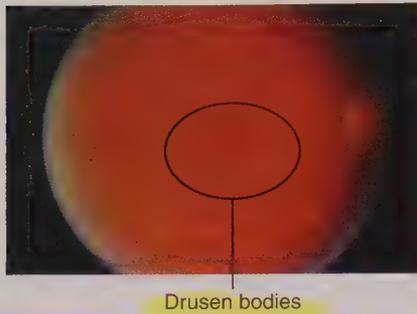

**Table 46.12 Comparison of Wet and Dry Macular Degeneration**

#### Wet Macular Degeneration

- One stage only, which is the most advanced form
- Vision loss in wet macular degeneration
- All patients with wet macular degeneration had dry macular degeneration first.

#### Dry Macular Degeneration

- Three stages—early, intermediate, and advanced
- Vision loss in advanced-stage dry macular degeneration
- Dry macular degeneration can progress to the wet form even during early-stage dry macular degeneration (no way to tell if or when the dry form of macular degeneration will progress to the wet form of the disease).

**FIGURE 46.10** Dry macular degeneration. One of the most common early indications of dry macular degeneration is drusen bodies, which are yellow deposits that are located under the retina.

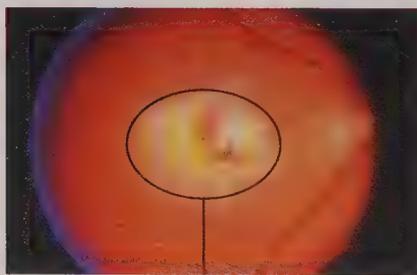

early dry macular degeneration, patients present with a few small to medium-sized drusen bodies. There are no other clinical manifestations, and no vision loss occurs. Patients with intermediate dry macular degeneration present with medium-sized drusen bodies, or one or more large drusen bodies are present on examination. Some patients see a blurred spot in the center of their visual field. The patient may require more light for reading and other tasks. Patients with advanced dry macular degeneration have a breakdown of the light-sensitive cells and supporting tissue in the central retinal area. The presence of drusen bodies is also noted on examination. The breakdown can cause a blurred spot in the center of vision that will gradually get bigger and darker, taking up much of the central vision.

### Wet Macular Degeneration

Wet macular degeneration occurs when abnormal blood vessels located behind the retina start to grow under the macula (Fig. 46.11). These new networks of blood vessels are known to be very fragile and often leak blood and fluid. The blood and fluid raise the macula from its usual position at the back of the eye, and damage to the macula occurs rapidly.

### Clinical Manifestations

Clinical manifestations of macular degeneration include straight lines that appear distorted; absent or distorted central vision; dark, blurry areas or whiteout on center vision;

Blood and fluid leakage raises macula

**FIGURE 46.11** Wet macular degeneration. Wet macular degeneration occurs when abnormal blood vessels located behind the retina start to grow under the macula and leak blood and fluid that raise the macula from its usual position at the back of the eye.

and diminished or changed color perception. The clinical presentation of macular degeneration is also related to the specific underlying pathophysiology. Dry macular degeneration causes a gradual blurring of the central vision, and the patient may have difficulty recognizing faces. As the condition worsens, a blurred spot may be seen in the center of the visual field; this leads to gradual loss of central vision in the affected eye. Wet macular degeneration usually causes a quick loss of central vision and is also known as advanced macular degeneration. One of the earliest symptoms of this disease is that straight lines begin to appear wavy.

### Connection Check 46.7

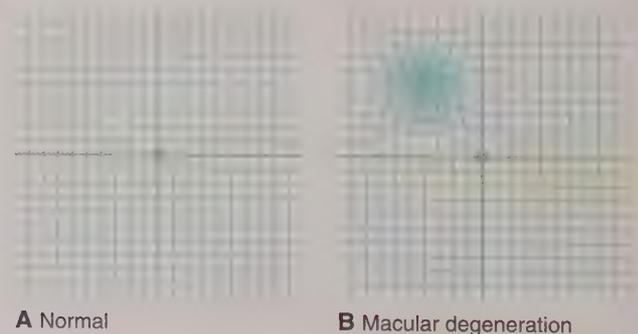

The nurse recognizes which finding as a complication of macular degeneration?

- Complete color blindness
- Disturbance in peripheral vision
- Blindness
- Nausea and vomiting

### Management

#### Diagnosis

Changes in central vision (straight-ahead vision), along with advanced age, may raise suspicion with the patient's health-care provider that the patient has macular degeneration. To assess for possible signs of macular degeneration, the provider completes a comprehensive eye examination, including dilation of the pupils for a better assessment of the back portion of the eye. **Tonometry** examination may also be done to measure the pressure inside the eye. The examination often also includes the use of an **Amsler grid**. This examination is done by asking the patient to look at a grid that resembles a checkerboard (Fig. 46.12). The patient covers one eye and stares at a black dot in the center of the grid. While staring at the dot, patients with macular degeneration may notice that the straight lines appear wavy or

A Normal

B Macular degeneration

**FIGURE 46.12** Amsler grid. A, Viewed with normal vision. B, Viewed with macular degeneration. The patient covers one eye and stares at a black dot in the center of the grid. While staring at the dot, patients with macular degeneration may notice that the straight lines appear wavy or may interpret that some of the lines are missing.

may interpret that some of the lines are missing. A fluorescein angiogram may also be performed for confirmation of wet macular degeneration. This test requires that a special dye is injected intravenously, and images are taken as the dye passes through the vessels within the retina, identifying leaking blood vessels.

### Medical Management

The three most common treatments for macular degeneration are laser surgery, photodynamic therapy, and injections directly into the eye. There is no cure for macular degeneration, and despite treatment, the disease and vision loss may continue to progress.

### Dry Macular Degeneration

Once dry macular degeneration reaches the advanced stage, no form of treatment can prevent vision loss. The NEI's Age Related Eye Disease (ARED) study has found that having patients take a specific high-dose formulation of antioxidant and zinc significantly reduces the risk of vision loss. Nutritional recommendations are made when treating a patient with macular degeneration. Recent research provides some foundation that using an ARED formula (vitamin C, vitamin E, beta-carotene, zinc, and copper) can slow the progression of intermediate macular degeneration to the advanced stage. Lutein and zeaxanthin supplements may also produce protective effects.

### Wet Macular Degeneration

Two therapies are used for wet macular degeneration.

#### Photodynamic Therapy

This is a specialized laser treatment for macular degeneration that uses the stimulation/activation of a photosensitive dye by exposure to a light (laser) of a known wavelength that results in the closure of new vessels. The treatment takes about 20 minutes to complete and can be performed in the provider's office. This therapy slows the rate of vision loss, but it does not stop vision loss or restore vision that has already been lost by macular degeneration. The treatment results are often temporary and may require the patient to undergo successive treatments.

Photodynamic therapy uses a medication called verteporfin (Visudyne), a light-activated medication, which is injected directly into the patient's arm. In the presence of oxygen, highly reactive short-lived reactive oxygen radicals are generated. Light activation of this medication results in local damage to the endothelium and therefore results in vessel occlusion. The medication travels through the body and eventually to the blood vessels in the patient's eye and sticks to the surface of new blood vessels. A light is then shined into the patient's eye for about 90 seconds to activate the medication. The activated medication then destroys the new blood vessels, therefore slowing the rate of vision decline. It is important to instruct the patient to avoid exposing skin/eyes to direct sunlight or bright indoor light for 5 days after treatment because the medication is activated by light.

### Anti-Vascular Endothelial Growth Factor Therapy

Vascular endothelial growth factor (VEGF) is secreted by oxygen-deprived cells, causing stimulation of the growth of abnormal blood vessels. Anti-VEGF therapy uses injections directly into the eye and is used to treat wet macular degeneration. This medication blocks the effects of the growth factor. The patient will need multiple injections that may be given monthly and that usually involve local anesthesia to the eye. This medication helps slow the progression of vision loss from macular degeneration and in some cases even improves sight.

### Surgical Management

Laser surgery uses a light beam to destroy the fragile, leaky blood vessels that are accumulating behind the macula. This high-energy beam of light aimed directly at the new blood vessels destroys them, therefore preventing further loss of vision. Only a small percentage of patients with wet macular degeneration can be treated with this surgery, and there is also concern that laser treatment may destroy healthy tissue as well as impact visual acuity. Surgery is most often performed in the provider's office or eye clinic, and the risk of developing new blood vessels after laser treatment is high. Vision loss may progress despite repeated treatment in some patients.

### Nursing Management

#### Assessment and Analysis

Due to the chances of progressive decrease in visual acuity, assessment for macular degeneration is important. The clinical manifestations of macular degeneration are insidious and result in the loss of sharp, central vision. Table 46.13 describes these changes.

#### Nursing Diagnoses

- **Disturbed visual sensory perception** related to degeneration of the macula
- **Anxiety** related to loss of vision
- **Risk** for injury related to visual loss

**Table 46.13** Assessment and Analysis of Macular Degeneration

Assessment Data	Rationales
<i>Loss of sharp, central vision</i>	Abnormal blood vessels located behind the retina start to grow under the macula. These new networks of blood vessels are usually fragile and often leak blood or fluid, resulting in a loss of sharp, central vision.
<i>Insidious onset</i>	Dry macular degeneration is most common with this onset. Light-sensitive cells slowly begin to break down, causing a gradual blurring; can progress to the more aggressive wet form of macular degeneration.

## Nursing Interventions

### Assessments

- Vital signs  
*There is no direct effect on vital signs, although a risk factor for the development of macular degeneration is elevated blood pressure.*
- Physical assessment/examination  
*On physical examination with an ophthalmoscope, yellow spots (drusen bodies) form on the retina. The presence of abnormal vessel leaking is also sometimes seen on ophthalmoscopic examination.*
- Visual acuity  
*Visual changes develop as abnormal blood vessels located behind the retina start to grow under the macula. These new networks of blood vessels are usually fragile and often leak blood or fluid, resulting in a loss of sharp, central vision. The onset may be insidious.*

### Actions

- Safety precautions  
*Maintain a safe environment related to increased risk of physical injury secondary to impaired vision*
- Provider follow-up  
*Routine scheduled follow-up appointments with provider to evaluate for any changes in visual acuity or the presence of other internal changes*

### Teaching

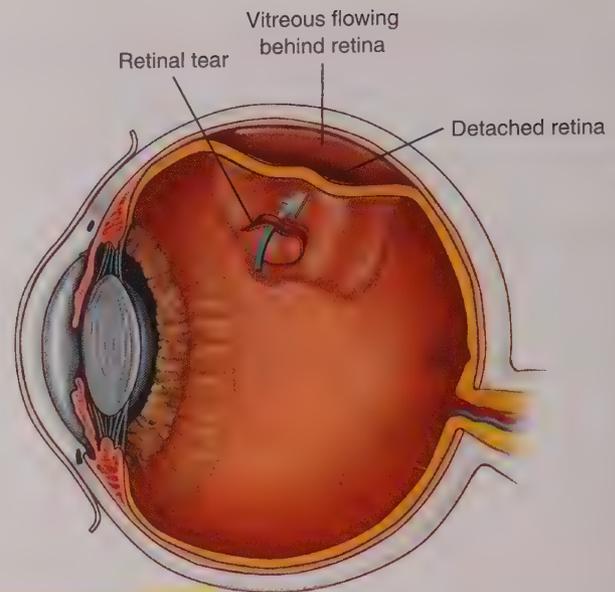

- Education regarding diagnosis  
*Provide detailed and understandable information regarding patient diagnosis so that patients are able to participate in care and meet expectations for treatment.*
- Community resource referrals  
*Referral to community services as patient circumstances dictate to help ensure that patient has access to care (i.e., Macular Disease Society, Prevent Blindness America)*

## Evaluating Care Outcomes

Macular degeneration has no complete cure; the goal of therapy is the preservation of vision. Clinical manifestations of macular degeneration start with a decline in visual acuity along with blurring or distortion of vision. Some of the manifestations may be slow to develop and therefore not initially obvious to the patient. Medical and surgical treatments are available depending on the specific condition.

## RETINAL DETACHMENT

Retinal detachment (Fig. 46.13) is a condition that may cause permanent vision loss and is considered a medical emergency, requiring the patient to seek immediate attention by an eye care professional. The retina is a structure within the eye that is light sensitive and sends visual messages to the brain via the optic nerve. Detachment of this structure can happen as it is lifted or pulled from its normal position. Clinical manifestations of retinal detachment experienced by patients may be sudden or gradual. Patients may notice

**FIGURE 46.13** Retinal detachment. Retinal detachment occurs when there is a separation of the inner layers of the retina from the underlying retinal pigment epithelium.

a sudden or gradual increase in the number of floaters in the visual field, or they may experience light flashes or the appearance of a curtain over the field of vision.

## Epidemiology

In the United States, it is estimated that the incidence of retinal detachment is one in 15,000 people. The disease is noted to be more common in patients over age 40 and affects men more often than women and Caucasians more often than African Americans.

Risk factors for retinal detachment include the following:

- Patients who suffer from extreme myopic refraction disturbances
- History of retinal detachment in the other eye
- Family history of retinal detachment
- Patients who have had cataract surgery
- Patients who have suffered eye injuries
- Patients with other eye diseases or disorders
- Presence of systemic diseases such as diabetes mellitus, tumors, sickle cell disease, leukemia, eclampsia, and prematurity

## Pathophysiology

Retinal detachment occurs when there is a separation of the inner layers of the retina from the underlying retinal pigment epithelium (choroid). The choroid is known as a vascular membrane containing large branched pigment cells located between the retina and the sclera. Separation of the retina from the retinal pigment epithelium occurs by the following three basic mechanisms:

1. *Rhegmatogenous*: This is the most common form of retinal detachment and occurs when a tear or break in

the retina allows vitreous fluid to move under the retina and separate it from the pigmented cell layer that nourishes the retina.

2. *Tractional*: The least common type of detachment, this condition occurs when scar tissue on the retina's surface contracts and causes the retina to separate from the retinal pigment epithelium.
3. *Exudative*: This form of detachment is usually caused by retinal disease, including inflammatory disorders and injury/trauma to the eye. With this type of detachment, vitreous fluid leaks into the area underneath the retina, but no tears or breaks in the retina are identified.

## Clinical Manifestations

Clinical manifestations of retinal detachment experienced by patients may be sudden or gradual. Patients may notice a sudden or gradual increase in the number of floaters in the visual field, or they may experience light flashes or the appearance of a curtain over the field of vision. Patients may describe a painless change in visual acuity or describe their vision as "looking through a veil or cobwebs."

## Management

### Medical and Surgical Management

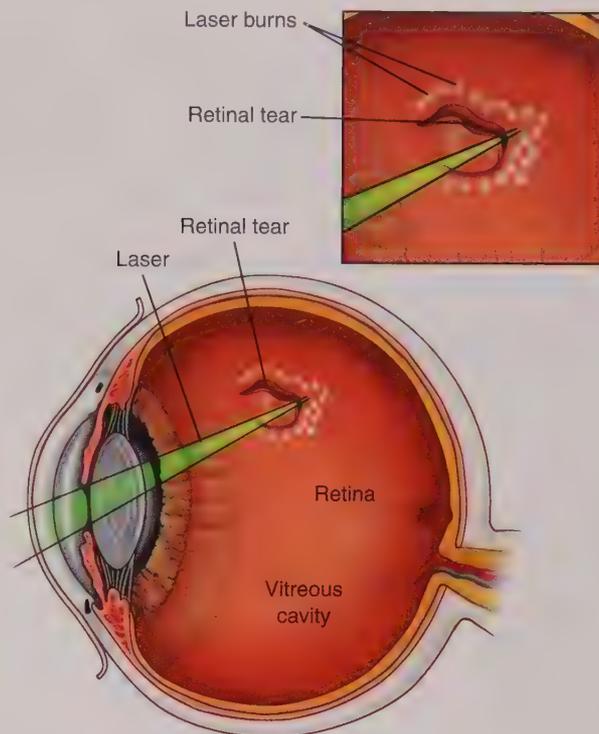

Immediate evaluation followed by surgical intervention is noted to be the only effective treatment for retinal detachment. The goal of many treatments is to stop any further progression of vision loss. In most cases, the damage that has already occurred cannot be reversed. The most common and successful treatments are discussed here.

Laser photocoagulation is most often used to repair a retinal tear or hole, and this procedure is usually done as an outpatient and does not require incisions. To perform this procedure, the surgeon directs a laser beam to burn small pinpoint holes on the peripheral retinal surface. The burns create scar tissue that causes the retina to adhere to the underlying tissue (Fig. 46.14).

Panretinal photocoagulation is used for advanced cases of diabetic retinopathy to shrink abnormal new blood vessels that are bleeding into the vitreous. In this procedure, the surgeon places multiple laser burns on the retina, excluding the macula. Two or more sessions are usually required. An advantage of this procedure is that the burns cause new blood vessels to shrink and disappear, thereby preserving central vision. The drawback of this procedure is that it includes some peripheral vision loss.

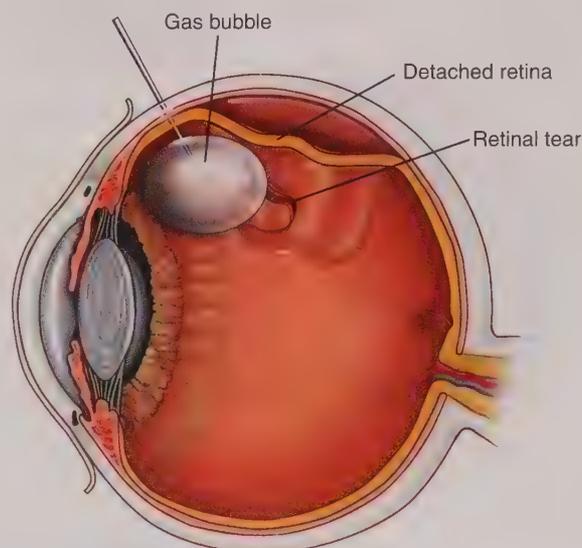

Cryopexy is an outpatient procedure that is done with local anesthetic and is used to treat tears along the retinal periphery that are difficult to reach with a laser. The surgeon uses intense cold to freeze the area around the tear. The freezing produces inflammation that leads to scarring. The scarring holds the retina in place to the underlying tissue, thereby preventing fluid from passing through the tear.

Pneumatic retinopexy, a treatment for uncomplicated retinal detachment when the tear is located on the upper

**FIGURE 46.14** Laser photocoagulation. A laser beam is used to burn small pinpoint holes on the peripheral retinal surface. The burns create scar tissue that causes the retina to adhere to the underlying tissue.

half of the retina, is an outpatient procedure that is performed under local anesthesia. The surgeon first performs cryopexy around the tear to seal it off. A bubble of gas is then injected into the vitreous cavity; this bubble expands over the next few days, sealing the retinal tear, and evokes a reattachment of the retina to the wall of the eye (Fig. 46.15). Patient positioning is important postop for this procedure.

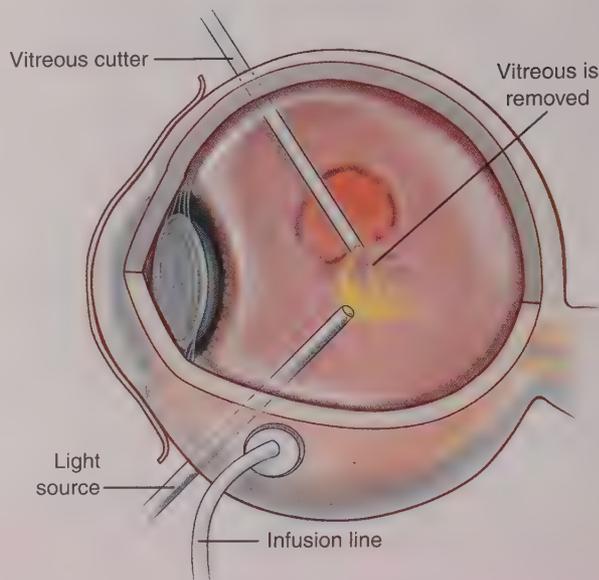

**FIGURE 46.15** Pneumatic retinopexy. A cryopexy is performed to seal the tear, and then a bubble of gas is injected into the vitreous cavity. This bubble expands over the next few days, sealing the retinal tear and reattaching the retina to the wall of the eye.

The patient needs to keep the head upright or sideways for a few days postoperatively to ensure that the bubble continues to press against the tear. The injected gas will dissipate from the eye and be reabsorbed by the body within 2 to 8 weeks. Patients must avoid sleeping on the back during this time to prevent a sudden increase in eye pressure or cataract formation.

Scleral buckling is done in an operating room under local or general anesthesia and most often on an outpatient basis. It is one of the most common surgeries done to repair retinal detachment by slightly reducing the size of the eyeball's circumference. The surgery starts with cryopexy, and the surgeon then sews a tiny synthetic band to the sclera. This buckle creation indents the sclera and pushes the wall against the retina. The indentation helps decrease the separation between the retina and underlying layers while also reducing the circumference of the eyeball. Pressure from the "buckle" helps prevent further separation (Fig. 46.16).

Vitrectomy is used to correct retinal detachment as well as to remove a foreign body or repair eye trauma. It is generally an outpatient procedure that may be performed under local or general anesthesia. The surgeon makes tiny incisions in the sclera and uses specific instruments to suction out blood-filled vitreous. A saltwater solution is injected into the eye to help maintain its shape (Fig. 46.17). This surgery is selected for cases where bleeding or inflammation clouds the vitreous and obstructs the surgeon's view of the retina. This procedure is often done in conjunction with

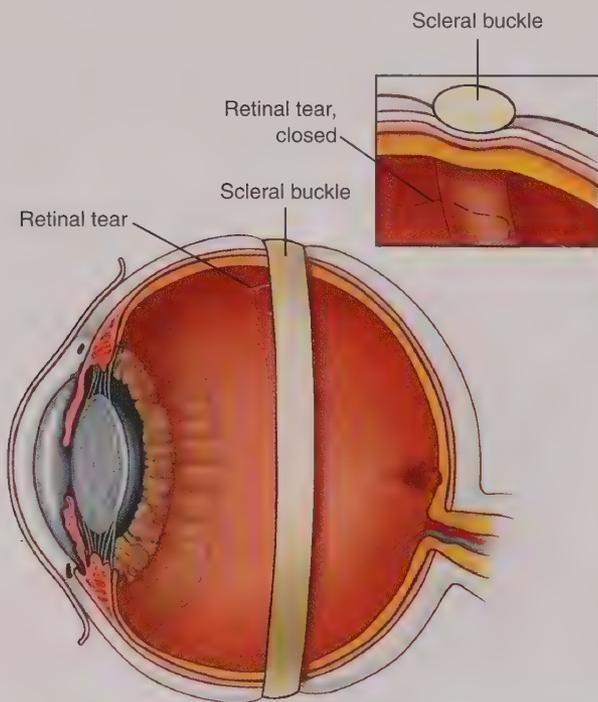

**FIGURE 46.17** Vitrectomy. A tiny incision is made in the sclera, and a specific instrument is used to suction out blood-filled vitreous. A saltwater solution is injected into the eye to help maintain the shape of the eye.

other procedures, such as laser photocoagulation, scleral buckle placement, or gas injection.

**Nursing Management**

**Assessment and Analysis**

Patients presenting with retinal detachment typically complain of "floaters" in the eye, accompanied by flashing lights. Table 46.14 presents an explanation of these clinical manifestations.

**FIGURE 46.16** Scleral buckling. Cryopexy is performed, and then the surgeon sews a tiny synthetic band to the sclera. This buckle creation indents the sclera and pushes the wall against the retina. The indentation helps decrease the separation between the retina and underlying layers while also reducing the circumference of the eyeball.

**Table 46.14 Assessment and Analysis of Retinal Detachment**

Assessment Data	Analysis/Explanation
<b>"Floaters" present in the visual field (as noted by patient verbal report)</b>	Naturally occurring with advancing age as little bits of debris or tiny specks of tissue appear in visual fields. With retinal detachment, large floaters appear that cause an obstruction of vision.
<b>Light flashes reported by patients</b>	Flashing lights represent the release of an electrical signal from the nerve tissue to the retina, where there is a pulling on the retina from the vitreous gel that separates it from the retina.
<b>Curtain covering visual field as described by the patient</b>	As detachment progresses, visual loss increases to represent what looks like a curtain covering the visual field.

## Nursing Diagnoses

- **Disturbed visual sensory perception** secondary to retinal detachment
- **Risk for injury** related to decrease in visual acuity

## Nursing Interventions

### ■ Assessments

- Visual changes

*Patients may notice a sudden or gradual increase in the number of floaters in the visual field, or they may experience light flashes or the appearance of a curtain over the field of vision.*

- Eye assessment changes

*An eye examination is completed by a provider with the use of an ophthalmoscope to view the internal retina of the eye. Abnormal results require further evaluation by an eye care professional who specializes in the treatment of retinal dysfunction.*

- Diagnostic results

*The ophthalmoscope examination shows detachment; a dye test also shows the exact locations of the detachment.*

### ■ Actions

- Assist with healthcare provider examination.

*A complete eye assessment is required to prevent further damage related to potential increased IOP.*

- Encourage rest and calm environment.

*The patient should remain in a resting state until a medical evaluation is done to prevent further damage to the eye.*

- Loosely cover both eyes.

*Movement of either eye can exacerbate internal eye injury. Because the eyes move together, both eyes must be covered to minimize injury.*

- Postoperative positioning

*The patient needs to assume the position ordered by the physician. For example, after pneumatic retinopexy, the patient needs to keep the head upright or sideways for a few days postoperatively to ensure that the bubble of gas, injected into the vitreous cavity during the procedure, continues to press against the tear. The injected gas will dissipate from the eye and be reabsorbed by the body within 2 to 8 weeks. Patients must avoid sleeping on the back during this time to prevent a sudden increase in eye pressure or cataract formation.*

- Administer stool softeners and increase intake of fluid and fiber.

*An increase in IOP may develop secondary to straining with bowel movements that can exacerbate the retinal detachment or interfere with reattachment.*

### ■ Teaching

- Preoperative instructions

*After evaluation, the patient should be given detailed instructions on the type of intervention that is to be done. Patient preoperative teaching is important for patient safety as well as the first step to understanding postoperative instructions. Instructions are usually also given to a family member or friend to decrease the chance of misunderstanding.*

- Postoperative instructions

*Postoperative instructions may differ slightly for each provider, but most include eye-patch care (when to leave on/off; how to change); instillation of eye-drop medications (including type of medication, schedule, and how to instill); monitoring for hemorrhage; notifying provider immediately for increased pain or drainage from the eye; prevention of vomiting, sneezing, sudden movement, lifting, or constipation because these may increase IOP and cause detachment to worsen; and no bending over at the waist to prevent an increase in IOP. Most providers also suggest dark glasses (sunglasses) in the presence of bright light to prevent further retinal damage.*

## Evaluating Care Outcomes

Retinal detachment is a known phenomenon that occurs more readily in females over age 40. Clinical manifestations are gradual or spontaneous and require immediate evaluation by an eye care specialist to minimize permanent visual loss. Treatment often includes surgical intervention directed at preventing further damage to the retina. Strict postoperative instructions provided by the provider must be followed for the best results.

## Connection Check 46.8

In providing education about retinal detachment to a newly diagnosed patient, what is the most important information for the nurse to give the patient?

- This condition is a separation of the retina from the epithelium.
- Partial detachment does not progress to complete detachment.
- Retinal detachments are easily treated.
- Complete detachment yields peripheral visual loss.

## EYE TRAUMA

Significant causes of visual loss are related to blunt and penetrating trauma (Table 46.15). Blunt trauma, the more common of the two, occurs when the eye is struck with a finger, fist, racket, tennis ball, or other solid object. These injuries produce damage to the internal eye secondary to the sudden compression and/or indentation of the globe on impact. Penetrating trauma refers to injuries in which the eye is pierced by a sharp object such as a knife or a high-velocity missile such as a piece of metal or a BB pellet. Clinical manifestations of eye trauma are readily visible most of the time but may not be immediately observable on occasion.

## Epidemiology

Eye trauma affects people of all ages and races. It is estimated that annually, 2.4 million individuals in the United States experience an eye injury requiring treatment in an emergency

**Table 46.15 Common Causes of Trauma to the Eye**

Blunt Trauma to the Eye	Penetrating Trauma to the Eye
<ul style="list-style-type: none"> <li>● Motor vehicle accidents</li> <li>● Assault</li> <li>● Assault with a weapon</li> <li>● Falls</li> </ul>	<ul style="list-style-type: none"> <li>● Assault where there is penetration of the eye with a sharp object</li> <li>● Industrial accidents causing impalement by an object</li> <li>● Any activity or sport where an object can penetrate the eye</li> </ul>

department, inpatient/outpatient facility, or healthcare provider's office. Persons under the age of 17 account for nearly 35% of these injuries, with the home being the most common setting.

The most common risk factors for eye trauma include:

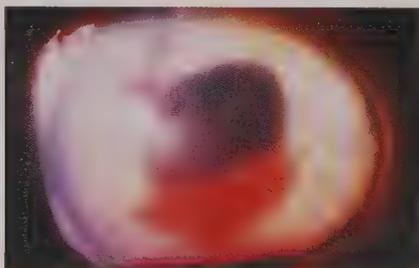

- Male gender
- Participation in sports
- Occupation (agricultural, construction, and manufacturing)
- Age group 18 to 45
- Consumption of alcohol

Although this is not a comprehensive list of risk factors, it does address the five most common threats in relation to eye trauma.

## Pathophysiology

Blunt trauma may yield an injury where bleeding occurs in the front of the eye between the clear cornea and colored iris. This condition is referred to as a **hyphema** (Fig. 46.18) and can vary in size from microscopic to the total involvement of the eye. Trauma of this nature can also cause damage to the lens, yielding cloudiness or displacement of the lens within the eye. Damage to the retina, causing detachments or tears, is also common with this type of injury.

The most common causes of **blunt eye trauma** include motor vehicle accidents, assaults with weapons, and falls. Periorbital contusion (commonly known as a *black eye*) is the most common injury; although such contusions are

**FIGURE 46.18** Hyphema. Bleeding occurs in the front of the eye between the clear cornea and colored iris.

usually benign, a full evaluation should be completed to rule out more serious injury.

**Penetrating eye trauma**, usually associated with a lack of protective eyewear, can occur at any time. Surface injuries involving the cornea or damage to the eye globe may occur. Corneal damage includes abrasions and lacerations as well as foreign bodies. Globe rupture is an ocular emergency that occurs from either blunt or penetrating trauma. Penetrating injuries to the globe are often caused by penetration with sharp objects.

## Clinical Manifestations

The clinical presentation of eye trauma varies widely depending on the type of trauma and the extent of the injury (Table 46.16). Common manifestations of eye trauma include eye pain; edema around the eye; scleral discoloration (redness); changes in vision, including blurred, double, and loss of vision; and excessive tearing.

## Management

### Medical Management

#### Diagnosis and Treatment

Medical management of blunt trauma to the eye is possible with some injuries. Rest, eye patching, and special eye drops may be prescribed. Antibiotic eye drops are prescribed to treat or prevent infection, particularly with penetrating eye trauma, and eye drops that dilate may be indicated because dilation can force the inflamed iris to move and keep it from sticking to the underlying lens. Additionally, constriction of the pupil may help to decrease intraocular pressure. Follow-up with an eye care specialist is usually on a frequent basis because close observation of the injury is essential to monitor for proper healing. To prevent further damage, including hemorrhage, patients who present to the provider with a penetrating object in the eye should never have the object removed by anyone other than the eye care professional. Removal of objects without professional guidance can eliminate pressure to the wound and increase bleeding or promote an extrusion of eyeball contents. Computed tomography (CT) scans or x-rays are often done first to observe the extent of the impalement. Verification of tetanus immunization is also part of the medical management.

### Surgical Management

Surgical management for eye trauma is dependent on the type of injury that has occurred. Evaluation of the patient by an eye care professional, CT scans, and x-rays to confirm or rule out injury are completed prior to any surgical procedure.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations observed in the patient with eye trauma are directly related to the type and extent of the injury. Table 46.17 includes common findings observed in patients with eye trauma.

**Table 46.16** Types of Eye Trauma

Eye Trauma	Treatments
<b>Orbital fracture</b>	Surgical repair usually occurs about 7 days after injury to allow swelling to decrease (exception would be if vision is impaired; may need surgical intervention sooner). Surgical repair involves debridement of the wound and surgically repairing displaced bones, sometimes using mesh or implants to rebuild the orbital area.
<b>Hyphema</b> (blood in the anterior chamber of the eye occurring when blood vessels in the iris rupture and bleed into the clear aqueous fluid of the anterior chamber)	Strict bedrest, head of bed elevated 30–45 degrees, beta-blocker eye drops to control IOP, and mydriatic eye drops to increase patient comfort
<b>Subconjunctival hemorrhage</b> (caused usually by minor trauma, even something as trivial as sneezing or coughing really hard; evaluation by provider to rule out other diagnosis is necessary)	No treatment is needed for this condition; it usually resolves within 2–3 weeks.
<b>Periorbital wounds</b>	Close assessment of these wounds is necessary because it may provide a clue as to other injuries present; elevation of the head and ice/cold packs help decrease swelling.
<b>Globe rupture</b> (results from blunt or penetrating eye injury and results in damage to the sclera of the eye; pain is usually severe, and nausea may be present)	A computed tomography scan is usually done to verify extent/type of injury present; pain medication and antiemetic medications are administered. Prepare for surgery, including making patient NPO. Eye drops should never be administered with a ruptured globe.

IOP, Intraocular pressure; NPO, nothing by mouth.

**Table 46.17** Assessment and Analysis of Eye Trauma

Assessment Data	Analysis/Explanation
<b>Visual loss</b>	Presence of visual loss occurs in traumatic cases of globe rupture because of a disturbance or loss of vision as the optic nerve is no longer able to receive and transport nerve signals.
<b>Pain</b>	The presence of pain following a traumatic episode indicates an injury to the eye is present. The degree of pain and location of pain depend on the pathology present.
<b>Nausea/Vomiting</b>	Cases involving increased IOP may yield nausea and vomiting in patients secondary to the rise in pressure.

IOP, Intraocular pressure.

### Nursing Diagnoses

- **Disturbed visual sensory perception** related to injury to eye structures secondary to trauma
- **Pain** related to traumatic injury to the eye
- **Risk for infection** related to eye injury

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Intraocular pressure may be elevated with certain injuries; pain may cause some elevations in blood pressure, pulse, and respiration.*
- Physical changes  
*Specific physical changes are seen depending on the injury present and may include bleeding, tearing, swelling, and pain.*

- Diagnostic results  
*X-ray, CT scan, and magnetic resonance imaging (MRI) scans may be ordered for specific patients to clarify the extent of the injury.*
- Age-related considerations include all ages.  
*No specific age is immune from eye injury, although it is known to be somewhat more prevalent in the age group of 18 to 25.*

#### ■ Actions

- Cover eyes/stabilize penetrating object.  
*Preventing excessive movement of the eye, particularly with an embedded object in the eye, is important to prevent additional injury. Loosely covering both eyes decreases eye movement. Objects penetrating the eye should only be removed by an eye care professional.*

- Comfort measures  
*Patient may require pain medication to help alleviate the intense pain that is often present in eye trauma patients.*
- Positioning  
*Specific positioning depends on the type of injury but often requires an elevation of the head of the bed to 30 to 45 degrees to decrease the patient's IOP.*
- Maintain a calm, quiet environment.  
*Minimizing environmental stimuli promotes rests and minimizes eye movements that can exacerbate the injury and/or increase pain.*
- Collaborative care  
*Referral to an eye care specialist should be made for any traumatic injury to the eye. The eye care professional may need to perform surgery immediately or follow up with the patient with regular examinations.*

### ■ Teaching

- Eye care follow-up  
*Patient should be instructed on compliance with all follow-up eye examinations. Regular follow-up examinations provide the patient with the best chance for retaining sight.*
- Specific instructions  
*Patients should understand all postprocedure/postoperative/postmedical treatment for an eye injury. Patient positioning, eye-patch care, medications, and activity restrictions are all paramount in the recovery from eye injuries (all injuries have specific instructions based on the pathology present).*

### Evaluating Care Outcomes

Traumatic eye injuries vary greatly in their type and degree of injury. Clinical manifestations commonly seen with eye trauma include eye pain, visual disturbances, and visible injury present on presentation. Prompt medical diagnosis with an eye care professional is the key to maintaining visual acuity. Eye injuries take many shapes and forms, and therefore, so do the instructions for care. It is essential that patients receive detailed, easy-to-understand instructions for follow-up in order to have a chance of maintaining vision.

### Connection Check 46.9

A patient arrives in the emergency department with a metal object protruding from the eye. What is the priority action for this patient?

- Remove the metal object right away to prevent any further damage.
- Apply a tight eye patch to prevent hemorrhage.
- Assess visual acuity.
- Instill 1% tetracaine eye drops for pain relief.

## Making Connections

### CASE STUDY: WRAP-UP

During the appointment, Mike discusses his visual concerns of “missing” objects in his peripheral vision. Immediately, the provider has concerns about a possible eye disease. Mike’s age, race, diabetes mellitus (for 50 years), and symptoms make the provider consider glaucoma. Upon ophthalmic examination, the provider is able to identify several bulging blood vessels in the posterior portion of Mike’s eye that are concerning. The general provider does not have a tonometer, so intraocular pressure (IOP) may not be evaluated at this time. As one final test, the provider completes a confrontation test with Mike and notes that Mike has several deficiencies in his peripheral field of vision. Mike is then referred to an eye care specialist for further evaluation and diagnosis.

### Case Study Questions

- The nurse correlates which assessment with the presence of bulging blood vessels within the posterior portion of the eye?
  - Expected changes associated with advancing age
  - Requires monitoring every 3 to 5 years by the provider
  - Requires immediate surgical intervention
  - Can indicate increased IOP
- The nurse recognizes which patients as at greatest risk for glaucoma?
  - Patients of Asian descent
  - Patients with chronic neuromuscular diseases
  - Patients with diabetes
  - Patients who have recently undergone cardiac surgery
- In providing discharge instructions to Mike, what is the rationale for follow-up with an eye care specialist?
  - Measuring intraocular pressure
  - Performing a pupillary assessment
  - Obtaining a complete and accurate visual acuity
  - Completing testing with an Amsler grid
- The provider prescribes reading glasses for Mike to treat which disorder?
  - Glaucoma
  - Peripheral vision loss
  - Presbyopia
  - Increased IOP
- The nurse expects the provider to prescribe which of the following to treat glaucoma?
  - Strict bedrest
  - Low-fat, low-sodium diet
  - A tight patch to the affected eye
  - Mydriatic eye drops

## CHAPTER SUMMARY

The visual system in the human body is complex and tied to many intricate networks within the eye itself, as well as pathways leading to and within the brain. Changes in visual ability may be gradual or acute but should always involve assessment and evaluation by a healthcare provider. Risk factors and advancing age all play a role in visual dysfunction. Comprehensive knowledge of eye function and disease pathophysiology helps to plan for appropriate treatment and continued care. Thorough, understandable teaching practices by nurses and eye care providers can provide the critical link between visual acuity and visual disruption.

Visual acuity disorders are related to refraction errors and include myopia or nearsightedness, hyperopia or farsightedness, and astigmatism that results from a misshaped cornea. Another abnormality, presbyopia, occurs almost exclusively with aging and results from the loss of lens elasticity; it occurs around age 45. All of these disorders are typically treated with corrective lenses (glasses or contact lenses) or surgical procedures, including radial keratotomy, photorefractive keratectomy, laser-assisted in situ keratomileusis (LASIK), or laser thermal keratoplasty.

Conjunctivitis involves an inflammation of the conjunctivae of the eye and can be secondary to allergies, bacteria, viruses, chlamydia, contact-lens use, mechanical means, or trauma. Clinical manifestations typically include eye irritation, tearing, and discomfort. Treatment is directed to the cause (e.g., antibiotics for infectious conjunctivitis), comfort measures, and protection of vision.

One of the most common eye disorders is corneal abrasions, which are a leading cause of visits to healthcare providers. These abrasions involve a loss of integrity of the cornea, and the patient usually complains of eye pain, photophobia, tearing, spasm, and blurred vision. Management focuses on the administration of antibiotic eye drops and other eye medications to decrease muscle spasms of the eye. Pain and photophobia can be minimized by wearing dark sunglasses.

Cataracts involve a clouding of the eye's lens that decreases vision due to interference with light reaching the retina secondary to the cloudiness. Management focuses on improving vision and is best accomplished by surgical procedures, including phacoemulsification and extracapsular or intracapsular cataract extraction. Lenses that help to maintain the structure of the eye are implanted during the procedure.

Glaucoma is an eye disease that develops secondary to increases in intraocular pressure that results in damage to the optic nerve, leading to loss of vision. Because of either overproduction or inadequate drainage of aqueous humor, intraocular pressure (IOP) increases. Medical management of glaucoma focuses on medications that inhibit aqueous humor production or facilitate drainage through the canal of Schlemm. Surgical procedures to treat glaucoma focus on increasing drainage of aqueous humor, including laser trabeculoplasty, trabeculectomy, and drainage implants. Because of the risk of increased IOP, it is important to teach patients to avoid activities that can potentially increase IOP, including straining with bowel movements and bending at the waist.

Macular degeneration is commonly age related and gradually destroys sharp, central vision due to damage to the macula. Because the degeneration is painless, the onset and progression may be insidious and the diagnosis delayed. Clinical manifestations of macular degeneration include straight lines that appear distorted; absent or distorted central vision; dark, blurry areas or whiteout on center vision; and diminished or changed color perception. Treatment includes laser surgery, photodynamic therapy, and injections directly into the eye. There is no cure for macular degeneration, and despite treatment, the disease and vision loss may continue to progress.

Considered a medical emergency that may cause permanent vision loss, retinal detachment requires immediate attention by an eye care professional. Clinical manifestations may be sudden or gradual and typically include floaters in the visual field as well as light flashes or the appearance of a curtain over the field of vision. Surgical interventions are the only effective treatment, with the goal of stopping further progression of vision loss. Procedures include laser photocoagulation, panretinal photocoagulation, cryopexy, pneumatic retinopexy, scleral buckling, and vitrectomy.

Eye trauma is typically classified as blunt or penetrating injury, and clinical manifestations are associated with the type and severity of the injury. Blunt trauma is often related to motor vehicle accidents, assaults with weapons, or falls, whereas penetrating injuries are often associated with a lack of protective eyewear and sharp objects penetrating the eye. Management is focused on the prevention of further injury, particularly interventions to decrease intraocular pressure and infection.

# Chapter 47

## Assessment of Auditory Function

*Kelley Miller Wilson*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the auditory system
2. Discussing the function of the auditory system
3. Describing the procedure for completing a history and physical assessment of the auditory system
4. Correlating relevant diagnostic examinations to auditory function
5. Explaining nursing considerations for diagnostic studies relevant to the auditory system
6. Describing methods to prevent ear trauma
7. Identifying ototoxic medications
8. Discussing changes in hearing associated with aging

### CONCEPTS

- Assessment
- Comfort
- Medication
- Nursing Roles
- Promoting Health
- Safety
- Sensory Perception

### Finding Connections

#### CASE STUDY: EPISODE 1

*Follow this patient throughout the chapter.*

Erin Hodge is a 22-year-old waitress who plans to see her provider this week for a physical examination. Erin has always enjoyed excellent health, though she did experience numerous ear infections as a child requiring surgical insertion of pressure-equalizing tubes (tiny tubes surgically inserted in the tympanic membrane to equalize pressure and prevent infectious buildup). Currently, Erin has no known chronic diseases and takes no medication on a daily basis. She has been noticing waxy buildup in her ear canal lately, which she has treated herself using a cotton swab to remove the wax. Erin has not noticed any hearing changes and plans to discuss the recent waxy buildup in her ears with her provider...

### ESSENTIAL TERMS

Apocrine glands	Ossicles
Audiometry	Otoscope
Cerumen	Ototoxic
Conductive hearing loss	Presbycusis
Decibels	Pure tone audiometry
Electronystagmography	Sensorineural hearing loss
Frequency	Speech audiometry
Hertz	Tinnitus
Hyperacusis	Tympanometry
Mixed conductive-sensorineural hearing loss	Vertigo
Nystagmus	Vestibulocochlear nerve

### INTRODUCTION

The ear is an extraordinary sensory organ that works in conjunction with the brain to interpret sounds. These sounds allow assessment of surroundings, warning of potential dangers, interactions with other people, and appreciation of sounds such as music, work, and play. Many aspects of daily life are affected by the ability to hear. Assessment of the anatomy and physiology of the ear provides essential data about hearing and balance. The interpretation of screening assessments and diagnostic results is also pertinent to providing comprehensive care to patients with hearing disorders.

### OVERVIEW OF ANATOMY AND PHYSIOLOGY

#### Anatomy

There are three parts of the ear that work together to allow hearing and processing of sound. Cranial nerve VIII (the **vestibulocochlear nerve** or acoustic nerve) is responsible for transmitting sound and equilibrium information from

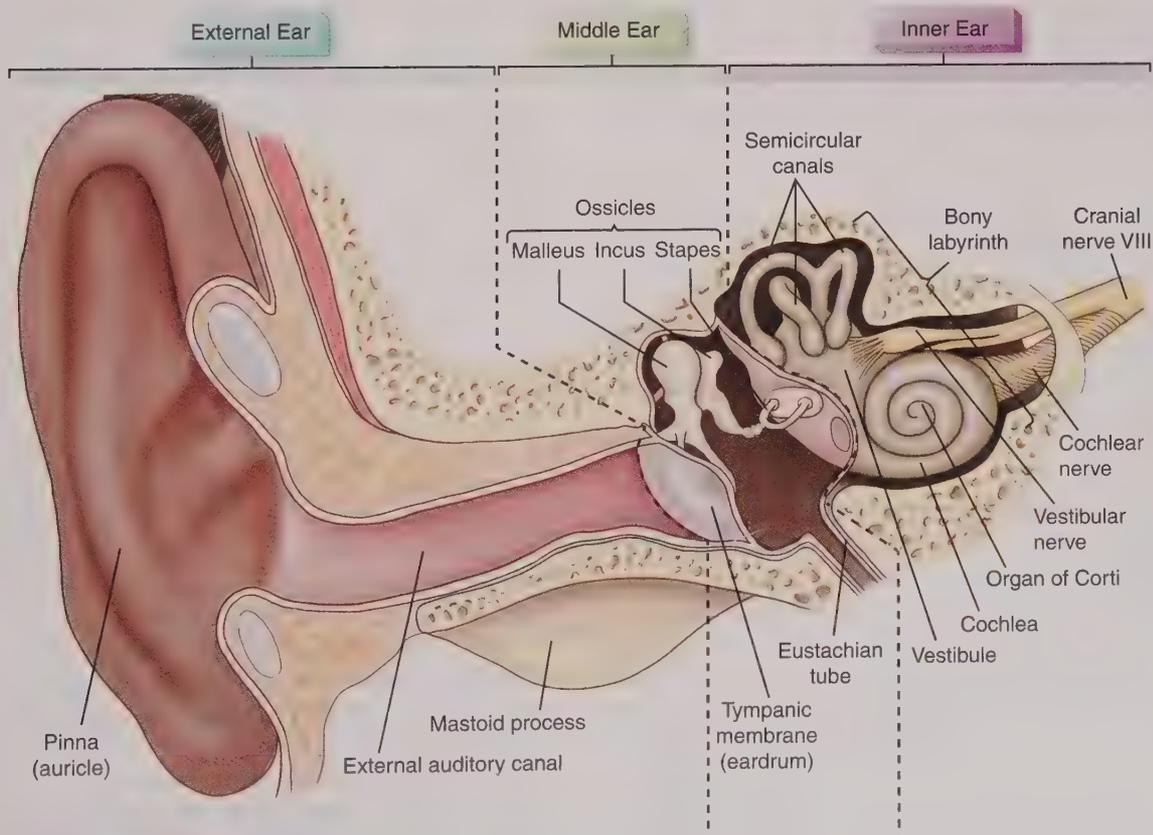

the inner ear to the brain. These parts are referred to as the external (outer) ear, the middle ear, and the inner ear (Fig. 47.1).

The external ear consists of the pinna, mastoid process, and external auditory canal, and the major function of this portion of the ear is to funnel sound waves. The middle ear includes the tympanic membrane (eardrum), the malleus, the incus, the stapes, and the eustachian tube. The middle ear has three functions that include conducting sound waves from the outer ear to the inner ear, protecting the inner ear from loud sounds, and equalizing pressure in the middle ear. The inner ear consists of the bony labyrinth, which holds the vestibule and semicircular canal. The cochlea is also housed here and contains the main hearing apparatus. Cranial nerve VIII contains the sensory cells (hair cells) of the inner ear and consists of the cochlear nerve, which carries information about hearing, and the vestibular nerve, which carries information about balance directly to the brain.

The following is a list of structures within the ear and a brief description of their main functions.

- *Pinnae* (also referred to as the *auricles*) are the most visible part of the ear, and their primary function is to collect sounds. Composed of cartilage covered by skin, the pinnae are present on both sides of the face and are embedded in the temporal bone bilaterally at the level of the eye.

- *External auditory canals* are structures 2.5 to 3.0 cm long in the adult that terminate at the eardrum. The canals are lined with glands that secrete **cerumen** (a yellow waxy material). The cerumen lubricates and protects the ear by forming a sticky barrier that helps prevent foreign bodies from reaching the tympanic membrane.
- *Mastoid processes* are parts of the skull that contain spongy bone located just behind the ear. The middle ear and the cochlea portion of the inner ear are embedded in the mastoid bone.
- *Tympanic membranes* (eardrums) are structures that separate the external ear from the middle ear. They are translucent membranes with a pearly gray color and are oval in shape.
- *Eustachian tubes* connect the middle ear with the nasopharynx, allowing for passage of air. These tubes are usually in a closed position but open with swallowing or yawning. Their function is to stabilize the air pressure between the external atmosphere and the middle ear. In children, this tube is flatter in appearance and gradually evolves in the adult to have a more slanted appearance, thereby making drainage more efficient and lessening the chance of infection.
- *Malleus* is the part of the middle ear that is in the shape of a hammer. The function of this structure is to transmit sound vibrations from the eardrum to the incus.

**FIGURE 47.1** Anatomy of the ear.

- *Incudes* are the tiny bones that pass vibrations from the hammer to the cochlea.
- *Stapes* are the smallest bones in the human body; they are stirrup shaped and located in the middle ear and are important for transmission of sound to the inner ear.
- *Semicircular canals* are tubes composed of cartilage that contain both fluid and hair cells. The sense of equilibrium is maintained here.
- *Vestibules* are the small, oval-shaped bony chambers located between the semicircular canals and the cochlea. This area contains structures that are important for the sense of balance.
- *Cochlea* are the spiral-shaped, curled tubes located in the inner ear. While sound enters the cochlea, vibrations cause movement of the hairs within the structure, creating nerve signals from cranial nerve VIII that the brain then interprets as sound.
- *Organs of Corti* are located in the cochlea and are the receptors and organs of hearing. They contain hair cells, and while the hairs bend, they change vibrations into electrical impulses that are then carried by cranial nerve VIII to the brain.
- *Bony labyrinth* is the structure that holds the sensory organs for equilibrium and hearing.

### Connection Check 47.1

The nurse correlates which anatomical structure as the location of the sensory organs for hearing and equilibrium?

- Eustachian tube
- Ossicles
- Bony labyrinth
- Tympanic membrane

## Auditory Function

Sound is transmitted by air and bone conduction, and air conduction of sound is the most common pathway of hearing. Transmission by air follows the subsequent sequence for sound to be successfully interpreted. Sound is gathered by the pinna, and the waves enter the ear traveling through the auditory canal until they reach the tympanic membrane (eardrum). The sound waves set up vibrations in the eardrum. These vibrations of the eardrum cause the auditory **ossicles** (the malleus, incus, and stapes) in the middle ear to move back and forth. The cochlea receives the sound vibrations next. Finally, the sound stimulus travels to the vestibulo-cochlear nerve (acoustic or auditory nerve), cranial nerve VIII, and terminates in the cerebral cortex. Cranial nerve VIII is the cranial nerve that is concerned with hearing, balance, and head position. The eighth cranial nerve branches into two parts, a cochlear part that is integral to hearing and a vestibular part that mediates the sense of balance and head position. The cerebral cortex is a most highly developed part of the brain that is divided into right and left

hemispheres. The temporal lobe of the cerebral cortex is involved with hearing and language.

Bone conduction transmission of sound occurs when the skull bones (commonly tested using the mastoid bone located behind the ear) transport vibrations directly to the inner ear and then to the auditory nerve. The skull transmits high frequencies with less intensity than air, and that is why a person's voice sounds different to them when recorded and played back.

The inner ear, with innervation from cranial nerve VIII, also controls equilibrium and balance. The labyrinth in this portion of the ear constantly provides information to the cerebral cortex of the brain about the body's position in space. It works like an imaginary line to determine verticality or depth. The ears register the angle of the head in relation to gravity. Inflammation of the labyrinth causes the wrong information to be sent to the brain, thus resulting in a staggering gait and a spinning, whirling sensation known as **vertigo**.

### Connection Check 47.2

The nurse recognizes which actions as essential functions of the auditory system? (*Select all that apply.*)

- Transfer of sound waves through the auditory canal
- Vibration of the eardrum
- Warming air while it enters the outer ear
- Balance
- Secretion of cerumen

## ASSESSMENT OF THE AUDITORY SYSTEM

### History

A detailed patient history is completed before the physical examination. During assessment of the auditory system, it is important that the provider carefully listen, ask questions regarding the patient's medical history and family history, and note any current medications the patient is taking. Observation of the patient's posture and facial expressions can also yield clues about hearing difficulties. For example, does the patient frequently lean toward the provider when questions are being asked? Other careful considerations include whether the patient is able to accurately answer the questions and if there are frequent requests to repeat questions. Box 47.1 provides common clinical manifestations of hearing impairment.

Personal history includes questions regarding past ear infections, past ear trauma, past ear surgeries, exposure to loud noises and music, possible occupational hazards regarding loud noises, and itching of the ears. Problems such as vertigo (spinning sensation), **tinnitus** (ringing in ears), **hyperacusis** (intolerance for sound levels not normally experienced by others), and difficulty hearing or

## Box 47.1 Signs of Hearing Loss

- Frequently asking for instructions to be repeated
- Turning the head or leaning forward to gain clarity on the question being asked
- Loud conversation initiated by the patient
- Failing to respond when spoken to (especially when not looking in the direction of the sound)
- Answering questions incorrectly on a consistent basis
- Raising the volume of the television/radio on a consistent basis
- Avoiding large groups
- Withdrawing from social functions or interactions
- Clinical manifestations of depression

understanding words are also addressed. In addition, history of current health, past illnesses (especially those requiring treatment with known **ototoxic** (causing damage to the ear or hearing) medications, smoking history (nicotine may cause damage to the sensory cells), allergies, and family history provide important information about the auditory system (see Genetic Connections). Questions to accurately and easily assess family history are included in Box 47.2.

## Genetic Connections

### Hearing Loss

Genetics may have a significant effect on hearing. More than 400 syndromes are linked to hearing loss, and often these disorders are diagnosed in childhood, although some genetic problems lead to progressive hearing loss in the adult years. Common examples of these disorders include the development of hearing loss in adulthood in patients with Down's syndrome. People with the genetic disorder osteogenesis imperfecta have bilateral and progressive hearing loss by their 30s. Other genetic hearing loss-associated syndromes are included in Table 47.1.

## Personal Hygiene

The physical examination is an ideal time to assess how the patient cares for and cleans the ears. This is also an opportunity for the nurse to instruct the patient regarding the dangers of using cotton swabs or other foreign objects in the ear canal because inserting foreign objects can cause tissue injury to the sides of the canal, as well as causing cerumen to be moved. Movement of the cerumen by a foreign object places the patient at risk for cerumen impaction, causing changes in hearing, as well as rupture of the eardrum.

Patients who wear a hearing aid require additional assessment. Hearing aids function as an accessory to make sounds more audible; they do not correct hearing loss. The device is designed to amplify and modulate sound for the

## Box 47.2 Assessment of Hearing Function

1. Does anyone in your family have hearing problems? If so, at what age did the hearing difficulties start? Did it affect both ears?
2. Do you notice that it seems that people seem to mumble or speak in a softer voice more than previously?
3. Do you frequently need to ask people to repeat themselves during conversations?
4. Do you have difficulty understanding conversations in a crowded room?
5. Do you often need to increase the volume on electronic items such as televisions or radios?
6. Do you have difficulty hearing conversations on the telephone?
7. Do you sometimes miss the telephone ringing or doorbell ringing?
8. Do family/friends complain about your hearing?

**Table 47.1 Genetic Causes of Hearing Dysfunction**

Syndrome	Characteristics of Hearing Loss
<b>Waardenburg syndrome</b>	Unilateral or bilateral; sensorineural
<b>Branchio-oto-renal (BOR) syndrome</b>	Conductive, sensorineural, or mixed
<b>Neurofibromatosis type 2</b>	Progressive sensorineural loss leading to deafness in many cases
<b>Stickler syndrome</b>	Progressive hearing loss; most usually conductive, though it can be mixed sensorineural
<b>Usher syndrome</b>	Three types: Type I—Profound sensorineural hearing loss with vestibular dysfunction Type II—Progressive sensorineural loss Type III—Progressive sensorineural loss and variable vestibular dysfunction

patient and is specifically designed on the basis of the provider's interpretation of the patient's hearing evaluation/testing. Many different hearing aids are available, and some are designed to be placed in the ear canal itself and others are designed to be placed behind the ear. Wireless technology also has an impact on hearing and advancing hearing aid capability. It is important that the provider continue to assess whether the use of the hearing aid is actually improving the patient's hearing and note when the patient last had a hearing evaluation. Future follow-up plans at predicted intervals should also be discussed with the patient before leaving the provider's office.

### Connection Check 47.3

When the nurse assesses a patient regarding the auditory system, which is the most important question to ask?

- “Do you have any chronic illnesses that require you to take daily medication?”
- “Have you ever been told that you are tone deaf?”
- “Did you ever have a foreign body in your ear?”
- “Do you notice that you have wax in your ears?”

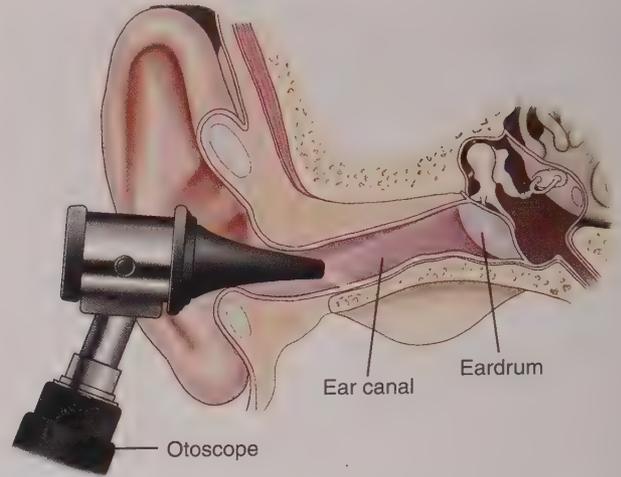

### Physical Inspection of the Ear

Before completing the physical examination of the ear, it is important to have the patient sit up straight with the head at the eye level of the provider. Full explanation of how the provider will assess the ear is given to the patient before beginning the examination. Assessment of the ear includes inspection, otoscopic examination, and evaluation of the vestibulocochlear nerve (cranial nerve VIII).

Inspection begins with palpation of the external ear. The provider notes the size and shape of the ears because they should be equal in size bilaterally without swelling or thickening. The color of the ears should be consistent with the facial skin tone of the patient. Inspection for lumps or lesions is also performed. The pinna should feel firm and should be freely moveable without causing any discomfort. Palpation of the mastoid process is also completed at this time, and there should be no swelling or complaint of pain present during the examination.

#### Examination With an Otoscope

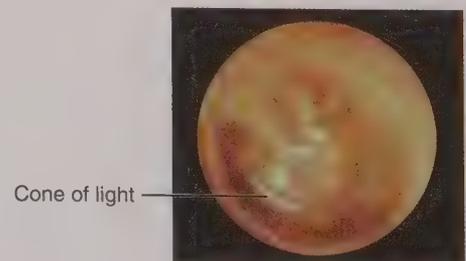

The **otoscope** is used to examine the internal structures of the ear and consists of a light, handle, magnifying lens, and pneumatic bulb (often used with children) to test the movement of the tympanic membrane (Fig. 47.2). To complete the examination, the provider tilts the patient's head away from the examiner. The pinna is pulled up and back in the adult and older child, and the pinna is pulled down on an infant or child younger than 3 years. This important action helps straighten the ear canal and affords better visualization due to the flat anatomical position of the infant's eustachian tube. The pinna is held lightly but firmly, maintaining a steady grip until the examination is complete and the otoscope is removed from the ear canal. The provider holds the otoscope in an “upside-down” position and steadily places the speculum of the otoscope into the ear canal using the hand along the patient's cheek to steady the otoscope. The provider takes care to watch the insertion to ensure safe and easy introduction. On occasion, the provider is unable to see any structures, and a reattempt is made to reposition the otoscope. (If cerumen is present and creating an obstruction, it will need to be removed before a visual examination can be performed.) Once the otoscope is in place, the provider rotates it slowly to visualize the eardrum. The otoscopic examination is usually completed before any hearing tests are conducted.

**FIGURE 47.2** Otoscopic examination. The otoscope is used to examine the internal structures of the ear.

The otoscopic examination provides a wealth of information about the current status of the ear. Visualization of the external canal is completed while the otoscope is placed in the canal and advanced. Evaluation of the tympanic membrane includes noting the color (red, white, yellow, or gray), translucency (translucent or opaque), and position (retracted, neutral, or bulging) of the drum. Air inflation with a pneumatic otoscope is important to evaluate the mobility of the tympanic membrane. Mobility is assessed by applying positive and negative pressures with a rubber squeeze ball. Any redness, swelling, lesions, or discharge is also documented at the time of examination.

The visual examination of the tympanic membrane is then completed. This is done in a systematic manner. The normal eardrum is shiny, translucent, and pearl gray in color (Fig. 47.3). The cone-shaped light reflex that is elicited is prominent in the anteroinferior quadrant (5:00 in the right eardrum and 7:00 in the left eardrum). This light is the reflection of the otoscope light. The eardrum is flat, slightly pulled in the center, and flutters when the patient swallows or holds the nose. The eardrum is inspected around its entire circumference to ensure that the tympanic membrane is intact (Fig. 47.4). White dense patches may be present on the drum and indicate scarring from repeated ear infections or past ruptures.

**FIGURE 47.3** Normal eardrum on otoscopic examination (left ear). The normal eardrum is shiny, translucent, and pearl gray in color. The cone-shaped light reflex, which is the reflection of the otoscope light that is elicited is noted in the anteroinferior quadrant (7:00 in the left eardrum).

**FIGURE 47.4** Perforated eardrum.

## CASE STUDY: EPISODE 2

Erin Hodge provides a detailed health, family, and medication history to the nurse provider. Erin's physical examination and simple hearing assessments are all noted as "normal" by the advanced practice nurse and yield no concerns. To complete the examination, the nurse practitioner removes the earwax to increase visualization. Erin notices an immediate improvement in her hearing ability after the wax is removed...

## AUDITORY ASSESSMENT

Auditory, or hearing, assessment is completed after the external and otoscopic examination of both ears has been completed. These simple but meaningful tests help identify deficiencies present; however, they cannot determine the extent of the deficiency. Hearing loss is categorized in three ways:

- **Conductive hearing loss** describes a physical obstruction of sound wave transmission.
- **Sensorineural hearing loss** describes a deficit present in the cochlea, cranial nerve VIII, or the brain.

- **Mixed conductive-sensorineural hearing loss** describes profound hearing loss that encompasses both conductive and sensorineural injuries.

Tests used to assess hearing function are detailed in Tables 47.2 and 47.3. Before any testing of a patient's auditory function, a detailed explanation and instructions are given by the provider. Instructions need to be specific to the type of test being conducted.

## Diagnostic Studies

In addition to the detailed history and physical examination needed for a thorough evaluation of auditory function, there are also diagnostic studies used to assess hearing and determine underlying pathology.

### Audiometry

Hearing acuity is measured through **audiometry**, and this test is most often performed by skilled technicians and nurses with specialized training. This test measures **frequency** (the highness or lowness of tones expressed in hertz; **hertz** is the international unit of frequency defined as the number of cycles per second of a sound). Low pitch is determined by fewer vibrations, and high pitch is determined by a greater number of vibrations. Sound intensity is noted in **decibels** (dB), and threshold is noted as the lowest level of intensity at which pure tones and speech are heard by a patient approximately 50% of the time. Normal conversation is heard at approximately 60 dB; whispers are 20 dB; and very loud, dangerous sounds are considered to be at approximately 110 dB. Documented injury can occur from sounds louder than 85 dB. Audiometric evaluations are often done in special facilities with sound laboratories to ensure that outside distracting noises do not interfere with the testing.

There are two types of audiometry: pure tone and speech. **Pure tone audiometry** generates tones with an audiometer that are presented to the patient at frequencies for hearing speech, music, and other common sounds. The

**Table 47.2** Hearing Tests

Test	Procedure
<b>Voice test</b>	Simple hearing acuity test performed on both ears at the same time. To perform, the provider stands 1–2 feet away from the patient and asks the patient to cover one ear. The provider whispers a short statement of four words or fewer into the patient's uncovered ear and asks the patient to repeat the words. If the patient is unable to respond or responds incorrectly, repeat the statement choosing new words and in a slightly louder whisper.
<b>Watch test</b>	This simple test is performed to assess high-frequency sounds and is performed with a ticking watch. The watch is held about 5 inches from each ear, and the provider verifies whether a patient is able to hear the ticking. The patient with normal high-frequency hearing is able to hear the watch tones.
<b>Audioscopy</b>	This procedure evaluates hearing ability with a handheld device to assess general tones. The test measures at 40-dB intensity and at frequencies of 500; 1,000; 2,000; and 4,000 cycles per second, or hertz. This test is done in a quiet setting with headphones in place and is most often seen as a screening device in schools or clinics.

**Table 47.3** Hearing Assessment

Name of Test	How to Perform Test
<b>Weber test</b>	This test is used to distinguish between conductive (bone conduction) and sensorineural (air conductive) hearing loss. To perform this test, activate the tuning fork by holding the stem and striking the two tines with the back of the hand. Place the vibrating tuning fork in the midline of the patient's skull and ask whether the tone sounds the same in both ears or better in one.
<b>Rinne test</b>	This test compares air conduction and bone conduction. The tuning fork is activated as described above. When activated, place the stem of the vibrating tuning fork on the patient's mastoid process, and the patient is asked to indicate when the sound goes away. The tuning fork is then quickly inverted, with the tines located approximately 2 inches from the patient's ear; the patient should still be able to hear the vibrating sound if hearing is normal.

testing is done by air conduction and bone conduction and determines whether hearing loss is present and, if loss is noted to be present, whether the loss is conductive, sensorineural, or mixed. An increase in air conduction threshold with a normal bone conduction threshold indicates a conductive hearing loss. An elevated threshold for both air and bone conduction thresholds indicates a sensorineural hearing loss, and an increase of air conduction that is greater than an increase in the elevated threshold of bone indicates a mixed hearing loss. In **speech audiometry**, the patient's ability to hear spoken words is measured through a microphone connected to an audiometer. The two components of speech audiometry are the speech reception threshold and speech discrimination. The speech reception threshold determines the softest level at which the patient begins to recognize speech. Speech discrimination determines how well speech is heard and understood when the volume is set at the patient's most comfortable level of hearing.

### Connection Check 47.4

Which is the most common examination used to assess a patient's auditory function?

- Examination using the tuning fork
- Assessment of all the cranial nerves
- Examination using the otoscope
- Evaluation of a written questionnaire

### Tympanometry

**Tympanometry** is completed in healthcare providers' offices and clinics and is performed by technicians, nurses, or other specially trained personnel. Patient preparation centers on educating the patient as to how and why the test will be completed. The equipment used is sensitive and requires delicate handling and usually has single-use earpieces that require disposal and replacement. Tympanometry is performed to assess the mobility of the eardrum and structures of the middle ear because these changes are consistent with presence of fluid in the middle ear. Changes in air pressure are systematically

introduced into the external auditory canal at a predictable rate. This test is helpful in distinguishing middle ear pathologic conditions such as otosclerosis, ossicular disarticulation, otitis media, and perforation of the eardrum. Earpieces are placed in the patient's ear before the start of the test, and the machine is able to determine the degree of progression or resolution of serous otitis media.

### Electronystagmography

The **electronystagmography** (ENG) test is done to detect both central and peripheral diseases of the vestibular system (the system in the inner ear that is responsible for maintaining balance and orientation in space) in the ear. The ENG detects and records **nystagmus** (involuntary eye movements), because the eyes and ears depend on each other for balance. To perform this test, electrodes are taped to the skin near the eyes, and one or more of the following procedures is completed to stimulate nystagmus. These procedures include caloric testing, changing gaze position, or changing head position. Changing gaze/position is an oculomotor (cranial nerve III) evaluation. This stimulus is initially accomplished with manually controlled objects such as dots placed on walls or ceilings at specific places. Changing head position is a test that is conducted with a rotating drum with stripes and color contrasts as well as a swinging pendulum or metronome. Caloric testing is performed by taking warm or cooler than body temperature water and instilling it directly into the ear. The expected response in a normal patient when any of these procedures are performed is onset of vertigo and nystagmus within 20 to 30 seconds. Movement of the eye is also noted; the eye shows movement toward the water if the water is warm and away from the water if it is cold in caloric testing.

Preparation for this test includes a detailed explanation of the purpose and procedure to the patient. The following teaching points are provided to the patient before the test is performed:

- The patient is to refrain from ingestion of caffeine for at least 24 hours before the test. Caffeine causes stimulation of the central nervous system that can possibly influence testing results.

- The patient is to be NPO for at least 3 hours before the test. Patients may experience nausea and vomiting with this test, and NPO status may help to decrease this sensation.
- Patients with pacemakers should not have this test because pacemaker signals interfere with the sensitivity of this test.
- Patients who normally wear eyeglasses are instructed to bring them to the test. Eyeglasses assist the patient in vision during the testing.
- Patients are informed that reintroduction of fluids after this test is to be gradual to prevent the occurrence of nausea and vomiting.
- Patients might want to consider having a family member drive them home from the test because sometimes nausea, vomiting, or vertigo can continue after testing.

### Computed Tomography and Magnetic Resonance Imaging

Detailed visualization of the internal structures of the ear is achieved by either computed tomography (CT) or with magnetic resonance imaging (MRI). A CT scan is noninvasive and completed with or without contrast. Contrast may be ordered because it can improve visibility of internal structures, especially those that may be difficult to see. This test is extremely helpful in diagnosing acoustic tumors, often known as acoustic neuromas.

The MRI is also used for its superior contrast resolution, allowing for very detailed imaging. Patient explanation and teaching by the nurse or the provider are important before this test. Many institutions and healthcare providers also require that a consent be signed by the patient before these tests are completed.

#### Patient Teaching Before Computed Tomography Scan

1. Explain to the patient about being placed on a table and systematically moved through a shallow tunnel. An IV may be started if the patient is going to receive contrast.
2. Verify that the patient does not have allergies to iodine or other IV dyes.
3. IV contrast, if used, may cause a very warm sensation to the body, which is temporary and disappears shortly after injection.
4. Drink plenty of fluids after the CT scan if IV dye is used to assist in helping the body excrete the IV dye. Instruct the patient that increased urination is to be expected secondary to an increase in fluid volume and the dye's diuretic effect on the kidneys.
5. Certain medications such as metformin (lowers blood glucose) may need to be "held" before and after the CT scan to prevent an increased serum level of the medication and, therefore, a decrease in blood glucose.

#### Patient Teaching Before the Magnetic Resonance Imaging Scan

1. Instruct the patient on the type of machine being used (MRI machines can be "open" or "closed." Sedation is

often needed by patients undergoing "closed" MRIs because many patients become claustrophobic when placed in the MRI machine.)

2. Patients with vascular surgical metal clips are not candidates for MRI because of the presence of the large magnet of this machine. Newer surgical clips that are made from titanium are acceptable for this test.
3. Patients with pacemakers or implantable defibrillators should check with their provider before having any MRI procedure.

### Connection Check 47.5

The nurse implements which actions before the patient undergoes diagnostic studies of the ear?

- A. Verify the patient's understanding of the scheduled test
- B. Request that the nurse technician obtain consent for the test
- C. Reassure the patient that the ordered test should be completed
- D. Inform the patient that teaching for this procedure is the provider's responsibility

### OTOTOXIC MEDICATIONS

The ear is a sensitive organ with many fragile parts. Several categories of medications can prove dangerous to the proper functioning of the ear (ototoxic), and often patients are not aware of this side and adverse effects. The most common categories of medications that pose ototoxic risks are in the following categories (see Chapter 48 for a partial list of specific medications):

- Antibiotics
- Diuretics
- NSAIDs
- Chemotherapeutic agents
- Miscellaneous

This is only a guideline and not all medications in each category pose this risk; medications should be assessed on an individual basis.

### Connection Check 47.6

The nurse recognizes which medication as ototoxic?

- A. Nonsalicylate pain medications
- B. Calcium channel blockers
- C. Antibiotics such as gentamicin
- D. Beta blockers

### HEARING PROTECTION

Protecting the numerous sensory organs of the ear is imperative for the long-lasting health and function of the ear. Evaluation of hearing function is an essential part of

the patient's yearly examination. This examination includes the basic screening tools discussed previously as well as more in-depth testing based on the presence of any ear abnormalities. Protection of the ears from excessive noise is facilitated by using earplugs, earmuffs, or other protective equipment. Figure 47.5 provides a graphic representation of decibels ranging from 0 (hearing threshold) to 160 (decibels created by a 12-gauge shotgun). The frequent use of "earbuds" for listening to music and other sounds can pose a serious risk to the ear structures if used well beyond recommended volume levels because damage may be done to sensitive hair cells or other structures within the ear.

Patient education regarding the relationship between volume levels and hearing loss is essential to facilitate awareness of the hazards. Patients with certain pathology and postoperative conditions also need to consider the use of specialized waterproof earplugs for use around and in water conditions. (Most ear-protective equipment is readily available at pharmacies and is often available from employers that have employees who are in the presence of loud noises on a routine basis). The use of cotton swabs or other foreign objects to "clean" out the ear canal is a risky practice because rupture to the eardrum and impaction of wax creating pressure buildup are results that can occur using these objects. Assessing potential needs for protective equipment is an important aspect of the hearing examination, because patient education can prevent possible hearing loss. Box 47.3 provides an overview of risk factors associated with hearing loss.

**Safety Alert** Certain measures should be taken to prevent hearing loss. These include yearly hearing evaluation with an annual physical examination; use of earplugs, earmuffs, or other protective equipment in the presence of loud or excessive noise to protect sensitive structures of the ear; limiting use of earbuds for listening to music at levels well beyond recommended sound levels; and use of waterproof earplugs for patients with recurrent ear infections or those with specific pathology requiring earplugs around water conditions. Additionally, cotton swabs should not be used to "clean out" ear canals because of the risk of eardrum rupture or impaction of cerumen.

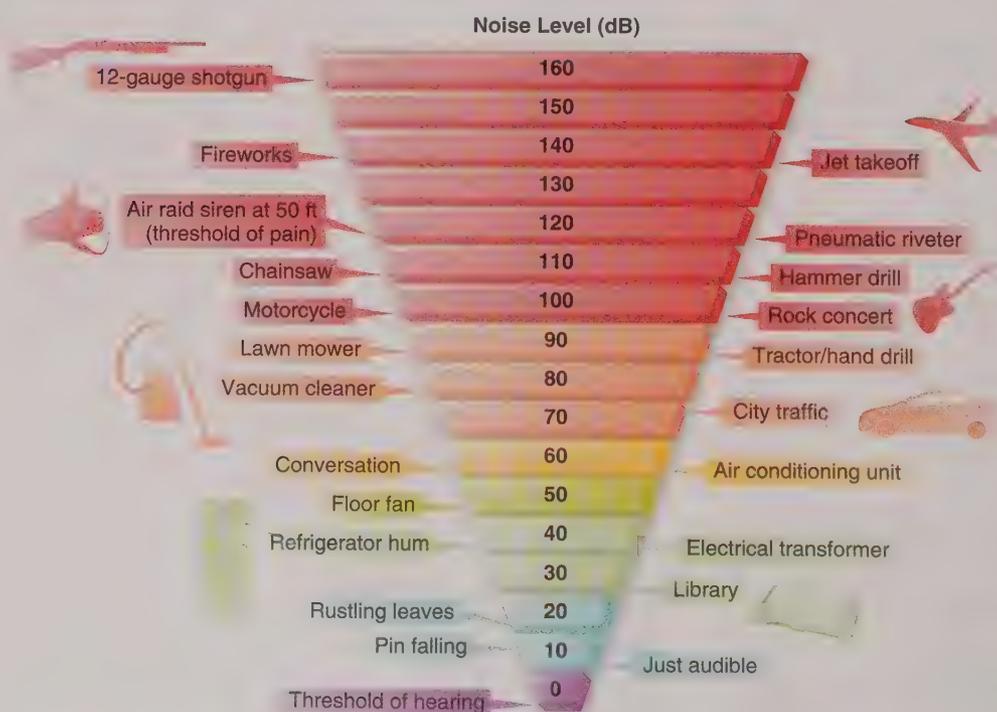

### Connection Check 47.7

The nurse should instruct the patient to perform which action to prevent possible ear trauma?

- Whisper when possible to prevent ear strain
- Select earbuds for electronic devices over external earphones
- Be cautious when taking oral medications
- Never use a cotton swab or other similar instrument in an attempt to remove wax

### AGE-RELATED CHANGES

As with most structures of the body, the ear also undergoes changes while a person ages, including the following changes.

**FIGURE 47.5** Noise levels of common sounds. Volume levels ranging from 0 to 160 dB.

## Box 47.3 Risk Factors for Hearing Loss

- Advanced aging
- Repeated infections of the ear
- Medications with ototoxic side effects
- Ear trauma
- Occupations that place the patient in the presence of loud noises
- Tumors of the ear
- Continuous exposure to loud noises

### Outer Ear

Cilia lining the ear canal become coarse and stiff, which may decrease hearing because it impedes sound waves from traveling toward the middle ear. Cerumen can also accumulate and oxidize secondary to the coarse, stiff cilia. Atrophy of the **apocrine glands** (glands that produce cerumen) causes the cerumen to become drier. Oxidation causing dryness of the cerumen is a common but reversible cause of hearing loss in older adults. Persons living near busy highways, airports, or other noise-polluted areas also have a greater risk of hearing loss.

### Middle Ear

Membrane changes that include stiffening of the tympanic membrane and stiffness or calcification of the ossicles occur with advancing age.

### Inner Ear

**Presbycusis** is a type of hearing loss that occurs with older adults. This loss is gradual and sensorineural (perceptive) in nature and is caused by nerve degeneration in the inner ear or auditory nerve. The onset for this type of hearing loss usually begins at approximately age 50 and then slowly progresses. While this occurs, the patient first notices

high-frequency tone loss; it is harder to hear consonants (which are considered high-pitched components of speech). Words may start sounding garbled. Localization of sound, especially in the presence of background noises, is also impaired. Patients aged 70 years or older may also have an increased auditory reaction time, that results in it taking longer for older adults to process and respond to sensory input.

**Safety Alert** There are several common age-related changes to be aware of, including atrophy of the apocrine glands that produce cerumen. This can cause dryness of the cerumen, therefore increasing risk of impaction. People between the ages of 50 and 70 years old commonly notice difficulty with hearing, both with frequencies and localized sounds. Constant exposure to loud noises in the home or at work can also increase risk for hearing loss.

### Connection Check 47.8

Which findings are expected age-related changes in the auditory system? (*Select all that apply.*)

- Increase in frequency of ear infections
- Hearing acuity may decrease.
- The ability to hear high frequencies is lost first.
- The tympanic membrane loses elasticity.
- Increased flexibility of the stapes

Patients with hearing loss may be sensitive to their condition. Because it is important to facilitate effective communication, there are specific strategies that can be implemented with patients with hearing impairment (Table 47.4). Additionally, it should be noted that when patients do not feel well or have decreased energy states, they may not hear as well. It takes energy, concentration, and motivation for patients with hearing impairments to function optimally.

**Table 47.4 Effective Communication With Hearing-Impaired Patients**

Intervention	Rationale
Face the patient directly when speaking to him or her	Direct visualization of the person talking helps the patient to interpret conversation better by being able to “lip-read” and assess nonverbal communication.
Speak slowly and be attentive to enunciation	Speaking slowly and enunciating all parts of words provides the best chance for hearing-impaired persons to be able to understand spoken communication.
Lower the pitch of voice	Because higher-frequency hearing tones are usually the first tones that are lost, speaking in a lower tone of voice may also help the patient to understand verbal communication.
Take care not to shout	Shouting increases the voice pitch, making it more difficult to understand spoken words; it can also be embarrassing to the patient.

## Making Connections

### CASE STUDY: WRAP-UP

The provider notes the opportunity for teaching regarding Erin's use of cotton swabs to clean the earwax from her ears. Concern is raised regarding the possibility of inducing trauma to the eardrum or other internal ear structures by use of this foreign object. Erin states that this is the way "everyone" in her family cleans his or her ears, and so she has performed this action for as long as she can recall. The provider concludes Erin's examination with teaching of ear hygiene without the use of introducing objects into the ear canal, thereby possibly preventing trauma or hearing loss to her.

#### Case Study Questions

- The nurse recognizes that ear infections are more common in children for which reason?
  - The immaturity of the hair cells within the ear canal
  - The increase in wax production in children younger than 5 years
  - The flat position of the eustachian tube
  - The immaturity of the immune system
- What teaching is most important for the provider to provide to Erin during this visit?
  - Not using cotton swabs or other similar instruments in the ear canal
  - Ways to remove the waxy buildup from the ear canal
  - What to do if the patient starts to notice hearing loss
  - Use of earbuds for listening to music
- The healthcare provider instructs the patient on which ear protective measures? (*Select all that apply.*)
  - Earbuds to reduce noise in areas with high-decibel noise levels
  - Earbuds to help prevent water from entering the ear canal
  - Headphones to listen to music at medium to high decibel ranges
  - Earplugs to help decrease water from entering the canal while swimming
  - Wearing earmuffs in the winter
- Erin does not notice any hearing changes; the provider verifies Erin's ability to hear by using which test?
  - An MRI for the most definitive testing
  - Audioscopy
  - A CT scan of the head
  - Electronystagmography (ENG)
- Erin's ability to hear better after her physical examination is directly related to which action?
  - The removal of the embedded wax from the ear canal
  - The examination with an otoscope
  - It is not clear why Erin is hearing more clearly.
  - The stretching of the ear canal while an otoscopic examination is completed

## CHAPTER SUMMARY

The ear and its many structures provide the sounds of life. Without the proper functioning of each of the structures within the ear, hearing is compromised. The auditory system includes the outer ear, middle ear, and inner ear. Sound is transmitted by air and bone conduction, and transmission by air is part of the sequence required for successful sound interpretation. Evaluation of auditory system function includes a detailed history, physical examination, hearing ability, bone conduction, as well as CT and MRI scans.

Preventive care is essential when occupational hazards and everyday noise levels pose a risk to well-being. Seeking care from a qualified healthcare provider for routine examinations is also crucial, as well as when unexpected events arise that threaten hearing health. Age-related changes to hearing develop secondary to stiffening of the cilia and tympanic membrane, and dryness of cerumen. Presbycusis may also develop and is associated with a type of hearing loss that is caused by nerve degeneration in the inner ear or auditory nerve.

## Coordinating Care for Patients With Hearing Disorders

*Kelley Miller Wilson*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of hearing disorders
2. Explaining the pathophysiological process of hearing disorders
3. Correlating clinical manifestations to pathophysiological processes of
  - a. Hearing loss
  - b. External otitis
  - c. Otitis media
  - d. Tinnitus
  - e. Vertigo
  - f. Ménière's disease
4. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the ear
5. Discussing the medical management of selected disorders of the ear
6. Describing complications associated with selected disorders of the ear
7. Developing a comprehensive plan of nursing care for patients with ear disorders
8. Developing a teaching plan for a patient with an ear disorder

### CONCEPTS

- Assessment
- Comfort
- Infection
- Medication
- Perioperative
- Promoting Health
- Sensory Perception

### ESSENTIAL TERMS

**Audiogram**  
**Cholesteatoma**  
**Cochlear implant**  
**Endolymphatic fluid**  
**External otitis**  
**Labyrinthitis**  
**Mastoiditis**  
**Ménière's disease**  
**Myringotomy**  
**Otitis media**  
**Otosclerosis**  
**Ototoxic**  
**Petrositis**  
**Presbycusis**  
**Tinnitus**  
**Tympanometry**  
**Tympanoplasty**  
**Vertigo**

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Margie Newsome, 56 years old, has been experiencing dizziness, nausea, and right-sided hearing loss intermittently for several hours every 2 to 3 days for the past month. Margie takes no medications on a routine basis and has no significant past medical or surgical history, although she does suffer from severe seasonal allergies in the spring. Margie's mother has a past medical history of Ménière's disease, and she wonders if there could be a connection with her symptoms. She plans to see her provider later this week to discuss her symptoms because these occurrences are becoming more frequent...

## INTRODUCTION

Nurses in many different settings manage patients and families with alterations in the auditory system, and because this may impact communication, it is important to understand the function of this important sense. Disturbances in the auditory system also impact balance and equilibrium. Loss of hearing and balance poses safety risks and socialization problems and understanding causes and treatments of these disorders allows the nurse to provide patient-centered care.

## HEARING LOSS

Many aspects of daily life are affected by the ability to hear, and hearing loss affects not only health but also the overall quality of life. Gradual hearing loss that occurs with advancing age is known as **presbycusis**, a condition that often develops while individuals age. Hearing loss is not expected in younger patients and is an indication of pathology.

### Epidemiology

Hearing disorders, although more common with advancing age (usually older than age 60 years), can occur at any time. Several factors are associated with placing a person at higher risk for developing hearing loss:

- Aging (risk increases while age increases)
- Heredity (see Genetic Connections)
- Occupational noises (exposure to loud noises on a regular basis for occupational reasons)
- Recreational noises (exposure to loud noises on a regular basis such as loud music and fireworks)
- Exposure to certain medications
- Illnesses including autoimmune disorders
- Congenital abnormalities

According to the National Institutes of Health, it is estimated that one-third of Americans between the ages of 65 and 75 years have some degree of hearing loss. Hearing loss is noted to be more common in men than in women and is noted to affect nearly half of adults older than 75 years. Box 48.1 summarizes findings from the National Health and Nutrition Examination Survey (NHANES) regarding the prevalence of hearing loss in the United States. Although hearing loss is clearly associated with age and a major health concern in older adults, a decline in hearing loss in adults 20 to 69 years of age was noted in a 2016 NHANES report.

## Genetic Connections

### Congenital Hearing Loss

Genetic factors are the etiology for more than half of all cases of congenital hearing loss, and most often are either autosomal recessive (both parents carry the recessive gene) or autosomal dominant (one parent has the abnormal gene for hearing loss).

## Pathophysiology

In a normally functioning ear, three parts of the ear work in harmony to allow hearing and processing of sound. Sound is gathered by the pinna, and the waves of sound enter the ear by traveling through the auditory canal until they reach the tympanic membrane. The sound waves set up vibrations in the eardrum, thereby causing the middle ear structures to move back and forth. The cochlea then receives the sound vibrations and, finally, the sound stimulus travels to the auditory nerve and the cerebral cortex.

Hearing loss is categorized as conductive, sensorineural, or both, which is termed a *mixed loss*. Conductive loss is most commonly caused by a lesion in one of the main structures (the tympanic membrane, ossicles, inner ear) of the ear. A lesion present in one of these structures prevents

### Box 48.1 Prevalence of Hearing Loss in the United States

- Eighteen percent of U.S. adults were noted to have speech-frequency hearing loss.
- Men were noted to be at 5.5% higher risk for developing hearing loss than women.
- African Americans were 70% less likely than white subjects to develop hearing loss.
- Increased prevalence was noted among those with smoke exposure or noise exposure, and those with cardiovascular risks.

Data from Centers for Disease Control and Prevention and National Center for Health Statistics. National Health and Nutrition Examination Survey. Hyattsville, MD: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention.

sound from being conducted to the inner ear. Sensorineural hearing loss is the result of a lesion present in either the inner ear (sensory) or the eighth cranial nerve (CN VIII; neural). Sensory hearing loss is sometimes reversible, whereas a neural hearing loss is permanent, and determining the etiology of hearing loss is essential in guiding proper treatment. Neural losses can be life threatening because they often are related to a brain tumor. Mixed loss is a combination of conductive and sensorineural loss involving both the middle and inner ear. This type of hearing loss may be caused by severe head trauma, chronic infection, or a genetic disorder. Table 48.1 describes the common pathologies, manifestations, and types of hearing loss.

Certain medications are known to have the potential to cause damage to some of the sensitive structures of the ear and are said to be **ototoxic**. Common medications with known ototoxic properties include but are not limited to:

- Vancomycin (Vancocin)
- Aminoglycosides (such as gentamicin [Garamycin] and tobramycin [Tobrex])
- Cis-platinum (Cisplatin)
- Acetylsalicylic acid (aspirin)—most common with chronic use or overuse
- Furosemide (Lasix)
- Quinine (Qualaquin)

### Clinical Manifestations

Patients with hearing loss begin to exhibit clinical manifestations that provide clues to family, friends, and coworkers that hearing loss is becoming more pronounced. Some of

these manifestations of increasing difficulty in hearing include:

1. Turning up the volume on electronics such as televisions and radios
2. Frequently asking others to repeat conversations
3. Withdrawal from conversations
4. Avoiding social situations in which the patient was once an active participant
5. Disturbance in the patient's own quality of speech
6. Intermittently fighting with spouse or family members over hearing-related issues

## Management

### Medical Management

#### Diagnosis

Medical management of hearing loss centers on history taking, otoscopic evaluation, and diagnostic testing to determine an accurate diagnosis.

History taking includes assessing onset (gradual or sudden) and duration of clinical manifestations, bilateral versus unilateral loss, history of recent trauma, history of recent infections, and medication history and exploring all past medical/surgical histories. The history needs to focus on any issues in childhood such as delays in talking or difficulty with academics at school because these are associated with hearing loss.

Otoscopic examinations are used to verify the presence and patency of the structures of the external ear as well as portions of the middle ear. The examination includes

**Table 48.1** Types of Hearing Loss

Pathology	Clinical Manifestations	Type of Hearing Loss
<b>Obstruction (foreign body, cerumen, external otitis)</b>	Pain, feeling as if ear is “plugged” or has something in it	Conductive
<b>Otitis media</b>	Fluctuating hearing loss, pain, pressure feeling in ear, fever	Conductive
<b>Ear trauma</b>	Pain, bloody drainage, visible blood on otoscopic examination	Conductive
<b>Tumors</b>	Unilateral hearing loss, visible lesion on examination and/or scan	Conductive
<b>Genetic disorders</b>	Positive family history, other genetic abnormalities often present, inability to hear normal sounds	Sensory
<b>Noise exposure</b>	Inability to hear	Sensory
<b>Presbycusis</b>	Progressive hearing loss bilaterally in the presence of a normal neurological examination	Sensory
<b>Tumor of the cerebellopontine angle (acoustic neuromas, meningiomas)</b>	Unilateral hearing loss, tinnitus, facial or trigeminal nerve deficits on occasion with examination.	Neural loss
<b>Demyelinating disease (such as multiple sclerosis)</b>	Unilateral loss with clinical manifestations that occur intermittently	Neural loss

assessment for cerumen (wax) impaction; foreign body presence; and acute/chronic infection as well as structural abnormalities.

*Pure-tone threshold* is an audiological test conducted with air and bone conduction assessment to quantify hearing loss. To complete this test, the patient wears headphones and multiple different frequencies are delivered. An audiometer is used to deliver specific frequencies known as pure sounds at different intensities. Test results are plotted on graphs called **audiograms**.

*Speech reception threshold* is used to measure the intensity at which speech is recognized by a patient. This test is used to determine the softest level at which the patient is able to recognize speech. Speech discrimination helps to determine the patient's type of hearing loss (conductive, sensorineural, or mixed). This test is done to determine how well the patient hears and understands speech when the volume is set at the patient's most comfortable level of hearing.

A variety of diagnostic tests are used to determine the etiology and type of hearing loss. **Tympanometry** is a test that measures the impedance of the middle ear to the acoustic energy. Commonly used to screen children for the presence of middle ear fluid, this test does not rely on active patient participation. The *acoustic reflex* is a test that notes the response of the stapedius muscle to the presence of loud sound. Computed tomography (CT) scan or magnetic resonance imaging (MRI) scans may also be considered in conjunction with standard hearing testing if bony tumors or bony erosion are suspected. Magnetic resonance imaging angiography is usually conducted if vascular abnormalities are suspected. Standard MRI with gadolinium enhancement is usually performed with patients who present with an abnormal neurological examination and/or when a cerebellopontine-angle lesion is suspected.

## Treatment

Treatment of hearing loss is largely dependent on the cause. Infections require antibiotic therapy, and chronic infection may require fluid drainage from the middle ear by **myringotomy** (surgical incision into the eardrum, usually to relieve pressure or drain fluid) and placement of tympanostomy tubes (Fig. 48.1) to ensure continued drainage. Lesions and growths (tumors) may also need to be removed. Autoimmune

**FIGURE 48.1** Tympanostomy tube. Tympanostomy tubes allow continuous drainage from the middle ear in patients with chronic ear infections.

disorders are usually treated with corticosteroids to improve hearing function. Patients taking known ototoxic medications are most often advised to discontinue if a less toxic substitute is available.

Hearing aids (Fig. 48.2) may be prescribed to amplify the sound to help patients improve their hearing and facilitate communication capacity. Different types of hearing aids are available to help magnify the sound and require specific fine-tuning with a licensed audiologist or ear care specialist.

Based on the etiology of the hearing loss, surgical procedures may be performed. If hearing loss is secondary to damage to the middle ear, then **tympanoplasty** (surgical reconstruction of the eardrum) may be indicated. There are two types of tympanoplasty, including reconstruction of the eardrum (myringoplasty) and replacement of the ossicles (ossiculoplasty). Before either procedure, the patient must be free of ear infection.

**Cochlear implants** (Fig. 48.3) are considered for severely hearing impaired or profoundly deaf patients. This treatment involves implanting a small electronic device that is used to provide a sense of sound. The implant includes an external portion that sits behind the ear and an additional portion that is surgically placed under the skin. The implant has several different very sensitive parts that include:

- Microphone: retrieves the sound from the environment
- Speech processor: selects and arranges sounds retrieved from the microphone
- Transmitter and receiver stimulator: receive signals from the speech processor and convert them into electrical impulses
- Electrode array: group of electrodes that collects the impulses from the stimulator and sends them to different regions of the auditory nerve

The cochlear implant does not restore normal hearing but does give profoundly hearing-impaired patients representation of sounds in the environments so that they may understand speech.

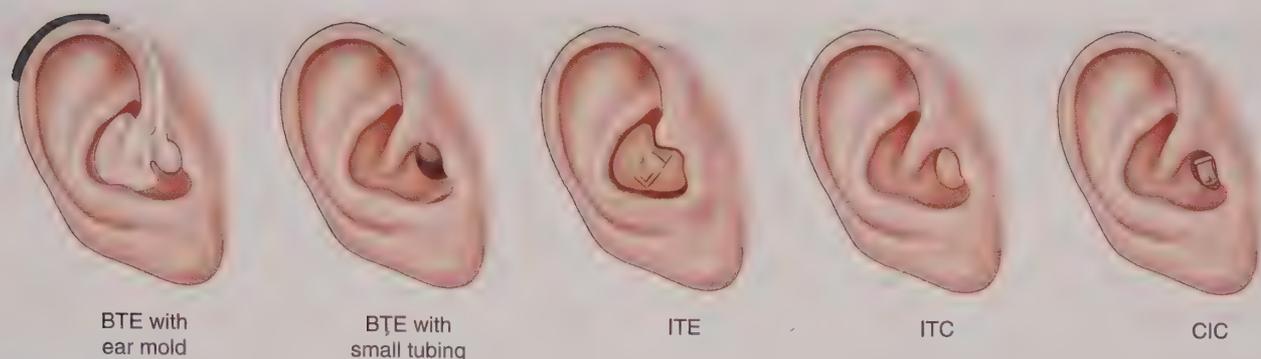

## Nursing Management

### Assessment and Analysis

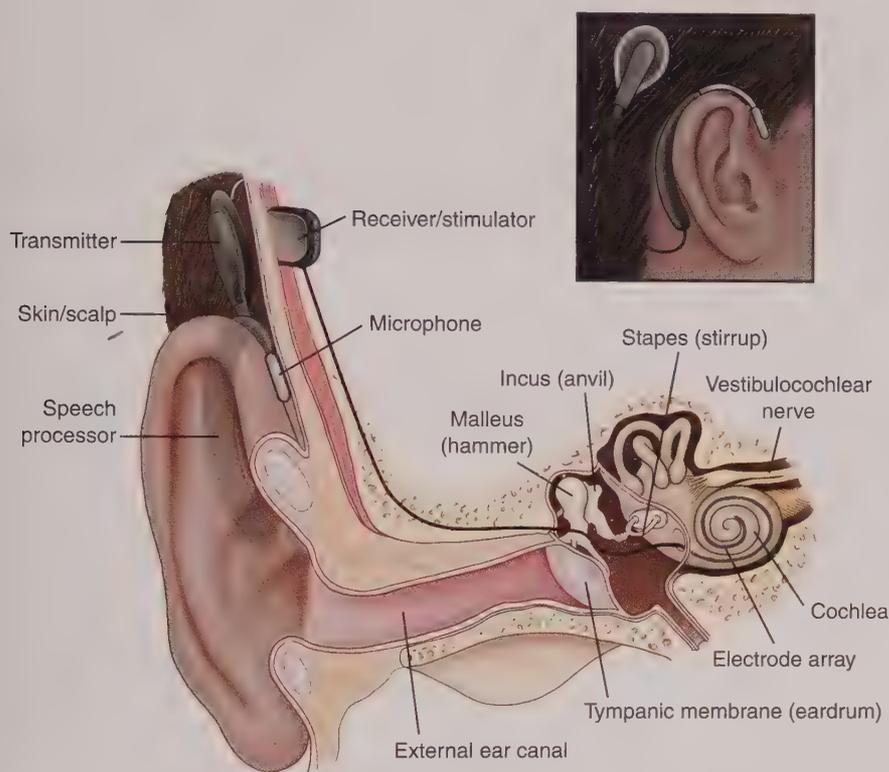

The clinical presentation of the patient with hearing loss may be insidious in onset, and family or friends may be responsible for the patient seeking out an evaluation of his or her hearing. Clinical manifestations typically observed include:

- Inability to hear at normal tones
- Speaking in a louder tone than others
- Decreased social interactions

See Table 48.2 for an analysis of the clinical manifestations of hearing loss. Because of the increased incidence of hearing loss associated with aging, in providing care to older adults in an acute care setting, there are physical functioning and safety considerations (see Evidence-Based Practice).

**FIGURE 48.2** Types of hearing aids. Hearing aids may be in the ear, in the canal, or behind the ear, with or without tubing. BTE—Behind the ear with ear mold; BTE—Behind the ear with small tubing; ITE—In the ear; ITC—In the canal; CIC—Completely in the canal

**FIGURE 48.3** Cochlear implant. The cochlear implant does not restore normal hearing but does give profoundly hearing-impaired patients representation of sounds to facilitate their understanding of speech.

## Evidence-Based Practice

### Hearing Impairment and Mobility in Hospitalized Older Adults

Hearing loss is known to increase with advancing age. In older adults admitted to hospitals, this decreased sensory function impacts physical functioning. This study focused on factors from the International Classification of Functioning, Disability, and Health that impact mobility in hospitalized older adults. Based on a secondary analysis of 959 adults age 65 and older admitted to a hospital, findings revealed that hearing impairment,

along with other factors including longer lengths of hospital stay and younger age, were associated with mobility decline. Based on the findings of this study the authors recommend development of evidence-based risk determination tools for hospitalized older adults, as well as development of environmental and policy-based interventions to promote physical activity in the hospital.

Chase, J.A., Lozano, A., Hanlon, A. & Bowles, K.H. (2018). Identifying factors associated with mobility decline among hospitalized older adults. *Clinical Nursing Research*, 27(1), 81–104.

**Table 48.2 Assessment and Analysis: Hearing Loss**

Assessment Data	Analysis/Explanation
<b>Turning up volume on electronics</b>	Commonly seen in patients who are having difficulty with hearing; often one of the first signs that family members notice. While function of hearing structures decreases, compensation of external stimulus takes place in the form of volume adjustments to electronic items.
<b>Frequently asking others to repeat conversation</b>	A patient unable to hear or having trouble interpreting sounds often needs to ask others to repeat words on a regular basis. Decreasing or failing function of structures within the ear makes it necessary for conversations to be repeated. (This can be combined with failing eyesight in older adults that does not allow them to easily read lips.)
<b>Withdrawal from conversation</b>	Patients unable to hear may resort to withdrawing from conversations because they may find their inability to hear both frustrating and embarrassing.
<b>Avoiding social situations</b>	Patients may choose to withdraw from social situations because it is embarrassing and/or too much work to keep asking others to speak louder or repeat conversations.
<b>Disturbance in patient's own quality of speech may become apparent</b>	Speech may become altered because hearing is necessary to make speech sounds correctly. The inability to hear correct sounds makes speech generation inaccurate; patients are unable to hear their own word formations.
<b>Arguing with family members over hearing-related issues</b>	Family members may also become frustrated with the patient's inability to hear "normal" tones as they tire of repeating conversations or hearing electronics at elevated levels. Often, this is what finally drives the patient to seek medical evaluation.

### Nursing Diagnoses

- **Disturbed sensory perception:** auditory related to hearing loss as evidenced by head tilting when talking to others, frequently asking others to repeat spoken messages, and verbal report of inability to hear
- **Knowledge deficit** related to cause of hearing loss
- **Impaired social interaction** related to decreased ability to hear conversations as evidenced by decreased participation in social activities

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*No expected permanent changes in vital signs occur with hearing loss, although there might be a temporary increase in blood pressure and/or pulse when patients experience periods of frustration associated with decreased hearing ability.*
- Changes within the ear structures  
*Changes within the ear canal itself may reveal increased drying or drying of the cerumen. The hardened cerumen visible on examination may become impacted and cause some decrease in hearing.*
- Diagnostic testing results  
*Audiological testing such as assessing pure-tone thresholds, speech discrimination, tympanometry, and acoustic reflex are evaluated with unexplained hearing loss so that proper diagnosis is made.*
- Age-related considerations  
*Decrease in hearing ability is known to occur in patients approximately age 60 years; presbycusis is a decrease in the ability to hear that is associated with advancing age.*

#### ■ Actions

- Preoperative interventions including taking prescribed antibiotics and avoiding people with upper respiratory infections  
*Decreases the risk of postoperative ear infection*
- Position the patient flat, turned on the side with the operative side facing up after tympanoplasty  
*Decreases the chance of packing being displaced*
- Make appointment for hearing evaluation  
*Seeking evaluation by a provider with the ability to evaluate and test hearing is essential in providing an accurate diagnosis.*
- Increase fluid intake  
*In patients with dried cerumen impacting hearing, the increase in fluid intake may decrease the thickening of the ear wax.*

#### ■ Teaching

- Pre-/post-test instructions  
*Lack of compliance with pre-/post-testing instructions is often linked to inadequate teaching/instruction from the provider. Comprehensive instructions should be provided to the patient and family members before and after testing.*
- Preoperative teaching  
*There may be transient hearing loss immediately after surgery because of packing placed into the ear. Avoid forceful coughing because this places increased pressure on the middle ear.*
- Postoperative teaching  
*Keep the ear and dressing dry to decrease the risk of infection. All dressing changes are performed using sterile technique.*

- Use of technology

*Instructions to patients and family members for use of new technology items (hearing aids or other hearing devices) are essential to ensure daily use of items as well as the patient being able to receive maximum benefit from the item(s).*

- Noise protection

*Instructions for use of devices to help protect the ears from further injury are essential. Earplugs (or similar noise-blocking devices) are suggested to reduce the presence of loud noises. Use of earbuds or earphones for listening to music is discouraged because of loud sounds directly entering the ear canal in a concentrated form and having a direct effect on the sensitive structures of the inner ear; further hearing loss could then result.*

- Avoid using cotton swabs or other devices to remove ear wax

*Damage to tympanic membrane or pushing the ear wax deeper into the ear may be the results of attempts to manually remove cerumen with cotton swab or other sharp devices.*

- Follow-up care

*Instructions should be provided on expected follow-up care with the provider to ensure that routine evaluations by providers are completed, thereby lessening the possibility of continued undetected decline in hearing.*

### Evaluating Care Outcomes

The diagnosis of hearing loss is the first step in obtaining proper treatment. Patients with hearing loss should be fully evaluated by a provider with expertise in speech/hearing disorders to help determine the etiology of their hearing loss. Treatment is therefore based on examination and diagnostic testing results. In many cases, interventions implemented in the home and support offered from technology can help make the patient's hearing dramatically improve.

## EXTERNAL OTITIS

**External otitis** (Fig. 48.4) is a condition commonly referred to as “swimmer’s ear” because it is most often related to infectious organisms that are contracted through swimming.

This condition is hallmarked by an inflammation of the outer ear with extension into the ear canal. Inflammation of the skin of the ear canal is caused by either bacterial or fungal agents. External otitis can be acute or chronic, with acute more commonly being bacterial in origin and chronic more often being fungal.

### Epidemiology

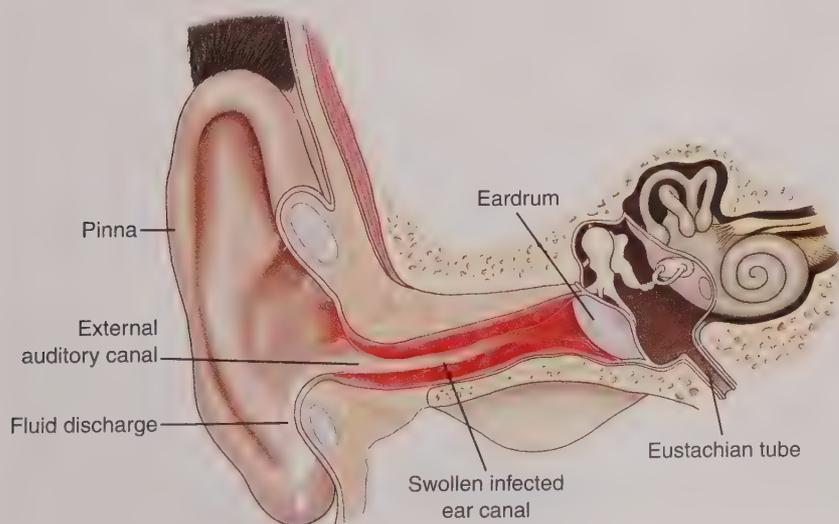

External otitis has several known factors that have been identified as high risk for developing this uncomfortable condition. The most common risk factors include:

- Recent history of trauma to the painful ear
- Warm temperature climates (water sports season is usually longer, increasing frequency)
- High-humidity climates
- Recent history of swimming
- Hearing aid use

Common in all parts of the world, external otitis occurs annually in four of every 1,000 persons. There is a marked increase in cases of external otitis noted in the summer months, with peaks noted in persons aged 7 to 12 years because this age group is most active with warm weather water sports. Ninety percent of cases are bacterial in nature, and 10% are noted to be resulting from fungal infections.

### Pathophysiology

The adult external auditory canal is approximately 2.5 cm in length and is lined with squamous epithelium. This canal functions to transmit sound to the middle ear as well as serving to protect the more proximal structures from foreign bodies. The canal is divided into three sections; the outer third of the canal is primarily cartilage and contains cerumen-producing apocrine glands. The inner two-thirds of the canal is bony in nature and covered with thin skin that is tightly adhered. This inner portion contains no

**FIGURE 48.4** External otitis (“swimmer’s ear”). External otitis is characterized by an inflammation of the outer ear with extension into the ear canal.

apocrine (wax-producing) glands or hair follicles. External otitis develops in swimmers as a result of excessive water exposure yielding a decrease in cerumen. The decrease in cerumen can lead to drying of the external auditory canal resulting in potential skin breakdown, providing an excellent entry port for bacterial or fungal infections. The most common offending bacteria include *Pseudomonas aeruginosa* (50%) and *Staphylococcus aureus* (23%). The most common source of fungal infections is *Aspergillus*, which accounts for 80% to 90% of fungal infections.

## Clinical Manifestations

Common clinical manifestations of external otitis include:

- Swelling visualized in and around the external ear
- External ear that is tender to touch
- Pain on movement or pressure to the outer auricle of the ear
- Visualized erythema and/or edema in the ear canal
- Scant clear drainage from the ear canal

## Management

### Medical Management

#### Diagnosis

History of presenting clinical presentation, recent activities, or recent trauma to the affected ear are important assessments for the provider to complete. Direct visualization of the external ear structures and otoscopic examination of the

internal structures are important and usually help to confirm a diagnosis of external otitis. Table 48.3 identifies the most commonly prescribed topical treatments for patients with this diagnosis.

### Treatment

The management of external otitis involves cleaning the ear canal, treating inflammation and infection, and managing pain. Typically managed by topical medications, rather than oral antibiotics, external otitis involves the skin of the ear canal. Fever and pain may be treated with acetaminophen or ibuprofen.

### Nursing Management

#### Assessment and Analysis

Assessment of the external ear provides the first clues as to the type of pathology present as well as the degree of infection involved. The assessment data in Table 48.4 provide a guide for evaluation. Clinical manifestations of otitis media include ear pain that may be exacerbated by movement of the outer ear, edema around the external ear, erythema in the ear canal, elevated temperature, and clear drainage from the ear.

#### Nursing Diagnoses

- **Pain** related to the infectious process of the external ear as evidenced by verbal report of pain on touch to the external ear, redness/swelling visualized in the external and internal ear canal, and scant amount of drainage exiting from the ear canal

**Table 48.3** Treatments for External Otitis

Common Topical Agents	Rationales
<b>2.0% Acetic acid (Vosol) may be ordered with or without steroids</b>	Effective for mild acute external otitis of bacterial or fungal nature. Apply every 4–6 hours; inexpensive and can sting or locally irritate tissues. This agent acidifies, making bacterial growth more difficult, and causes drying of moisture to further inhibit bacterial growth.
<b>2.75% Boric acid or 90% to 95% isopropyl alcohol</b>	Effective for mild acute external otitis of bacterial or fungal origin. Often used as a prophylaxis after swimming because alcohol commonly mixed with 50/50 2% acetic acid evaporates quickly, causing a drying effect in the ear canal. These solutions cause increased drying (evaporation) of moisture, and the acidity component helps to decrease bacterial growth.
<b>Aminoglycosides (such as tobramycin and gentamicin)</b>	Usually an otic preparation of gentamicin or tobramycin; is effective for acute bacterial infections of external otitis. Preparation is instilled every 6 hours and is minimally irritating. These potent broad-spectrum antibiotics inhibit bacterial growth.
<b>Neomycin, polymyxin B, hydrocortisone</b>	Effective for acute external otitis of bacterial nature; applied every 6 hours
<b>Fluoroquinolone with or without steroid</b>	Effective for acute external otitis; applied twice daily; only medication approved with tympanic membrane rupture
<b>Corticosteroids (such as prednisone)</b>	Treats underlying dermatitis/inflammation if present from bacterial invasion. Inflammatory response from bacteria may be significant and requires a decrease in inflammation to enhance healing.
<b>Tolnaftate (Tinactin) or clotrimazole (Lotrimin)</b>	Effective for acute or chronic external otitis that is fungal in nature

**Table 48.4** Assessment and Analysis: External Otitis

Assessment Data	Analysis/Explanation
<b>Swelling visualized in and around the external ear</b>	Swelling that is present in the external ear and is visualized is secondary to the inflammation caused by the presence of a bacterial or fungal infection.
<b>External ear that is tender to touch</b>	Inflammatory response created by bacteria or a fungus causes swelling and therefore increased pain on movement of the affected area.
<b>Pain on movement or pressure to the outer auricle of the ear</b>	This pain is secondary to the inflammatory response that is occurring, resulting in swelling and therefore pain on pressure to or movement of the affected area.
<b>Visualization of erythema and edema in the ear canal</b>	The inflammatory response set in motion secondary to the presence of bacteria or fungus causes the erythema/edematous reaction to occur.
<b>Scant drainage from the ear canal</b>	This drainage is secondary to the extra fluid present in the tissues secondary to the inflammation process.

- **Knowledge deficit** related to cause and treatment of external otitis
- **Risk for infection** related to the inflammatory process created by the presence of bacteria/fungi

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Elevations in temperature are sometimes seen in the presence of an ear infection. There may also be an increase in blood pressure and pulse with increased pain.*
- Edematous external ear  
*The outer ear (auricle) area can be erythemic and swollen; the appearance of the inner canal is often erythemic and edematous with clear drainage sometimes present.*
- Pain  
*The patient exhibits pain on movement of any part of the external ear or palpation of the ear canal secondary to bacterial or fungal organisms and the inflammatory response.*
- Culture and sensitivity of ear drainage  
*Culture and sensitivity by swab may be collected to identify the causative organism. Identification of the organism then allows the provider to select the best course of medical treatment.*
- Age  
*Adults and children are both affected by external otitis. Children may have a slightly higher incidence because they tend to be more active in water-related activities than adults.*

#### ■ Actions

- Pain relief measures  
*Pain relief is usually accomplished by over-the-counter (OTC) medications (such as acetaminophen or ibuprofen preparations).*
- Comfort measures  
*Dry warm heat may provide some comfort when applied to the ear directly.*

- Positioning  
*Having the patient in a sitting or semi-sitting position with the affected ear on a soft object such as a pillow may provide additional comfort.*

#### ■ Teaching

- Medications  
*Instructions for patients and families regarding antibiotic/antifungal eardrops are essential to proper healing. Table 48.5 provides additional instruction on eardrop instillation. Instructions regarding the completion of the entire medication course are imperative so that a reinfection does not occur. Over-the-counter pain medications also require information so that they are administered properly and the patient receives the most comfort.*
- Follow-up care  
*Instructions to patients or families regarding the necessary follow-up are necessary to ensure that complete and proper healing has taken place.*

### Evaluating Care Outcomes

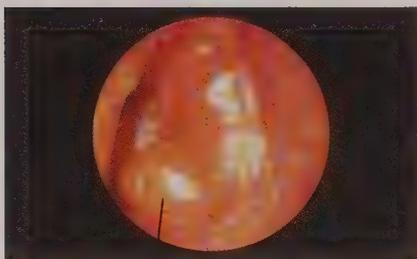

Patients generally have a very favorable response to the topical eardrops prescribed and the suggested OTC pain relief medications for the management of external otitis. Summer months yield an increase in cases of external otitis secondary to the increase in water sport activities. On occasion, a patient will present with a very difficult-to-treat infection that requires cultures and additional antibiotic or antifungal treatment.

### OTITIS MEDIA

**Otitis media** (Fig. 48.5) is a common disease process that causes an inflammation of the middle ear canal, most commonly by a bacterial source. This inflammation often leads to a buildup of fluid behind the eardrum, thus leading to bacterial growth and then infection. Otitis media affects adults but is most commonly seen in children because of the smaller and more flattened nature of the eustachian tube.

**Table 48.5 Eardrop Administration**

Procedure	Rationale
Wash hands and verify the medication ordered ( <i>Donning gloves after washing hands is preferred for the person instilling medication if they are available.</i> )	Washing hands prevents the accidental introduction of foreign substances into the ear canal. Verifying the medication name/dose/route and time ensures that proper medication and dosing are taking place.
Place bottle of eardrops in warm bowl of water for 3–5 minutes	Placing the eardrop medication bottle in warm water warms the medication to approximate body temperature. Warm eardrop preparations provide more comfort for the patient and prevent the possibility of the patient becoming nauseated.
Tilt the patient's head in the opposite direction of the ear that drops are to be instilled in	Instructing the patient to turn his or her head in the opposite direction ensures that drops are instilled into the canal and they do not just remain on the surface of the outer ear.
Pull the pinna up and back	Pulling the pinna up and back in adults straightens the ear canal and allows the medication to reach all aspects of it.
Instill the correct number of ordered drops of medication down the side of the ear canal	Instilling the medication down the side of the ear canal provides the most comfort for the patient.
Gently move head back and forth two or three times	This repetitive motion ensures that drops are well incorporated into the ear.
Insert a cotton ball into the ear canal	Insertion of a cotton ball into the ear canal serves as a barrier to prevent drops from leaving the canal.
Wash hands and put away supplies	Washing hands after installation of eardrops helps to remove any foreign substances that may have inadvertently gotten on hands (medication or infectious drainage).

Fluid and inflammation

**FIGURE 48.5** Otitis media. Otitis media is characterized by an inflammation of the middle ear, which often leads to a buildup of fluid behind the eardrum.

## Epidemiology

Although otitis media can affect anyone, the most commonly identified risk factors for developing the condition are:

- **Anatomical features:** The eustachian tube is flatter in children and other congenital features that can accentuate infection. This flattening of the eustachian tube prevents drainage and makes fluid in the ear more likely to become stagnant or to accumulate.
- **Presence of an upper respiratory infection:** Inflammation from this common illness can cause narrowing of passages in the ear, thereby predisposing the patient to fluid accumulation and infection.

- **History of seasonal allergies:** Inflammation that causes narrowing of passages in the ear tubes, increasing the chance of fluid accumulation and infection
- **Craniofacial abnormalities:** The presence of abnormal bone formations can cause narrowing or obstructions, thereby increasing the risk of infections.
- **Genetic predisposition:** Patients with family members with an identified genetic predisposition for otitis media are at greater risk for this disorder.
- **Smoking in the household:** Smoking can cause chronic inflammation to the airways, thereby increasing a person's risk for otitis media.

Adult-onset otitis media is often secondary to sinusitis, allergies, and being in the presence of cigarette smoke. Exact statistics for the prevalence of these infections are therefore difficult to obtain. An increase in the occurrence of otitis media is found in Native Americans, particularly those of Navajo and Eskimo descent. It is thought that this increase may be caused by an anatomical difference in the ear structure, most notably the eustachian tube, in these races.

## Pathophysiology

Acute otitis media is often seen secondary to a viral upper respiratory infection. Under normal circumstances, the middle-ear mucosa absorbs air in the middle ear. In otitis media, the inflammation and secretions can cause an obstruction of the eustachian tube. If air is unable to infiltrate the

eustachian tube because of an obstruction, a negative pressure is created that then pulls interstitial fluid into the eustachian tube, creating a serous effusion. The serous effusion provides the perfect medium for microbial growth in the middle ear. Rapid growth of the bacteria becomes overwhelming and yields a middle ear infection otherwise known as otitis media.

## Clinical Manifestations

The clinical manifestations of otitis media can be sudden or they may evolve over a couple of days. Some of the most common clinical manifestations are:

- Ear pain
- Tugging or pulling at ears (children)
- Trouble sleeping or lying flat
- Fever (can be quite pronounced in children)
- Fluid or blood draining from the ears (especially with tympanic membrane rupture)
- Hearing loss
- Infants/children often refuse to feed (sucking causes increased ear pain)

## Management

### Medical Management

#### Diagnosis

Comprehensive history taking and otoscopic evaluation are essential in determining the origin of clinical manifestations seen in the patient presentation. A comprehensive history includes past medical/surgical history as well as recent history, including exposures to respiratory illnesses. Assessing the patient's home/work environment may also yield clues as to the patient's current state of health. Tympanometry may also be completed by the provider to evaluate for the presence of fluid in the middle ear.

#### Treatment

On diagnosis of otitis media, oral antimicrobial therapy is the most effective treatment, particularly when effusions are present. The most commonly prescribed medications are noted in Table 48.6. Antimicrobial ear drops are also prescribed with tympanic rupture. Other therapies that are suggested include medications such as analgesics and antipyretics to help with pain and fevers. Decongestants and antihistamines may relieve some of the nasal manifestations of upper respiratory infections; their value in treating otitis media is unclear.

## Connection Check 48.1

The nurse correlates which complication with a diagnosis of otitis media?

- Labyrinthitis
- Mastoiditis
- Tinnitus
- Bilateral hearing loss with inability to hear high-pitch tones

**Table 48.6 Antibiotics Used With Otitis Media**

Oral Antibiotic Prescribed	Commonly Prescribed Adult Dosage
<i>Amoxicillin trihydrate (Amoxil)</i>	250–500 mg every 8 hours
<i>Amoxicillin and clavulanate potassium (Augmentin)</i>	250–500 mg amoxicillin with 62.5–125 mg clavulanate every 8 hours
<i>Trimethoprim (TMP)/sulfamethoxazole (SMZ) (Bactrim, Bactrim DS, Septra, Septra DS)</i>	160 mg TMP with 800 mg SMZ twice daily
<i>Cefixime (Suprax)</i>	400 mg daily or in divided doses twice daily
<i>Cefuroxime axetil (Ceftin)</i>	250–500 mg every 12 hours
<i>Cefprozil (Cefzil)</i>	250–500 mg every 12 hours
<i>Azithromycin (Zithromax)</i>	500 mg day 1; then 250 mg on days 2–5

### Surgical Management

Surgical treatment for otitis media is usually considered for patients with chronic otitis or frequent reinfections. Tympanocentesis and myringotomy are the surgical interventions most often performed. Tympanocentesis is a diagnostic procedure that provides access for the provider to the middle-ear effusions for culture and evaluation. Myringotomy is a surgical intervention in which a tiny slit is created in the eardrum to relieve pressure caused by fluid accumulation. In many cases, a small plastic tube called a *tympanostomy tube* is inserted into the slit in the eardrum, where it remains for a period of time. Eventually in most cases, the tubes are discarded by the ear and exit the ear through the ear canal. Loss of the ear tubes before the evolution of anatomical changes (in children, the change in position of the eustachian tube) may require an additional surgery to replace the expelled tube.

### Complications

The most common complications seen with otitis media include:

- *Chronic suppurative otitis media* occurs when fluid/pressure builds up and a perforated tympanic membrane occurs with persistent drainage from the middle ear.
- *Facial nerve (CN VII) paralysis* reflects the spread of infection beyond the pneumatized (air-filled) area of the temporal bone and associated mucosa and thereby results in paralysis of this nerve.
- **Labyrinthitis** is an inflammatory disorder of the inner ear labyrinth that occurs as a complication of otitis media, which results in a disturbance in balance and hearing. This complication may be unilateral or bilateral.

Labyrinthitis often results from a benign overgrowth of squamous cell epithelium called a **cholesteatoma** from the middle ear directly into the semicircular canal.

- *Labyrinthine fistula* occurs when an abnormal communication develops between the inner ear and the middle ear or mastoid.
- **Mastoiditis** is the spread of infection to the mastoid bone that causes an inflammation of the mastoid air cells of the temporal bone.
- **Petrositis** develops when there is inflammation of the temporal bone that penetrates deep into the ear.
- *Meningitis* is an inflammation of the meninges which is the outer covering of the brain. Bacteria entering the meninges via the nasopharynx or respiratory tract leads to this potentially life-threatening complication.

### Connection Check 48.2

The nurse recognizes which diagnostic test as the best method to confirm the presence of fluid in the ear that increases the patient's risk for developing otitis media?

- Pure tone audiometry
- Speech audiometry
- Tympanometry
- Acoustic reflex

### Nursing Management

#### Assessment and Analysis

Otitis media presents with many common clinical manifestations that are directly related to pathophysiological changes in the ear. The provider may then use additional assessments to confirm otitis media (Table 48.7).

### Nursing Diagnoses

- **Pain** related to inflammation and pressure on the tympanic membrane of the ear as evidenced by verbal reports of pain and nonverbal cues such as guarding or grimacing
- **Knowledge deficit** related to causes and management of otitis media
- **Disturbed sensory perception: auditory** related to scarring and damage secondary to recurrent infections

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Fever is often present with otitis media secondary to the presence of bacteria and the increase in the body's metabolism (immune system function) in an attempt to overcome the invasion. Pulse and respiratory rate may also be elevated secondary to the body's rise in temperature, as well in response to pain.*
- Internal ear  
*On otoscopic examination of the ear, fluid may be detected, and the normally pearly grey internal ear is now erythemic and/or edematous. (Examination may be completed with the pneumatic tube placed on the otoscope to assess for movement of the tympanic membrane.)*
- Tympanometry results  
*This test is often used by the provider to assess for the presence of fluid in the middle ear. The machine notes pressure changes within the ear and documents them on a graph for the provider to evaluate.*
- Age-related considerations  
*Otitis media can occur at any age but is known to be more prevalent in children secondary to the position of the eustachian tube being more flat. Children and adults with structural deformities of the ear may also be at increased risk.*

**Table 48.7 Assessment and Analysis: Otitis Media**

Assessment Data	Analysis/Explanation
<b>Ear pain</b>	Pain is often one of the first clinical manifestations and is due to the presence of fluid behind the tympanic membrane (causing pressure buildup) and the presence of bacteria, which is creating an inflammatory response.
<b>Difficulty sleeping or lying flat</b>	Lying in a flat position causes an increase in pressure on the tympanic membrane (in cases where fluid is present), and this increased pressure causes an increase in pain.
<b>Fever</b>	The increase in the inflammatory response and the body's own immune response cause an increase in body temperature.
<b>Fluid or blood draining from the ear canal</b>	This is a common clinical manifestation observed when the tympanic membrane has ruptured; infectious fluid and blood are seen exiting through the ear canal.
<b>Hearing loss</b>	Hearing loss can occur with repeated insults to the ear or with a very severe infection that has damaged one of the major structures of the middle ear.

### ■ Actions

- Administer prescribed medications  
*Commonly prescribed medications are listed in Table 48.7. Medication therapy focuses on management of infection, pain, and pressure.*
- Position of comfort  
*Assisting the patient to a sitting or semisitting position helps to keep increased pressure off the tympanic membrane and results in a decrease in pain for the patient.*
- Pain/fever  
*Over-the-counter pain medications are often advised to help increase patient comfort from pain or fever. Common OTC medications for pain/fever include acetaminophen (Tylenol) and ibuprofen (Motrin).*

### ■ Teaching

- Antibiotic therapy  
*It is essential that patients understand to complete all prescribed oral medication as ordered and not to stop when “feeling better.” Incomplete courses of medication put patients at risk for a reinfection or a resistant infection called a “super infection.”*
- Medication instructions  
*Patients are to be given instructions about OTC medications for pain and discomfort to ensure proper dosage and time intervals*
- Avoid getting water into the ear  
*Getting water into the ear can exacerbate the risk of infection and increase pressure and pain*
- Follow-up care  
*Patients need to be given specific instructions regarding follow-up care with the provider. Follow-up is key to determining the resolution of the infection and to assess for any possible complications from the infectious process.*

**Safety Alert** The reoccurrence of otitis media is increased if the patient does not complete the full course of antibiotic therapy. After the antibiotics are completed, follow up with the healthcare provider is important to verify absence of infection. Pain and pressure are exacerbated with the patient in a flat position; elevating the head of bed facilitates drainage and decreases pain.

### Evaluating Care Outcomes

Otitis media can be very painful for patients, but use of antibiotics, pain medication, positioning, and provider follow-up usually provide curative results within a relatively short period of time. Patients' and family members' ability to follow instructions for treatment provide the best results in the quickest amount of time. Additionally, teaching to minimize risk factors of reoccurrence of otitis media facilitates positive patient outcomes.

### Connection Check 48.3

The medical management of the patient with otitis media includes which priority interventions?

- Administration of oral antibiotics
- Administration of steroids
- Use of anesthetizing eardrops such as tetracaine
- Administration of decongestants to prevent eardrum rupture

### Connection Check 48.4

The nurse recognizes that which priority assessments are included in the evaluation of a patient with a hearing disorder? (Select all that apply.)

- CN III assessment
- CN VII assessment
- Complete and comprehensive history
- Otoscopic examination
- Diagnostic audiogram

## TINNITUS

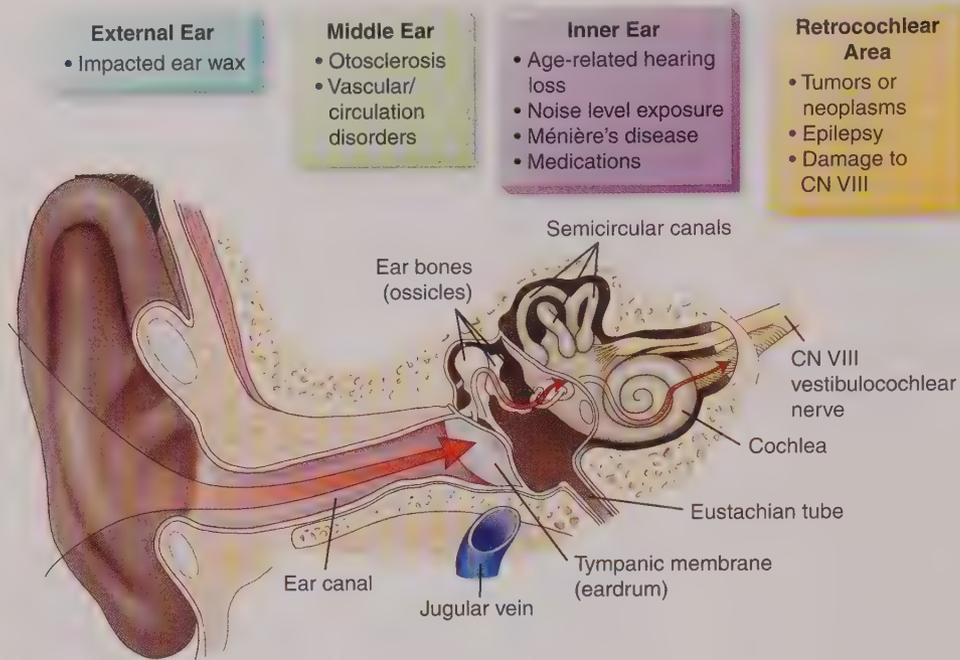

**Tinnitus** (Fig. 48.6) is most commonly described as a noise or ringing in the ears and is a relatively common affliction that is often a manifestation of an underlying disorder. Common causes include age-related hearing loss, ear injury, or circulatory system disorders. The clinical manifestations are often annoying and make it difficult to cope with the recurrent ringing or noise in the ears.

There are two types of tinnitus: subjective and objective. Subjective tinnitus is defined as sounds that are heard only by the patient and is the most common form. The cause is thought to be secondary dysfunction of the middle or inner ear or a dysfunction of the vestibulocochlear nerve (CN VIII). Objective tinnitus is defined as sounds that the provider may actually hear on examination of the patient. The cause is usually secondary to muscle contractions, blood vessel bruit, or inner-ear bone conduction disturbance.

### Epidemiology

Certain known risk factors have been identified as associated with the development of tinnitus and include:

- **Advanced age:** Hearing loss that occurs at approximately age 60 years can cause tinnitus.
- **Exposure to loud noises:** Common loud noises that can affect a patient's hearing include construction equipment, portable music devices with earbuds, and firearms. Short-term exposure to loud sounds, such as attending a loud music concert with resulting tinnitus, usually resolves in a matter of hours. Long-term exposure tends to cause permanent tinnitus.

**FIGURE 48.6** Causes associated with tinnitus. The pathophysiology of tinnitus can be associated with structural changes in the auditory system

- **Earwax blockage:** Obstruction of the eardrum can induce pressure and hearing loss with development of tinnitus.
- **Genetics:** **Otosclerosis**, or stiffening of the middle ear bones, can cause tinnitus, and this etiology is often seen within families.
- **Medications:** Many prescription and OTC medications increase the risk of tinnitus, including salicylates, NSAIDs, and selected antihypertensive, antidepressant, and chemotherapeutic agents. The relationship between these medications and the development of tinnitus is thought to be cochlear changes.

**Safety Alert** Tinnitus is associated with salicylate toxicity which is the reason patients are instructed to follow dosing directions with these medications. Even with normal doses of these medications, tinnitus has been reported in some patients.

### Connection Check 48.5

The nurse recognizes which risk factors for the development of tinnitus?

- Overuse of medications containing salicylate
- Family history of chronic respiratory infections
- Involvement in water sports activities
- History of migraine headaches

A marked increase of tinnitus is observed in both sexes at approximately the age of 40 years and peaks again between the ages of 65 and 79 years. A decline in clinical manifestations usually begins around age 80 years. Overall, males have a

slightly higher incidence than females, but it is thought this might be secondary to occupational noises that are present in predominantly male-oriented occupations. Nearly 36 million Americans have constant tinnitus, and nearly half of the normal population has suffered from intermittent tinnitus.

### Pathophysiology

Because tinnitus is a clinical manifestation and not a disease process, its pathophysiology may be secondary to many different disorders. Tinnitus can be caused by disorders of the outer, middle, or inner ear. Frequently, tinnitus occurs because there is a disruption of the background noise that is always present, making the body more aware of the sounds present within the ear itself that are part of normal body function. Table 48.8 describes some of the common pathologic causes associated with tinnitus.

### Clinical Manifestations

The most common bothersome sensations of sound described by patients, when no sound is actually present, include ringing, buzzing, roaring, clicking, whistling, and hissing sounds in the ear. These sounds may be present consistently or intermittently.

### Management

#### Medical Management

#### Diagnosis

Because tinnitus is defined as a clinical manifestation and not a disease, it is imperative that the healthcare provider try to discover the underlying cause of the clinical presentation. Determining the underlying cause leads to the most effective treatment for the patient. Obtaining a comprehensive

**Table 48.8 Etiology of Tinnitus**

Etiology	Explanation
<b>Ménière's disease</b>	Abnormal (usually increased) inner ear fluid, pressure, or composition can result in tinnitus.
<b>Stress and depression</b>	Tinnitus often worsens with increased states of stress or depression, which is thought to be secondary to vasoconstriction and increased adrenaline secondary to stress.
<b>Temporomandibular joint (TMJ) dysfunction</b>	TMJ is considered a somatic tinnitus and is thought to be caused by the sensory input from the jaw that interacts with the hearing pathways.
<b>Head/Neck injuries</b>	Neurological damage from head/neck injuries can affect the inner ear or cranial nerves, thus yielding tinnitus.
<b>Acoustic neuroma</b>	Benign tumor that develops on cranial nerve VIII, usually unilaterally, that can result in tinnitus
<b>Head/Neck tumors</b>	Tumor pressing on vessels in the head and neck that can cause a tinnitus sensation
<b>Atherosclerosis</b>	Buildup of cholesterol deposits may cause vessels close to the middle ear to lose some elasticity making flow more turbulent, therefore creating tinnitus.
<b>Elevated blood pressure</b>	Elevated blood pressure and factors contributing to elevated blood pressure, such as stress, alcohol consumption, and caffeine, make tinnitus more noticeable.
<b>Medications</b>	Certain antibiotics, cancer chemotherapies, diuretics, quinine, and salicylates are all well-known medications that can cause tinnitus to occur.
<b>Vitamin B<sub>12</sub> deficiencies</b>	A deficiency in this vitamin is known to cause the clinical manifestations of tinnitus as well; it is thought to be secondary to microvascular compression.

medical and surgical history is an important starting point and includes assessment for the following findings:

- Impacted earwax
- Otosclerosis
- Vascular problems such as circulation disorders
- Ménière's disease
- Medication list from patient
- Noise level exposures
- Damage to CN VIII from trauma or previous surgical procedure
- Presence of tumors
- Epilepsy or history of seizure disorders

### Treatment

The healthcare provider often prescribes medications aimed at reducing the clinical manifestation and not as a curative treatment. The medications most frequently prescribed for tinnitus include:

- Alprazolam (Niravam, Xanax)
- Anticonvulsant medications (phenytoin, carbamazepine)
- Antihistamines (diphenhydramine)
- Acamprosate (Campral)
- Niacin (vitamin B complex)
- Gabapentin (Neurontin)
- Tricyclic antidepressants (nortriptyline; usually reserved for the more severe cases)

Treatment also includes identifying potential triggers for tinnitus in order to minimize or avoid exposure. New research points to possible sound therapy with or without counselling as possible treatments for tinnitus.

### Nursing Management

#### Assessment and Analysis

Nursing management of tinnitus focuses on the careful ability of the provider to assess the clinical manifestations, as well as the present and past medical/surgical history. Additionally, correlating the assessment data with the underlying pathophysiologic changes facilitates a more comprehensive approach to the management of tinnitus (Table 48.9).

#### Nursing Diagnoses

- **Disturbed sensory perception: auditory** related to dysfunction of the ear or neurological system as evidenced by ringing, buzzing, or other abnormal sound sensations in the ear
- **Anxiety** related to abnormal sounds present in the ears

#### Nursing Interventions

##### Assessments

- Vital signs  
*There is no significant effect of tinnitus on vital signs other than increased anxiety from the clinical manifestations, which may cause an increase in blood pressure, pulse, or respirations.*
- Physical assessment  
*Changes in physical condition are dependent on whether there is an identifiable cause of the tinnitus. The presence of brain tumors may yield very noticeable neurological assessment changes, whereas medication-induced tinnitus yields no detectable changes at all in assessment.*
- Character of tinnitus sounds  
*Based on the etiology, the sounds associated with tinnitus are different. For example, with atherosclerosis, the buildup of*

**Table 48.9 Assessment and Analysis: Tinnitus**

Assessment Data	Analysis/Explanation
<b>Impacted earwax</b>	Earwax that is impacted in the ear canal can cause a disturbance in air conduction and pressure within the ear and therefore cause tinnitus to occur.
<b>Otosclerosis</b>	This condition, which relates to abnormal bone growth in the middle ear, can create conduction disturbances that lead to tinnitus.
<b>Vascular/circulation disorders</b>	Abnormal or disturbances in circulation flow can create sound similar to a bruit, resulting in a tinnitus sound.
<b>Ménière's disease</b>	Disturbance in the canals located within the inner ear can create these abnormal tinnitus sounds.
<b>Medications (such as salicylates or those containing salicylates)</b>	Medications can cause tinnitus sounds to occur; some occur with prescribed usage, and some occur with overuse.
<b>Noise levels</b>	High noise levels can cause short-term tinnitus to occur (such as after a loud concert), or it can be long term with repetitive daily exposure to loud noise (such as construction equipment or fireworks). Tiny hairs lining the ear canal are often damaged from these loud noises and cause the tinnitus sounds to occur.
<b>Cranial nerve VIII damage</b>	Damage to the vestibulocochlear nerve from trauma, tumor, illness, or a previous surgical procedure can cause the ringing or buzzing sounds of tinnitus to occur.
<b>Presence of tumors or neoplasms</b>	Any abnormal growth can create an obstruction (large or small) and generate abnormal sounds to occur in the ear, thus yielding tinnitus.

*cholesterol deposits may cause vessels close to the middle ear to lose some elasticity making flow more turbulent and creating tinnitus, while with CN VIII tumors, the pressure on the nerve causes the abnormal sounds.*

#### • Diagnostic results

*An MRI/CT scan may be ordered in an attempt to locate a cause for the clinical manifestations of tinnitus. Careful history taking is one of the most important clues in diagnosing tinnitus.*

#### • Age-related considerations

*Tinnitus clinical manifestations tend to occur with advancing age; 40 years is when clinical manifestations often begin to occur, peaking at ages 65 to 79.*

### ■ Actions

- Administer medications as prescribed  
*Medications have specific rationales and indications in the treatment of tinnitus. Most are used to decrease the problem as opposed to curing it.*
- Discontinuation of possible tinnitus-causing medications  
*Discontinue medications that have tinnitus as a possible side effect if another suitable substitute is available. This may require consultation with the healthcare provider.*
- Discontinuation of portable music devices that require the use of earbuds or earphones  
*Earbuds/earphones are known to aggravate patients who have tinnitus; discontinuing the use of these items may cause some improvement in tinnitus clinical manifestations*

### ■ Teaching

- Diary of clinical manifestations  
*Instructing patients to keep a diary of clinical manifestations may help to identify a causative agent. This diary should*

*include date/time/symptoms experienced to see if an identifiable trend is present.*

#### • Medication instructions

*Instructions should be given regarding any new medications being prescribed and about any well-known medications that can aggravate tinnitus (such as medications containing salicylates).*

### Evaluating Care Outcomes

Success of treatment of tinnitus usually depends on the ability to discover the definitive cause of the clinical manifestations. Abolishment of clinical manifestations is then geared toward treating the pathology itself. In many cases, treatment of the underlying pathology results in reduction or remission of the clinical manifestations of tinnitus.

## VERTIGO

**Vertigo** is a clinical manifestation that evokes a feeling of illusory movement and like tinnitus, is not a specific disorder. Transient feelings of spinning and dizziness are experienced by nearly everyone at one time or another; however, patients with a documented diagnosis of vertigo exhibit these feelings on a regular basis. Senses of swaying or tilting are also common.

### Epidemiology

Several risk factors are associated with an increasing possibility of developing vertigo:

- Medications (including salicylates, anticonvulsants, antihypertensive medications, and tranquilizers)

- Head injury
- Upper respiratory tract viral infection
- Cerebral vascular disease
- Advanced age; older than age 60 years
- Family history of vertigo
- Presence of another disease such as Ménière's disease, labyrinthitis
- Presence of tumor
- Migraine headaches

According to the National Institutes of Health statistics, approximately 40% of people in the United States experience feeling dizzy at least once during their lifetime. Prevalence is also noted to be slightly higher in women and increases with age.

## Pathophysiology

Abnormalities in the semicircular canals (canals within the ear that contain fluid that allow a person to know the position in space) or the central nervous system (CNS) structures that process signals from the semicircular canals are thought to be responsible for the spinning sensation experienced by patients with vertigo. Disorders of the inner ear and CN VIII are termed *peripheral disorders*, whereas disorders of the vestibular nuclei and their pathways to the brain are considered *central disorders*. The visual, vestibular, and proprioceptive systems provide input to the CNS about problems with balance. Disturbances in any of these body systems can result in vertigo and are often related to specific pathologic conditions.

### Connection Check 48.6

The nurse correlates the pathology of hearing disorders with which change in function?

- An abnormality in the auricle
- Disturbances in the semicircular canals
- Disturbances in CN IX
- Disturbances in CN VIII

Clinical manifestations of vertigo include a spinning sensation at rest or with minimal movement, imbalance, light-headedness, nausea and vomiting, and hearing loss.

## Management

### Medical Management

#### Diagnosis

Because vertigo is typically an episodic disorder, not a specific disorder, a comprehensive history is the primary approach to diagnosis. Due to vertigo being a clinical manifestation observed in disease processes such as CN VIII tumors, head injury, and Ménière's disease, other diagnostic studies, including CT, MRI, and hearing tests may also be completed as part of the evaluation.

## Treatment

Treatment goals for vertigo focus on treating the cause of the vertigo. If a vestibular disorder has been identified, the most effective vestibular nerve suppressants include the following medications:

- *Diazepam (Valium)*, 2 to 5 mg orally every 6 to 8 hours; this medication depresses all levels of the CNS and is most effective for acute episodes.
- *Mecizine (Antivert)*, 25 to 50 mg orally three times daily; this medication decreases excitability of the inner ear labyrinth and blocks conduction of inner ear vestibular-cerebellar pathways.
- *Prochlorperazine (Compro)*, 10 mg intramuscularly (IM) four times daily or 25 mg rectally; this medication, usually used to treat nausea, blocks postsynaptic mesolimbic dopaminergic receptors in the brain and decreases stimuli to the brainstem reticular system.
- *Scopolamine (Buscopan)*, 0.6 mg orally every 4 to 6 hours or by patch as ordered by the provider; this medication blocks the action of acetylcholine at parasympathetic sites in smooth muscle, secretory glands, and the CNS.
- *Glycopyrrolate (Robinul)*, 1 to 2 mg orally two to three times daily; this medication blocks the action of acetylcholine at the parasympathetic sites.
- Vertigo secondary to Ménière's disease may also include dietary modifications that lower sodium in the diet and the addition of a potassium-sparing diuretic.

In addition to pharmacological management, slowly changing body position may greatly decrease clinical manifestations of tinnitus.

## Complications

Vertigo can have a profound effect on activities of daily living in patients, including the ability to operate an automobile independently, maintain employment outside the home, and many simple daily activities. Injuries from falls are not uncommon and may be of particular concern to older adults, who can suffer catastrophic effects from a fall. Depression and anxiety are other common complications that arise while patients often begin to feel desperate and at times helpless.

## Nursing Management

### Assessment and Analysis

Nursing management of patients with vertigo involves comprehensive assessment in an attempt to identify possible causes (Table 48.10). The clinical presentation includes complaints of sensations of spinning, that may be accompanied by dizziness and nausea.

### Nursing Diagnoses

- **Disturbed sensory perception** associated with disturbance in the body's equilibrium system as evidenced by verbal report of dizziness, sensations of spinning, history of falls or accidents, and clumsy behavior
- **Anxiety** associated with changes in sensations of homeostasis

**Table 48.10 Assessment and Analysis: Vertigo**

Assessment	Analysis/Explanation
<b>Spinning sensation at rest or with minimal movement</b>	The spinning sensation, even at rest, is caused by an abnormality of the semicircular canals within the inner ear; usually related to tiny debris being present in the inner ear that interferes with balance or equilibrium
<b>Imbalance</b>	The imbalance sensation that occurs when there is a suspected disturbance with the vestibular system; often with tiny debris being present for unknown reasons
<b>Light-headedness</b>	Light-headedness is associated with the vestibular system.
<b>Nausea/Vomiting</b>	Feelings of nausea and vomiting are a direct result of the imbalance or spinning sensation that occurs in the body.
<b>Hearing loss</b>	The occurrence of hearing loss with vertigo is usually a clinical manifestation of another pathology being present such as a tumor or damage from a traumatic event.

- **Risk for injury** associated with imbalance and disturbances of equilibrium

## Nursing Interventions

### ■ Assessments

- Vital signs  
*There is no specific disturbance in vital signs noted with vertigo other than possible increases in blood pressure, pulse, or respiratory rate secondary to anxiety.*
- Balance  
*Physical assessment usually reveals difficulties with patients maintaining balance or the sense of proprioception caused by changes in the inner ear or CNS.*
- Diagnostic results  
*CT or MRI scans as well as other diagnostic tests are often ordered to determine pathophysiology and to evaluate nerve conduction.*
- Age-related considerations  
*Increase in age has been noted with vertigo, but it can happen at any age and is dependent on pathology.*

### ■ Actions

- Administer prescribed medications  
*Rationales and indications are specific to each agent and are aimed at decreasing dizziness and other clinical manifestations*
- Minimize frequency and speed of position changes  
*Patients with vertigo can benefit from limiting position changes to decrease feelings of dizziness.*
- Decrease intake of salt, nicotine, alcohol, and aspartame in the diet  
*Omissions from the diet are thought to be helpful, though the exact rationales are not well understood. Decreasing salt intake probably decreases tinnitus based on its impact on fluid retention and blood pressure. Limiting salt intake is particularly important in the patient with hypertension who experiences tinnitus. Avoiding caffeine is most likely associated with the stimulant effects of caffeine. Aspartame may have a toxic effect on the inner ear and brain.*

- Reduce stress

*Decrease in stress is also thought to decrease CNS excitability and therefore decrease clinical manifestations of vertigo.*

- Complementary and alternative therapies  
*Ginkgo biloba and ginger are also cited as possible remedies in treating clinical manifestations of vertigo, although no real explanation has been given as to how these substances work to decrease vertigo.*

### ■ Teaching

- Change positions slowly  
*Instructions to plan slow, methodical position changes help to decrease vertigo in patients. Decreasing the clinical manifestations of vertigo with changing position may also decrease the patient's risk of falling.*
- Safety  
*Instructions to patient and family members regarding potential falls are important. Clutter-free environments and use of assistive devices (such as a cane or walker) to steady patients when walking also are advisable in an attempt to prevent falls.*
- Medication/dietary  
*Compliance with dietary modifications and medications is increased if the patient understands the indications and rationales.*

## Connection Check 48.7

The nurse includes which information in the teaching plan for a patient suffering from vertigo?

- Addressing safety issues
- Administering antipyretics as ordered
- Taking a hot shower when clinical manifestations are severe
- Maintaining strict bed rest for 24 to 48 hours after clinical manifestations appear

### **Safety Alert** Safety Considerations for Patients With Vertigo

Patients with vertigo are at risk for falling and should take safety precautions including changing positions slowly, maintaining a clutter-free environment, and limiting intake of medications and other substances such as nicotine and alcohol that can exacerbate the tinnitus.

### Evaluating Care Outcomes

Vertigo is a very challenging clinical problem that has many possible etiologies. Finding the cause of the vertigo is often key to management and providing effective treatment. Medications may help lessen the effects of vertigo but may have undesirable side effects. Safety is a key concern because falls are noted to happen because of the disturbance in sense of balance. With proper treatment and management, patients with vertigo should be able to lead healthy, active lives.

### MÉNIÈRE'S DISEASE

**Ménière's disease** is a disorder of the inner ear that affects the patient's balance and hearing. First described by French physician Prosper Ménière in 1861, this well-known disease is most noted for three clinical manifestations: unilateral sensorineural hearing loss, tinnitus, and vertigo. The patient usually describes these symptoms occurring as an "attack" that can last for several hours to several days.

### Epidemiology

Patients typically seek healthcare when the clinical manifestations of tinnitus, vertigo, and hearing loss continue with no specific cause. The risk factors associated with this disorder include the following:

- Head injury
- Middle ear infection

- Syphilis
- Allergies
- Alcohol abuse
- Fatigue
- Respiratory infection
- History of recent viral illness
- Smoking
- Certain medications

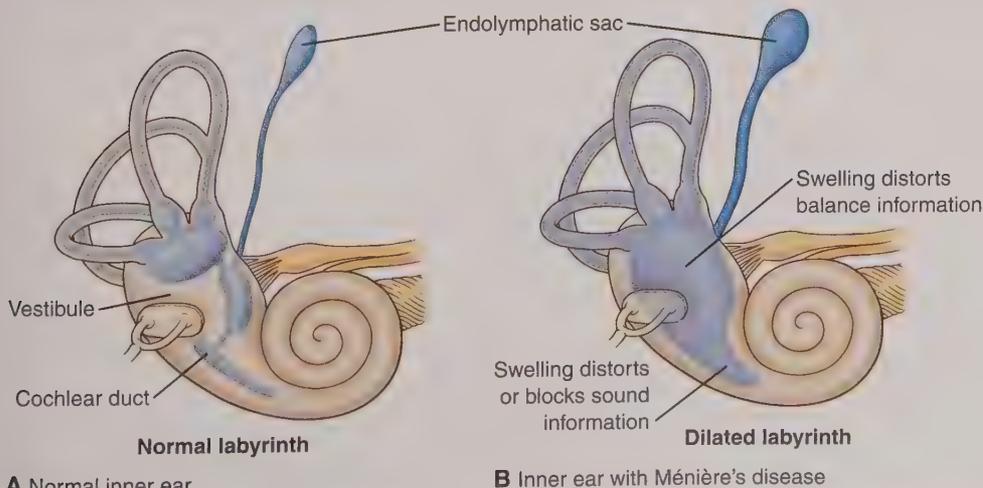

Ménière's disease is a disorder known to affect 615,000 people in the United States, with more than 45,000 new cases diagnosed each year. Studies indicate that whites and those of European descent are affected most often, females more often than males, and the peak age range is between the ages of 40 and 60 years.

### Pathophysiology

Although the exact cause of Ménière's disease is unknown, several correlations have been made about the disease. It is known to occur most often with infections, during periods of high stress, after traumatic injury, and with allergens. The clinical presentation of Ménière's disease is characterized by a clinical triad of vertigo, tinnitus, and hearing loss. These patients also exhibit an excess of **endolymphatic fluid** (lymph fluid within the ear) in the inner canals of the ear, which causes an obstruction of the inner canal system, and may lead to distention of this portion of the inner ear. This disruption leads to vertigo because of damage to the vestibular system. Decreased hearing from dilation of the cochlear duct that stimulates development of tinnitus is also observed in patients with Ménière's disease (Fig. 48.7).

### Clinical Manifestations

The clinical presentation of Ménière's disease varies from daily to rare clinical manifestations and may have an onset with or without warning. Severity of episodes also varies

**FIGURE 48.7** Ménière's disease. A, Normal inner ear; B, Inner ear with Ménière's disease. An excess of endolymphatic fluid in the inner canals of the ear (B) causes an obstruction of the inner canal system in Ménière's disease.

and is usually unilateral. Clinical manifestations of Ménière’s disease include the following:

- Vertigo
- Nausea and vomiting
- Sweating
- Increase in clinical manifestations with sudden movements
- Unilateral and sometimes bilateral hearing loss
- Tinnitus
- Diarrhea
- Headaches
- Abdominal pain
- Uncontrollable eye movements

**Management**

**Medical Management**

Although there is no known cure for Ménière’s disease, diagnosis is based on clinical presentation and ruling out other disorders, and treatment is aimed at providing symptomatic relief. Clinical manifestations may be relieved with medications and dietary changes including low-sodium diets in an attempt to decrease the amount of total body fluid. It is thought that this decrease in fluid also decreases the fluid present in the semicircular canals of the ear and therefore relieves pressure in the inner ear. Balance testing (Romberg’s test) can also provide useful information. Medications used in the management of Ménière’s disease are listed in Table 48.11.

Other supportive measures that can help alleviate clinical manifestations in patients with Ménière’s disease include:

- Low-sodium diet
- Avoiding sudden movements
- Avoiding bright lights

- Ensuring at least 8 hours of sleep per night
- Acupuncture
- Regular daily exercise
- Limit caffeine and alcoholic beverage intake

Some of these measures are effective because they also decrease fluid in the body. They also work by decreasing the CNS stimulation, leading to a decrease in the likelihood of developing clinical manifestations of Ménière’s disease.

**Surgical Management**

Surgical intervention may also be considered for those with severe (unrelenting) Ménière’s disease. Vestibular nerve transection helps control vertigo without damaging hearing. Surgically instilling gentamicin directly into the middle ear can also help decrease vertigo symptoms in some patients. A more radical surgery reserved for very severe cases includes removal of part of the inner ear called a *labyrinthectomy*. Although this surgery also improves the clinical manifestations of vertigo, complete hearing loss in the ear on the affected side is a result of the procedure.

**CASE STUDY: EPISODE 2**

Margie’s provider performs comprehensive current and past medical histories, as well as a complete physical examination. Although nothing is apparent on physical examination, the provider is surprised to learn that Margie has been suffering from severe seasonal allergies and that she has a parent who suffers from Ménière’s disease. The provider refers Margie to an otolaryngologist for further evaluation...

**Table 48.11 Medications for Treatment of Ménière’s Disease**

Medication	Rationale
Diazepam (Valium) or other benzodiazepines	Depresses all levels of the central nervous system and thereby decreases clinical manifestations.
Promethazine (Phenergan) or other antiemetic medication	This antihistamine medication blocks histamine at the site to decrease nausea and vomiting.
Meclizine (Antivert) or other antihistamine	This medication decreases excitability of the inner ear labyrinth and blocks conduction of the inner ear vestibular cerebellar pathways.
Dimenhydrinate (Dramamine)	This antihistamine affects the ear and decreases the exaggerated sense of motion.
Scopolamine (Isopto)	This medication blocks acetylcholine at the parasympathetic sites and decreases the exaggerated sense of motion.
Diuretics such as furosemide (Lasix)	Helps decrease fluid and decreases pressure in the ear

## Nursing Management

### Assessment and Analysis

The clinical presentation of Ménière's disease presents a challenging examination for the provider. Focused assessments are performed to identify possible clues to the disease (Table 48.12).

### Nursing Diagnoses

- **Disturbed sensory perception** related to Ménière's disease as evidenced by dizziness, balance or gait disturbance, nausea/vomiting, and tinnitus
- **Risk for injury** related to equilibrium/balance disturbances
- **Ineffective coping** related to vertigo and impaired hearing

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Specific vital sign changes are not noticed until there are secondary changes due to other processes such as anxiety or infection that may lead to increases in temperature, blood pressure, pulse, and respiratory rate.*
- **Positive Romberg's test**  
*Patients may exhibit a positive Romberg's test on examination (meaning they have a disturbance in balance) and may also have nystagmus. Sensations of dizziness and strange sounds may be experienced by the patient.*

- **Caloric test**  
*The caloric test evaluates the patient for the presence of nystagmus, which is often present in Ménière's disease.*
- **MRI/CT scans**  
*Magnetic resonance imaging/CT scans are often performed for patients presenting with balance/vertigo/tinnitus issues to rule out the presence of tumors or other structural abnormalities.*

#### ■ Actions

- **Medications**  
*Rationales and indications are specific to each agent and are aimed at decreasing the clinical manifestations. Specific medications and rationales are presented in Table 48.12.*
- **Limit sodium intake**  
*Decreasing sodium intake minimizes fluid retention and can minimize the excess endolymphatic fluid associated with Ménière's disease*
- **Positioning of patient**  
*Positioning the patient in a way that minimizes frequent or vigorous head turns is helpful in decreasing vertigo by decreasing fluid movement within the vestibular system of the inner ear.*
- **Safety measures**  
*Take care to prevent falls, including decreasing clutter present in rooms. Use of a cane or walker may also help provide stability with ambulation.*

**Table 48.12 Assessment and Analysis: Ménière's Disease**

Assessment Data	Analysis/Evaluation
<b>Vertigo</b>	Membranous portion of the labyrinth is encased by bone necessary for hearing and balance; it is filled with fluid called <i>endolymph</i> , and a disturbance in the volume of fluid may be responsible for the clinical manifestations of vertigo.
<b>Nausea/Vomiting</b>	The disturbance in balance that occurs with the endolymph can cause feelings of nausea and vomiting.
<b>Sweating</b>	Overstimulation of cranial nerve VIII is thought to be the cause of sweating.
<b>Increase in clinical manifestations with sudden movement</b>	Sudden movements can increase clinical manifestations because of the movement of the endolymph.
<b>Unilateral or bilateral hearing loss</b>	Hair cell death in the inner ear has been reported with Ménière's disease and provides a possible reason for the hearing loss.
<b>Tinnitus</b>	Extra or unusual sounds may be heard because of the increase in endolymph within the labyrinth.
<b>Diarrhea</b>	Overstimulation of the sympathetic nervous system may cause diarrhea.
<b>Headache</b>	Overstimulation of the sympathetic nervous system is thought to be a possible cause of headache in Ménière's disease.
<b>Abdominal pain</b>	Overstimulation of the sympathetic nervous system resulting in increased secretion of gastric acid is thought to be a causative agent.
<b>Uncontrollable eye movement</b>	This uncontrollable movement, known as nystagmus, is a clinical manifestation that occurs as the eyes are controlled by input from the labyrinth of the ear; the disturbance in the labyrinth system that occurs with Ménière's disease can cause nystagmus to occur.

- Collaboration with neurology or otolaryngology providers  
*Collaboration with other specialty providers can help to ensure that patient-centered, comprehensive care is provided.*
- Acupuncture  
*Although this is a nontraditional method of treating disease in the Western world, positive effects on balance and nausea symptoms have been demonstrated with this alternative therapy.*

### Teaching

- Disease process  
*Teaching patients and family members about the disease itself helps to decrease anxiety and increase compliance with the medical regimen.*
- Testing (pre- and post-testing)  
*Instructions for pre- and post-testing are necessary for patients and family members so that compliance may be achieved and anxiety decreased.*
- Medications  
*Information regarding specific new medications should be provided to the patient and family members to increase compliance.*
- Safety  
*Information regarding the use of assistive devices (canes/walkers) should be provided so that patients may decrease the risk of falling.*
- Follow-up care  
*Instructions to the patient and family regarding all necessary follow-up care because frequent regular evaluations provide the best possible control of clinical manifestation in patients with Ménière's disease*

### Evaluating Care Outcomes

Ménière's disease is a disorder characterized by varied clinical manifestations that range in severity and also in time frame of attacks. A definitive diagnosis is the key to addressing the clinical manifestations and effectively managing this disease process. Treatments depend on the severity of the illness as well as the frequency of attacks. Because there is no known cure for this disease, the goal in most cases is to control the clinical manifestations. Medications, patient teaching, and follow-up care help the patient achieve the best possible outcomes.

### Connection Check 48.8

The nurse correlates which clinical manifestations in the patient with Ménière's disease being received from the emergency department?

- Fever greater than 101°F (38.3°C)
- Seizures with nystagmus
- Bloody drainage from the ear canal
- Vertigo and tinnitus

## Making Connections

### CASE STUDY: WRAP-UP

At Margie's initial appointment with the otolaryngologist, the provider is concerned about her symptoms of nausea, dizziness, and right-sided hearing loss that have been occurring on such a regular basis. On the basis of the clinical manifestations and physical examination, including the Romberg's test, a tentative diagnosis is made of Ménière's disease and Margie is started on a low-sodium, caffeine-restricted diet and Antivert and Phenergan. An MRI of the head is also ordered to evaluate for a tumor on CN VIII.

### Case Study Questions

- The provider is most concerned with which clinical manifestations that could represent early presentation of Ménière's disease?
  - Seasonal allergies and right-sided hearing loss
  - Her age and episodic nausea
  - Her dizziness and right-sided hearing loss
  - Seasonal allergies and nausea
- The provider is concerned about what other aspect of Margie's history?
  - Her mother's past medical history of Ménière's disease
  - Her severe seasonal allergies
  - Her hearing loss on one side only
  - Her age
- What is the priority nursing consideration for Margie?
  - Making sure that her allergies do not progress to asthma
  - Implementing safety measures
  - Providing medication to help suppress nausea
  - Reassuring her that symptoms will be relieved after allergy season
- Assuming that Margie is diagnosed with Ménière's disease, what is the next step in her care?
  - Referral to an ear, nose, and throat specialist
  - A STAT CT scan to definitively diagnose Margie
  - Administration of medications to stimulate the CNS
  - Antibiotic therapy to determine if the symptoms are infection related
- What does the nurse teach Margie about surgical intervention for patients with Ménière's disease?
  - It is a well-known cure
  - It may be considered for those with severe, unrelenting disease.
  - There is no surgical intervention for this disease.
  - It is only about 25% effective

## CHAPTER SUMMARY

Hearing disorders are not only associated with the ability to hear sounds but also with the body's sense of equilibrium. Hearing loss is categorized as conductive, sensorineural, or mixed. Presbycusis is a term referring to hearing loss that occurs with advancing age. Although the clinical presentations of the different disorders are similar, the underlying pathophysiology of these disorders varies. Hearing loss may have specific etiologies associated with structural changes in the ear and may be enhanced by hearing aids or other technologies such as cochlear implants. Health screening and noise prevention measures are also important interventions associated with maintaining auditory system function.

Inflammatory conditions such as external otitis and otitis media are typically associated with pain and discomfort in the affected ear. Usually short term and self-limiting, these disorders are successfully treated with appropriate antibiotics. Permanent changes in hearing are not common with these disorders unless the inflammation or infection becomes recurrent and results in damage to the ear structures.

Tinnitus and vertigo are disorders with multiple etiologies and are often the clinical manifestations associated with tumors on or around CN VIII, or disorders such as Ménière's disease. Expert evaluation should be initiated without delay in instances in which patients' hearing, balance, and equilibrium are affected. Based on the specific diagnosis, there are common treatment modalities including decreasing sodium and caffeine in the diet.

## Promoting Health in Patients With Integumentary Disorders

### Chapter 49

## Assessment of Integumentary Function

*Mary Donnelly*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the integumentary system
2. Discussing the function of the integumentary system
3. Describing the procedure for completing a history and physical assessment of integumentary function
4. Discussing changes in integumentary appearance and function associated with aging
5. Correlating relevant diagnostic examinations to integumentary function
6. Explaining nursing considerations for diagnostic studies relevant to integumentary function

#### CONCEPTS

- Assessment
- Infection
- Medication
- Nursing Roles
- Promoting Health
- Skin Integrity

#### ESSENTIAL TERMS

Albinism  
Alopecia  
Apocrine sweat glands  
Braden scale  
Cryosurgery  
Dermis  
Ecchymosis  
Eccrine sweat glands  
Epidermis  
Erythema  
Hirsutism  
Keratin  
Keratinocytes  
Langerhans cells  
Merkel cells  
Melanocytes  
Onycholysis  
Petechiae  
Primary lesions  
Pruritus  
Sebaceous glands  
Secondary lesions  
Subcutaneous tissue  
Vitiligo

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Lacy Bloom is a 72-year-old white female patient who presents to her healthcare provider because of recent skin changes on her anterior chest. She reports itching, burning, redness, and blistering at the site as well as a low-grade fever. The patient reports that she spends a lot of time outdoors working in her garden. Also, she has an allergy to latex but has not had any recent exposures...

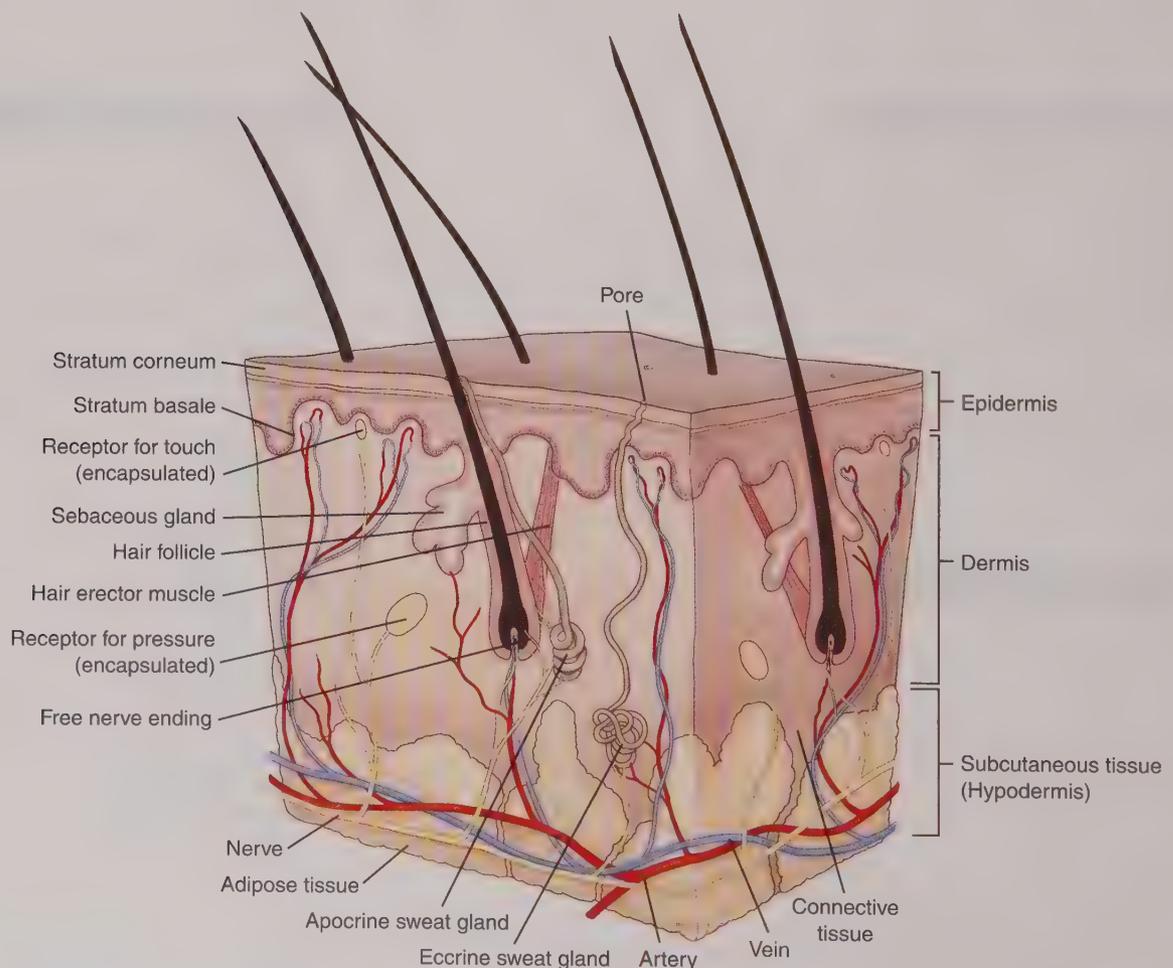

## INTRODUCTION

The integumentary system, including the skin, hair, and nails, comprises the protective coating that guards the body from injury. Because the skin is the largest and most visible organ, alterations in integumentary appearance and function

may signal underlying pathologies of other body systems. Careful assessment and interpretation of skin, hair, and nail abnormalities as well as expedient implementation of nursing interventions sustain the body's protective shield.

## OVERVIEW OF ANATOMY, PHYSIOLOGY, AND FUNCTION

The skin layers include the **epidermis** and **dermis** (Fig. 49.1). The five major functions of the skin are protection, temperature regulation, vitamin D metabolism, sensation, and excretion. Providing protection from the external environment, as well as to underlying structures and organs, the skin is essential to homeostasis. Supporting temperature regulation, the skin also plays a role through facilitating heat loss or heat conservation through the skin. Vitamin D metabolism is another major function of the skin, because the epidermis is the major source of vitamin D for the body. Activated in the epidermis by ultraviolet (UV) light, vitamin D enters the circulation and works in the gastrointestinal system to facilitate calcium absorption. Sensation is controlled in the dermis, the location of many nerve receptors that communicate with the central nervous system. The

**FIGURE 49.1** Anatomy of the skin.

role of the skin in excretion is linked to losses of fluid through the sweat glands; the evaporation of water through the skin also aids in cooling the body. **Eccrine sweat glands** cover most of the body's surface and **apocrine sweat glands** are present in hair follicles of the armpits and genitalia.

## Skin

The integumentary system comprises approximately 15% of the body's total weight and requires 33% of the body's blood volume for optimal function. During times of decreased cardiac output, highly acute illness, and long-term chronic illness, the skin is highly susceptible to damage. Several factors place the skin at increased risk for damage, including reduced mobility, decreased perfusion and oxygenation, increased skin moisture and temperature, friction and shear, decreased sensory perception, hemodynamic instability, vasoactive medications, intensive care unit length of stay, surgery, and overall health status. Pressure from medical devices, such as urinary catheters, intravenous lines, endotracheal and nasogastric tubes can cause pressure injuries. Therefore, careful skin assessment and evidence-based interventions to promote adequate skin tissue perfusion represent essential nursing responsibilities.

## Epidermis

The outermost skin layer is called the *epidermis* (Fig. 49.2) and protects the body by forming a barrier that resists pathogen invasion. Five compact sections of **keratinocytes** at various stages of maturation compose the epidermis. Keratinocytes are stratified epithelial cells that produce **keratin**, which is a waterproof fibrous protein that protects skin and hair. These cells push upward from the basement membrane to the skin surface during a cycle that lasts approximately 1 month.

The innermost layer, referred to as the *stratum basale*, is composed of newly formed, actively replicating basale keratinocytes, whereas the outermost level, the *stratum corneum*, contains approximately 25 layers of flattened, dead keratinocytes that slowly slough away. In addition to protective keratinocytes, the epidermis houses dendritic structures

called **Langerhans cells**, **melanocytes**, and Merkel cells. Langerhans cells migrate to the epidermis from the bone marrow, making them the outermost cells of the immune system. Langerhans cells ingest foreign substances that enter the body through the skin, then present the antigen to the immune system's T cells. The T cells then orchestrate the inflammatory response to destroy the pathogen if required. The epidermis is anchored to the dermis by rete ridges that point downward into the dermis (Fig. 49.3). This structural feature creates a more secure bond between the two skin layers.

The epidermal layer also contains melanocytes and Merkel cells. **Melanocytes** produce melanin, which is the pigment that prescribes skin color and protects underlying skin structures from UV damage. Under normal circumstances, melanocytes are present in a 1:36 ratio with basale keratinocytes. Each melanocyte has a dendritic structure that allows melanin to be transported through and released into the group of 36 keratinocyte cells. Differences in the appearance of skin color result from variations in melanocyte activity rather than the number of melanocyte cells present. Darker skin tones reflect increased melanin production from that individual's melanocytes. **Merkel cells** are mechanosensitive cells that are innervated by slowly adapting type 1 (SA1) afferent neurons that detect light touch stimuli. Merkel cells are touch-sensitive cells that transduce mechanical stimuli through cation channels. The sense of touch assists in gathering information about the external environment and in accomplishing skilled movements.

## Dermis

The dermis is approximately 2 to 4 mm thick and encases blood vessels, nerves, immune system cells including macrophages and mast cells, dermal proteins including collagen and elastin, hair follicles, and sweat and **sebaceous glands** (glands that secrete sebum, which lubricates the hair follicles to the skin and hair). Each of these structures supports the five functions of the skin. Table 49.1 provides an explanation of how each structure correlates to specific functions.

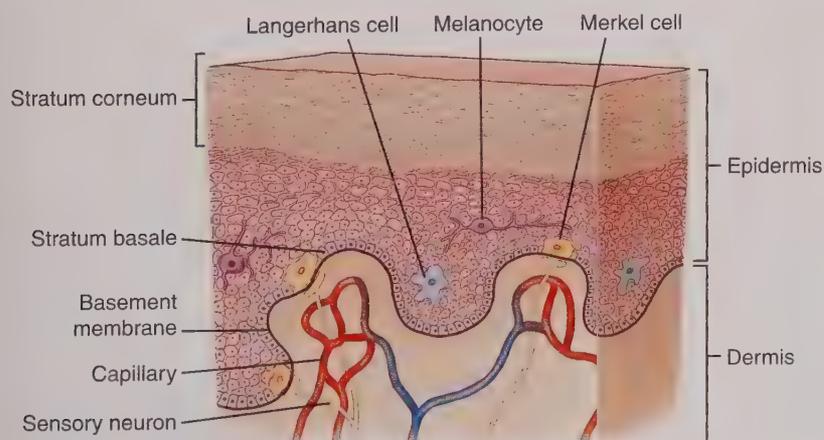

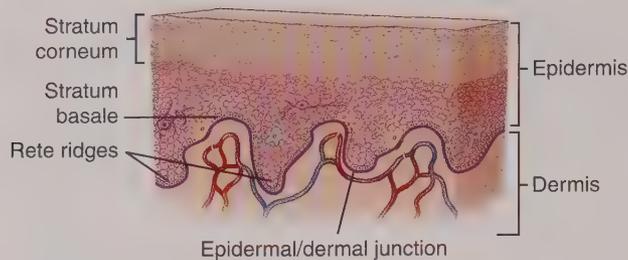

FIGURE 49.2 Epidermis.

**FIGURE 49.3** Rete ridges. The epidermis is anchored to the dermis by rete ridges that point downward into the dermis that creates a secure bond between the two skin layers.

### Subcutaneous Tissue

Below the two skin layers lies the **subcutaneous tissue** or hypodermis, which contains adipose tissue, connective tissue, nerves, and blood supply. The adipose tissue located in this layer surrounds and insulates the deeper structures including organs, muscle, and bone. Distribution of adipose tissue varies depending on gender, genetic predisposition, and lifestyle habits.

### Hair

In addition to having significant cosmetic importance, hair reduces heat loss and shields the skin from sun exposure. Although distribution varies, hair is present on most of the

body. Both hair and hair follicles are composed of keratinocytes. Hair follicles are anchored in the dermis and then protrude into the epidermis. The hair itself is referred to as a *root* when contained within the follicle, and the portion that emerges from the follicle is referred to as the *shaft* (Fig. 49.4).

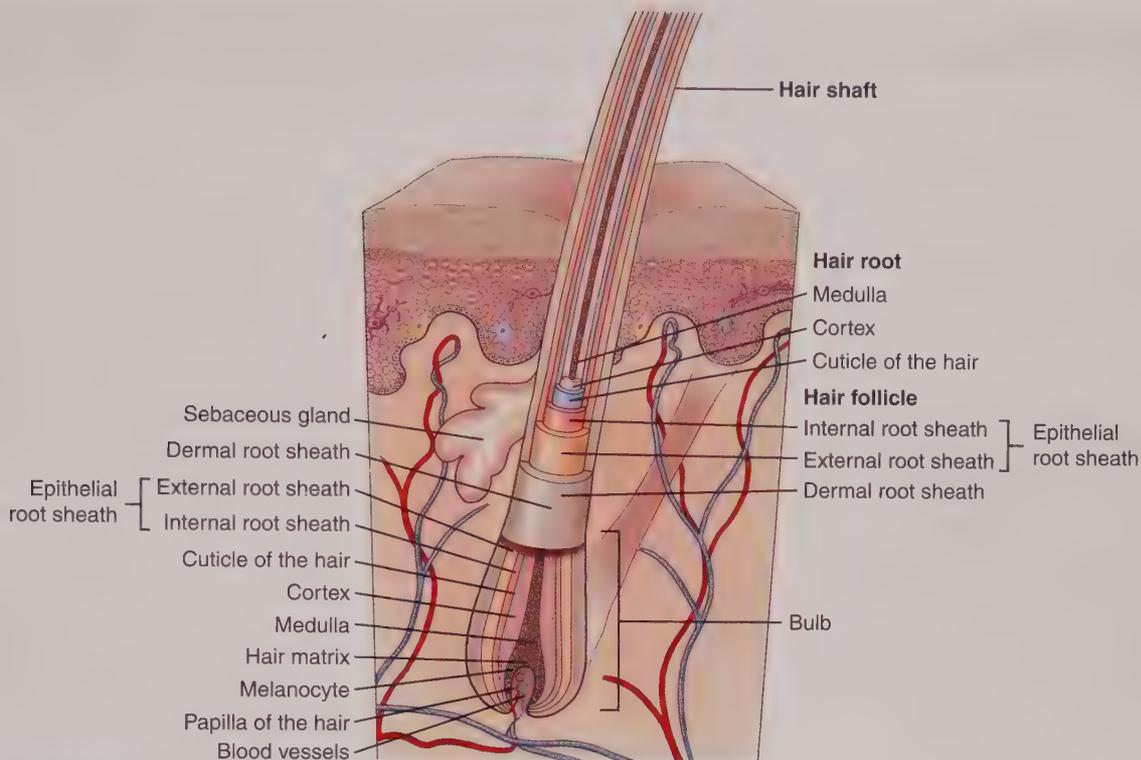

Extension of the hair shaft cycles between growth and rest. During the hair growth cycle, dead keratinocytes are tightly packed together within the follicle to be pushed toward the skin surface. This process results in lengthening of the hair shaft. During the resting cycle, active accumulation of keratinocytes is absent. However, the hair follicle holds onto the hair shaft, which minimizes hair loss during the resting cycle. Usually, the growth phase follows a resting phase, and the time frame varies depending on the hair's location. Complete death of a hair follicle results in baldness or **alopecia**, and causes include heredity, stress, and illness.

### Nails

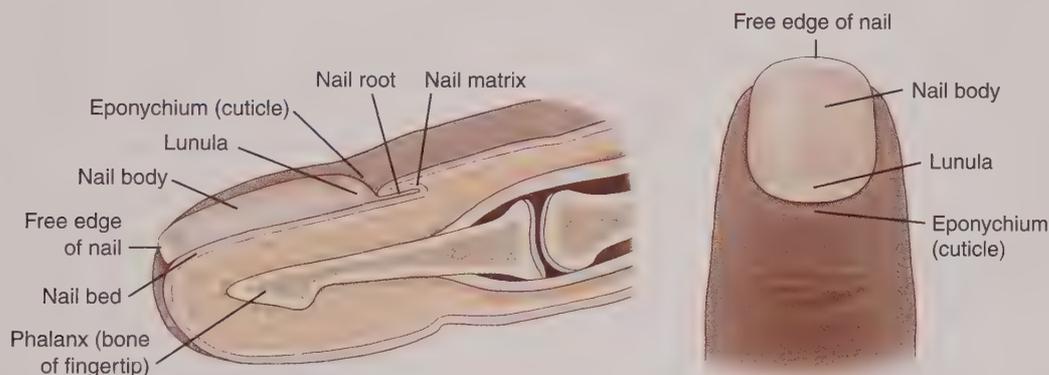

Nails protect the tips of the fingers and toes. They are composed of a hard keratin and have a slow but continuous growth process. Beneath the skin, the nail matrix houses constantly dividing basale keratinocytes that form the nail root (Fig. 49.5). The nail body refers to the visible portion that adheres to the nail bed. The condition of the nails reflects general health, state of nutrition, occupation, and habits of self-care. Coloration of the nail bed provides

**Table 49.1** Structure and Function of the Dermis

Structure	Function
<b>Blood vessels</b>	Supply nutrients, white blood cells, and oxygen for skin maintenance and healing and remove waste products Support temperature regulation via dilation and constriction
<b>Nerves</b>	Allow for recognition of pain, pressure, temperature, and touch
<b>Skin immune system: Langerhans cells (epidermis), macrophages and mast cells (dermis)</b>	Recognizes and reacts to invading pathogens using the inflammatory response Langerhans cells are located in the epidermis. They are the outermost immune system cells and detect initial pathogen invasion. Macrophages and mast cells are located in the dermis. Macrophages destroy bacteria while mast cells mediate the inflammatory response using histamine.
<b>Dermal proteins: Collagen and elastin</b>	Sustain resiliency; collagen creates tensile strength, and elastin provides elastic recoil
<b>Hair follicles</b>	Enclose the hair shaft In the presence of epidermal skin damage, cells within the hair follicle replicate to heal the injury.
<b>Glands: Sebaceous and sweat</b>	Sebaceous glands produce sebum, which exits from the hair follicle. Sebum is a lipid-rich substance that moisturizes hair and skin. Eccrine sweat glands cover most of the body's surface. They produce a water and salt mixture that evaporates to cool the body. Apocrine sweat glands are present in hair follicles of the armpits and genitalia. Secretions from these glands contribute to body odor.

**FIGURE 49.4** Structure of the hair follicle.

**FIGURE 49.5** Structure of the nail.

information about the perfusion status of the body's most distal locations.

### Connection Check 49.1

Which properties of the epidermal and dermal layers contribute to wound healing? (Select all that apply.)

- A. The 30-day maturation time of epidermal keratinocytes
- B. Eccrine gland sweat production
- C. Melanocytes in a 1:36 ratio with keratinocytes
- D. Presence of Langerhans cells, macrophages, and mast cells
- E. Blood vessels in the dermis and subcutaneous tissue

### Connection Check 49.2

Which statement accurately describes the skin's protective capabilities?

- A. The epidermis can resist damage when exposed to continuous moisture.
- B. Melanocytes always provide adequate protection to underlying structures from UV exposure.
- C. Langerhans cells, located in the epidermis, often provide the initial signal to the immune system that pathogen invasion has occurred.
- D. Temperature is regulated by blood vessels and sweat glands.

## ASSESSMENT

### History

Examination of the skin, hair, and nails involves a thorough history followed by physical assessment. A careful evaluation allows the nurse to identify existing skin conditions, current skin care practices, and individual risk factors. When the nurse detects a specific alteration in normal skin function, pertinent questions are posed to collect relevant data (Box 49.1). This information can also

### Box 49.1 Skin Assessment: Questions to Ask During a History

#### Health History/Medications

Tell me about your disease history.  
Tell me about your allergies.  
When was the last time you had a health examination?  
What medications do you take (including herbal remedies)?  
Have you had any recent changes to your medication regimen?

#### Family History

Has anyone in your family or household experienced recent skin changes?  
Has anyone in your family travelled recently? If yes, to where?  
Has anyone in your family ever had a serious skin condition or skin reaction?

#### Environmental Factors

What is your occupation?  
How much sun exposure do you receive each day?  
Are you exposed to chemicals at work?  
Are you a current or past smoker?

#### Social History

What is your normal bathing routine?  
What skin care products do you use?  
Do you have someone at home who regularly looks at your skin?

#### Focused Skin Assessment Questions

Tell me about the skin changes that you have noticed.  
When did you notice the area, at what location, and how has it changed?  
Describe how the affected area feels (examples include itching, burning, pain, tingling, numbness).  
How has the discomfort changed since it first began?  
How have you treated the area, and what has been effective?

be used to implement interventions to promote skin integrity. Nursing care involves a proactive approach to skin maintenance to ensure the integrity of this protective organ.

### Demographics

When obtaining a history, the nurse gathers demographic data, including age and race, because the skin's primary functions are affected by age. Key physiological skin changes in older adults include increased fragility caused by thinning of skin layers, decreased subcutaneous tissue, decrease in excretion from sebaceous and sweat glands, and fewer sensory receptors and immune system cells. These factors contribute to aged skin being more prone to damage. With older patients, it is important to discuss skin changes that present as an alteration in normal function.

Specific skin conditions are caused by pigmentation disorders or sun damage, including common depigmentation disorders including vitiligo and albinism that affects individuals of various races and skin colors. **Vitiligo** describes a confined type of depigmentation caused by the loss of melanocytes at a specific body area and affects all races and has a genetic background with more than 30% of affected individuals reporting vitiligo in a parent, sibling or child. The increased prevalence reported in some countries and among darker skinned persons results from a dramatic contrast between vitiligo macules and dark skin. The skin phototype (SPT) is determined by the combination of genetically determined constitutive melanin pigmentation and inducible melanin pigmentation. **Albinism** is an autosomal recessive condition leading to generalized depigmentation caused by a lack of melanin production despite having a normal melanocyte to keratinocyte ratio.

### Personal History: Comorbid Conditions

The nurse collects a personal history that includes comorbid conditions. Advancing comorbid conditions that affect other body systems can frequently lead to the emergence of wounds, skin and nail bed discoloration, textural changes, and hair distribution changes. When these deviations from normal are detected, the common underlying pathology is inadequate oxygen and nutrient delivery to the integumentary system. However, common conditions including diabetes mellitus, cardiovascular disease, respiratory disease, liver and kidney disease, and obesity each have a specific pathophysiology that results in an alteration in skin tissue perfusion. A patient with one or more of these complicated illnesses frequently experiences a disruption in skin integrity. Refer to Table 49.2 to explore how common comorbidities affect integumentary appearance.

According to *Healthy People 2020*, diabetes mellitus, cardiovascular disease, and cancer are widespread disease processes that impact many Americans. Each of these conditions has a unique pathophysiology that impacts overall body function. Because the skin is the body's most visible organ, evidence of damage caused by these diseases may be observed during assessment of the integumentary system.

**Table 49.2** Prevalent Diseases and Associated Skin Complications

Disease Process	Associated Skin Complications	Relationships Between Disease Process and Skin Complications
<b>Type 2 diabetes mellitus (DM)</b>	Pain Numbness of extremities Increased risks for wounds Diabetic foot ulcers (DFUs) Increased incidence of bacterial and fungal skin infections	Type 2 DM is a complex disease that alters the function of many body systems. Nerves do not require insulin for glucose transport and are particularly vulnerable to the pathologic effects of chronic hyperglycemia. Advanced glycation end products contribute to demyelination, nerve degeneration, and delayed conduction. Peripheral neuropathy affects as many as 50% of individuals with diabetes. Decreased blood supply results from vascular changes and autonomic dysfunction, which decreases the supply of white blood cells to open wounds. Chronic hyperglycemia impairs both the innate and adaptive immune responses.  DFUs are caused by trauma to the site. Neuropathy makes it difficult for people to recognize that a wound is present.  Failure to identify the presence of wounds or skin abnormalities because of neuropathy in combination with high levels of glucose in the blood-stream makes patients with type 2 DM prone to infection.
<b>Heart disease: Coronary artery disease (CAD)</b>	Hypoperfusion to integumentary system  Acute: Pale pink, blue, or purple discoloration of nail beds, fingers, toes, feet, and mucous membranes  Chronic: Finger clubbing  Complications of immobility	The ability of the heart to function as an adequate pump to supply organs and tissues with adequate blood volumes becomes suboptimal when CAD damages the heart muscle.          For patients who require invasive therapies such as mechanical ventilation, intra-aortic balloon pumps, extracorporeal membrane oxygenation, or other types of invasive monitoring after a major myocardial infarction are at risk for pressure injury as a result of immobility.  Activity intolerance for patients with advanced congestive heart failure may lead to pressure injury.
<b>Peripheral vascular disease affects lower extremities</b>	Arterial insufficiency: Pain, pale to blue discoloration, dry skin, shiny skin, alopecia, dry wounds near toe tips that are very difficult to heal unless blood flow is restored  Venous insufficiency: Edema, dermatitis, itching, hemosiderin staining, wet wounds from ankle to mid-calf	Atherosclerosis in systemic blood vessels leads to inadequate blood flow to lower extremities. Symptoms are related to the lack of oxygen to the tissues.   Most often, dysfunction of venous valves in the lower extremities is the underlying problem in venous insufficiency. Blood pools in the legs because the valves are not able to close properly to prevent backflow.
<b>Cancer</b>	Wounds with excessive pain, odor, drainage, bleeding, and itching  Skin inflammation caused by radiation (radiation dermatitis)  Incontinence-associated dermatitis  Complications of immobility	Tumors from internal structures may become visible outside the body. One example is a fungating breast tumor. These tumors often have complicated symptoms that require interprofessional management.  Skin damage from radiation therapy occurs because radiation is very harmful to all rapidly reproducing cells including those in the skin layers. The extent of damage ranges from an erythematous rash to full-thickness wounds.  Chemotherapy agents, nutritional deficiencies, and a high-acuity illness may lead to incontinence of urine and/or stool.  Generalized weakness caused by therapies and end-of-life situations may lead to the formation of skin problems caused by immobility, such as pressure injury.

### Personal History: Medications

Commonly used medications frequently have side effects that affect skin appearance and function. For example, corticosteroid therapy leads to thin, fragile skin that tears easily because the medication interferes with the formation of the epidermis and collagen production. The Safety Alert below lists commonly used medications that have the potential to cause mild skin irritation to full-thickness necrosis. Collecting a complete medication history assists with identifying whether a specific medication or a combination of medications has contributed to the skin abnormality.

#### Safety Alert Medications That May Disrupt Skin Integrity

**Antibiotics:** Ampicillin, amoxicillin, penicillin, polymyxin B, sulfonamides, tetracyclines

**Anticoagulants:** heparin, warfarin, enoxaparin, rivaroxaban, apixaban

**Cardiac medications:** angiotensin-converting enzyme inhibitors, amiodarone, beta blockers, calcium-channel blockers, hydralazine, lipid-lowering agents

**Chemotherapy:** Doxorubicin, rituximab, infliximab, vinca alkaloids

**Other:** allopurinol, anticonvulsants, antiepileptic, antimalarials, glucocorticoids, NSAIDs, opiates, oral contraceptives, radiocontrast media, steroids

### Family History

After discussing the patient's current skin conditions and personal history, the nurse inquires about family history. It is important to collect data about skin, hair, and nail conditions affecting family members because many conditions are genetically linked. Also, skin, hair, and nail conditions can be caused by infective organisms transmitted among people living within close quarters, such as bacterial, viral, or fungal infections, scabies, or lice.

### Diet

Consumption of adequate amounts of protein, carbohydrates, fats, vitamins, and minerals is required to maintain a healthy integumentary system. If a patient lacks sufficient intake of nutrients, it is often visible in the appearance of the skin, hair, and nails. When wounds exist, whether surgical or caused by another etiology, the need for protein, B vitamins, vitamins A and C, fats, carbohydrates, iron, and zinc increases during the healing process. Therefore, diet is a key component to address when developing a plan for patients who have developed or are at risk for developing skin disorders. The nurse evaluates the adequacy of nutrition through reviewing results of plasma protein levels (Table 49.3) and body mass index (BMI) (Table 49.4).

**Table 49.3 Plasma Protein Guidelines**

Protein Type	Normal	Malnutrition
<b>Serum albumin</b>	3.4–5.1 g/dL	Less than 3.5 g/dL
<b>Serum prealbumin</b>	19.5–35.8 mg/dL	Less than 19.5 mg/dL
<b>Transferrin</b>	230–390 mg/dL	Less than 100 mg/dL

**Table 49.4 Defining Body Mass Index**

Body Mass Index (BMI)	Weight Classification
Less than 18.5 kg/m <sup>2</sup>	Underweight
18.5–24.9 kg/m <sup>2</sup>	Normal weight
25–29.9 kg/m <sup>2</sup>	Overweight
Greater than or equal to 30 kg/m <sup>2</sup>	Obese

### Environmental Factors

Occupational exposures, lifestyle habits, and sun exposure impact skin integrity. Chemical exposures in the workplace or at home can lead to skin inflammation or chemical burns. Allergic contact dermatitis is a T cell–mediated hypersensitivity reaction to a substance after repeated exposures. Depending on the strength of the allergen, a skin reaction may take days to years to emerge. Common substances that cause allergic contact dermatitis include latex, topical ointments, plant products, chemicals, dyes, cleaning agents, metals, personal care products, and fragrances.

Lifestyle habits such as tobacco use and travel may impact skin integrity. Smoking leads to vasoconstriction of blood vessels. Chronic vasoconstriction can be very damaging to vasculature and surrounding skin layers, causing dryness, cracking, and increased risk for wound development and even tissue necrosis. Travel to areas of the world without access to preventive healthcare may lead to exposure to unusual infectious skin disorders.

The sun's ultraviolet rays (UVRs) expose the skin and its structures to radiation that quickens the skin's aging process. In addition, excessive exposure to the radiation from UVRs can disrupt the normal function of the DNA of various skin cells. For example, sun-damaged skin has 50% fewer Langerhans cells, which impacts the immune system's ability to identify pathogen invasion in the epidermis. Ultimately, the risk for developing skin cancers, including melanoma, is much higher for patients who have experienced frequent sunburns. Because environmental factors are frequently modifiable, educating the patient or caretaker regarding preventive measures may minimize the risk for injury.

**CASE STUDY: EPISODE 2**

Because of Ms. Bloom's advanced age, her skin is at increased risk for dryness caused by the physiological changes associated with aging. The patient reports a latex allergy that causes redness but denies any serious skin reactions in the past. She has struggled with being overweight since her late-30s, and her current BMI is 28 kg/m<sup>2</sup>. Ms. Bloom denies any recent dietary changes or any travel outside the country. She lives with her husband, and they are retired. Ms. Bloom reports spending a lot of time working outdoors in her garden, and she regularly wears sunscreen. Her daily skin care regimen includes bathing and moisturizing her skin once a day, and she reports using a new fragrance spray for approximately 2 weeks...

## Physical Assessment

After conducting a thorough history, the nurse performs a comprehensive, head-to-toe inspection of the integumentary system. The assessment is conducted in a well-lit area while the patient is minimally clothed. Visual inspection and manual palpation are used to detect abnormalities. The nurse observes for visual inconsistencies in the color, moisture, and presence of lesions and palpates the tissue to identify atypical findings in relation to temperature and texture.

When abnormalities are detected, the nurse considers the cause of the condition. Etiologies may stem from endogenous sources such as comorbid or hereditary conditions or exogenous sources including pressure or incontinence. By first determining the cause, the nurse is able to individualize problem-specific solutions to prevent further skin deterioration.

For patients who are acutely or chronically ill, all skin surfaces are inspected because deviations from the normal color and texture of the skin, as well as the development of lesions or wounds, may be correlated to the onset of new complications of the illness. The nurse pays particular attention to changes in the color, temperature, and texture of pressure points including the occiput, scapula, sacrum, ischium, ankles, and heels. The risk for pressure injury development escalates when these patient populations develop decreased sensory perception, increased moisture on the skin, decreased level of activity, decreased mobility or ability to reposition the body, inadequate nutritional intake, and increased friction and shear.

After inspection and palpation, the nurse documents observations regarding the following characteristics:

- Color and temperature
- Moisture
- Integrity
- Cleanliness

- Tissue changes
- Vascular markings
- Lesions

The nurse uses the findings of an in-depth skin assessment to formulate a plan of care to promote skin integrity. Also, the patient or caregiver is educated about ways to improve the daily skin care regimen. Ultimately, these initiatives promote comfort as well as amplify the skin's ability to resist deterioration.

### Color

Under normal circumstances, skin color is determined by circulatory status and genetic predisposition. When evaluating skin color, the nurse collects information regarding recent or gradual changes in skin tone. Frequently, variations in skin color may correlate with changes in blood flow or the presence of inflammation. Refer to Table 49.5 for common skin color variations, including the cause and significance. The nurse also palpates for a change in skin temperature when color change is present. A cooler temperature of the affected tissue can indicate decreased perfusion, whereas warmer temperatures may reveal increased circulation or inflammation.

When changes in color, temperature, or both are noted, further assessment is needed to identify the cause. For patients with decreased mobility or highly acute conditions, the nurse regularly inspects pressure points for redness and texture change. These patients are at higher risk for pressure-related skin damage, which often begins with red discoloration. Blanchable **erythema** (redness of the skin) describes reddened skin discoloration over a bony prominence that turns white when the site is palpated. This characteristic indicates that blood vessels at the site have dilated to reperfuse tissues that received inadequate blood flow while the site was exposed to excessive pressure. However, if the erythematous area does not blanch when pressure is applied, deep tissue damage is probable. Blanching occurs when normal red tones of the light-skinned patient are absent. When assessing for pressure injuries in dark-skinned individuals, dark skin may not show the blanch response. Instead, after applying light pressure, an area darker than the surrounding skin or one that is taut, shiny, or indurated is noted. Check for localized changes in temperature and texture of the skin, and request the patient to report any change in sensation.

### Moisture

The level of moisture present in the skin assists the nurse in predicting whether a patient is at risk for skin breakdown. Excessively dry skin lacks adequate lubrication, which increases the potential for fissures and cuts. In addition, dry skin is less pliable, thus increasing the risk for damage caused by shearing and friction. Conversely, moist skin folds create an optimal environment for yeast and bacterial invasion. Moisture caused by incontinence, gastric drainage, or other caustic substances can lead to skin irritation that may result in wound development. For both excessively dry and moist

**Table 49.5 Skin Color Abnormalities**

Color	Cause	Location	Significance
<b>Pallor: Acute</b>	Decreased blood flow Low hemoglobin levels	May be generalized or isolated to specific body regions	May indicate: Anemia, restricted blood flow (arterial insufficiency), shock
<b>Pallor: Nonacute</b>	Genetic predisposition	Generalized	Albinism
<b>Erythema (red)</b>	Increased blood flow	May be generalized or isolated to specific body regions	May indicate: Fever, inflammation, infection, pressure-related injury
<b>Cyanosis (blue)</b>	Poor perfusion Deoxygenated hemoglobin	Often localized to finger and toe tips, lips, mucous membranes	May indicate: Exposure to cold temperatures, heart failure (acute or severe chronic)
<b>Yellow</b>	Liver disease – Jaundice (icterus)  High levels of carotene	Generalized or isolated to sclera  Palms, soles, and face	May indicate: Increased bilirubin levels, increased hemolysis of red blood cells, increased carotene consumption
<b>Yellow: Nonacute</b>	Genetic predisposition	Generalized	Varies on the basis of ethnicity
<b>Brown</b>	Hemosiderin from RBCs becomes trapped in dermal layers  Increased melanin production	Ankle-to-calf region  Hormones cause darkening of the nipples, areola, genitalia, and face	Indicates chronic venous insufficiency  Occurs during pregnancy
<b>Brown: Nonacute</b>	Genetic predisposition	Generalized	Varies on the basis of ethnicity

skin, gentle cleansing techniques using products that contain skin protectants are used to minimize friction and protect the epidermis.

Increased moisture and humidity on the skin disrupt the stratum corneum's ability to function as a water-resistant

layer. Incontinence of urine, stool, or both may lead to incontinence-associated dermatitis (IAD), which is an inflammation of the skin caused by exposure to urine and/or stool. The condition leads to erythema, swelling, and skin breakdown that may be mild to severe. Table 49.6

**Table 49.6 Strategies to Promote Moisture Balance of the Skin**

Problem	Intervention	Rationale
<b>Excessive dryness</b>	Hydrate with emollients to soften skin	Soft, supple skin resists damage inflicted by pressure, shear, and friction.
<b>Excessive moisture</b>	Apply a moisture barrier  Avoid diaper use  In chronic or severe cases of incontinence, consider containment measures	Barrier products offer a protective layer that shields the epidermis from damage caused by moisture.  Diapers trap moisture and humidity against the skin, thus increasing the potential for development of skin lesions.  In severe cases, removing the presence of urine and stool using the least-invasive method should be considered to minimize skin damage.

provides effective moisture management strategies that can prevent serious and painful skin complications.

### Integrity

Skin integrity refers to the degree of intactness of the skin. Commonly, hospitalized persons face problems such as excessive moisture or dryness, **pruritus** (itching), skin tears, puncture sites, abrasions, edema, blistering, and immobility, and all of these conditions threaten skin integrity. The nurse examines the overall condition of the patient to implement etiology-based management strategies to minimize further skin deterioration.

Many factors can disrupt skin integrity (Table 49.7). When a skin condition is detected, the nurse documents the location, size, color, lesion characteristics, distribution, moisture and drainage, clinical manifestations of infection, and subjective findings. Subjective symptoms such as pruritus and burning may have many underlying causes, but early management helps minimize further skin deterioration. Once this information has been collected, members of the interprofessional team, which may include the primary healthcare provider; specialized physician teams such as dermatology, infectious disease, gastroenterology, and rheumatology; the wound ostomy continence nurse; and the primary nurse, can identify the underlying cause and develop a strategy to promote healing.

### Cleanliness

Poor self-care and hygiene habits such as the inability to clean the skin regularly because of functional, psychological, or economic causes can lead to a variety of problems that range from mild discomfort to full-thickness skin breakdown. These patients are at risk for localized and systemic infection as well as discomfort. Observation of self-care by the nurse provides the opportunity to evaluate the patient's functional status and helps identify areas for health-related education.

**Table 49.7 Factors That Disrupt Skin Integrity**

Factors	Causes
<b>Skin infections</b>	Fungal, bacterial, and viral pathogens
<b>Mechanical</b>	Friction, shear, immobility, adhesives, abrasion injuries
<b>Chemical</b>	Urine, stool, gastric fluids, caustic chemicals, soaps with high pH
<b>Inflammatory conditions</b>	Lupus, Crohn's disease, allergen exposure

### Tissue Changes

Many classifications for wound descriptions exist depending on the underlying wound etiology. When wounds emerge, they have the potential to penetrate through skin layers, subcutaneous tissue, and muscle into the bone. When describing skin damage in general, the terms “partial thickness” and “full thickness” may be used. In a partial-thickness wound, skin breakdown is limited to the epidermis and superficial dermis. These tissues are capable of healing by regeneration, whereas a full-thickness wound pervades through the dermal layers into subcutaneous tissue and muscle and may even expose bone. These wounds heal by scar formation, which has only 80% of the strength of normal skin. Refer to Chapter 50 for details about wound classifications.

### Vascular Markings

Vascular markings arise from malformations in a blood vessel that are visible on the skin. Spider angiomas (Fig. 49.6) and cherry angiomas (Fig. 49.7) are benign findings, whereas a port-wine stain (Fig. 49.8) is present at birth and may lead to dermal deformity with increased age. If an individual develops low platelet counts (thrombocytopenia) or severe systemic infection, microvascular dysfunction can lead to hemorrhage beneath the skin that has a red to purple discoloration. **Petechiae** are pinpoint-sized, nonblanching, red to purple flat lesions (Fig. 49.9). **Ecchymosis** refers to bruising that results from larger areas of hemorrhage under the skin.

### Lesions

In order to describe skin conditions using a uniform approach, the nurse uses a classification system. When

**FIGURE 49.6** Spider angioma.

**FIGURE 49.7** Cherry angioma.

**FIGURE 49.8** Port-wine stain.

**FIGURE 49.9** Petechial rash.

characteristics of lesions are documented, the anatomical location, type of lesion, color, distribution, and arrangement are identified. **Primary lesions** may emerge as a direct result of an infectious disease process, an allergic reaction, or an environmental cause. In addition, birthmarks are considered to be primary lesions and most often present as macules or patches. Primary lesions are described in Table 49.8. **Secondary lesions** describe a transformation of the primary lesion that may be caused by manual disturbance of the site that may develop secondary to itching or picking at the lesion, the treatment method implemented, or advancement of the underlying disease. Terms such as *clustered and coalesced* may be used to describe lesions that are grouped together or merge together. Secondary lesions are described in Table 49.9. Distribution refers to the extent and pattern of the lesions, and Table 49.10 provides an overview for commonly used terminology. The nurse describes in detail the arrangement of lesions when there are multiple affected areas.

### Screening for Malignancies of the Skin

Nevi, or moles, are circumferential, benign epidermal or dermal growths that are less than 1 cm in size and more common in patients with lighter skin tones. During skin assessment, the nurse evaluates these sites for cancerous cell changes. Guidelines from Table 49.11 offer an efficient way to identify when moles require evaluation from a skin care expert.

### Assessment of Dark Skin

Genetic predisposition and the level of activity of the melanocytes determine skin color, and when these factors produce darker skin tones, the assessment of erythema, cyanosis, and pallor becomes very difficult to visually detect. Specifically, erythema often appears as a deeper shade of the patient's natural skin color, and cyanosis and pallor may be noticeable only when assessing mucosal membranes or capillary refill. Therefore, the nurse uses information gathered from the patient's history and physical inspection and palpation to make an accurate assessment.

The nurse first questions the patient about normal skin appearance to better identify skin variations that may require further investigation. Visual inspection assists in identifying skin areas with an appearance that is inconsistent with the patient's natural skin tone. The nurse uses touch to detect temperature variations and the presence of edema, induration, or pain. If areas of suspected injury are noted, an interprofessional treatment approach is implemented.

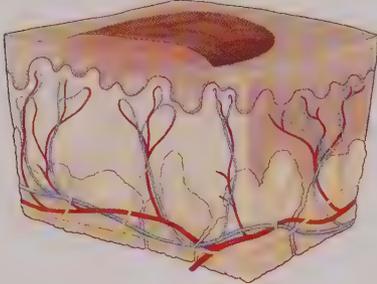

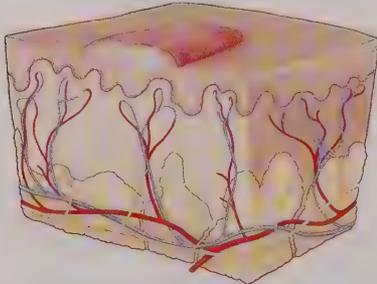

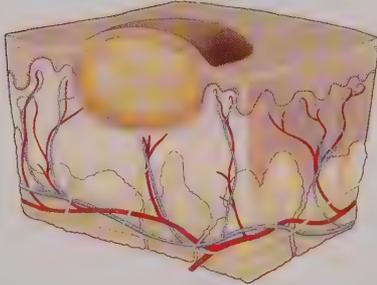

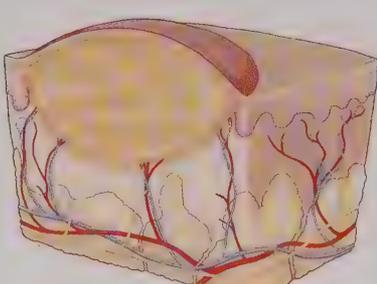

For patients in acute and long-term care settings, research supports using a proven risk assessment tool such as the Braden scale to predict risk for subtle skin changes caused

Table 49.8 Primary Skin Lesions

Lesion	Characteristics and Size	Examples	
<b>Macule</b>	<ul style="list-style-type: none"> <li>● Circumscribed</li> <li>● Flat</li> <li>● Nonpalpable</li> <li>● Shade other than skin color</li> <li>● Less than 1 cm in diameter</li> </ul>	<ul style="list-style-type: none"> <li>● Freckles</li> <li>● Flat moles</li> <li>● Petechiae</li> </ul>

**Table 49.10 Terms to Describe Distribution and Arrangement of Skin Lesions**

Distribution	
<b>Localized</b>	Limited to a small area
<b>Regional</b>	Distributed across a specific body part
<b>Generalized</b>	Distributed across numerous body parts
Arrangement	
<b>Annular</b>	Ring-shaped
<b>Iris/Target lesions</b>	Concentric rings
<b>Linear</b>	In a line
<b>Polymorphous</b>	Presenting in several different shapes
<b>Zosteriform</b>	Follows a dermatome
<b>Satellite</b>	Outlying lesion near a larger area of lesions

by immobility, moisture, and inadequate nutrition. The National Pressure Ulcer Advisory Panel has stated that nursing home residents with darkly pigmented skin have increased incidence of pressure injury in comparison to Caucasian residents. Difficulty with identifying the initial color change associated with tissue damage in darker skin leads to a delay in pressure injury identification and initiation of treatment.

**Table 49.11 Guidelines for Abnormal Skin Growths**

Characteristic	Normal Finding	Possible Malignancy
<b>Shape</b>	Symmetrical	Asymmetrical
<b>Border</b>	Regular	Irregular or blurring edges
<b>Color</b>	No color variation	Mixture of shades or colors
<b>Diameter</b>	Less than 6 mm	Greater than 6 mm and evolving or expanding

**Safety Alert Guidelines for Assessing Changes in Dark Skin**

- The following assessment strategies for patients with dark pigmented skin should be used:
1. Gather subjective information from the patient regarding normal skin appearance.
  2. Use inspection and palpation to investigate symmetrical differences in skin tone and texture.
  3. Use touch to detect increased heat, edema, boggy (excessive softness), and induration.
  4. Complete the patient's Braden score and evaluate the level of mobility to guide the selection of preventive measures.

5. Pay particular attention to skin covering pressure points and areas where the patient reports increased pain or discomfort.
6. Document findings upon completion of the skin assessment and closely monitor for any change in the patient's normal skin appearance.

## Braden Scale

In all healthcare settings, nurses must be knowledgeable about the risk of pressure injury as well as prevention strategies. The **Braden scale** is a commonly used tool that assists the nurse with identifying patients who are at risk for pressure-related skin damage. This tool requires the nurse to evaluate specific parameters for each patient: sensory perception, moisture, activity, mobility, nutrition, friction, and shear. Scores can range from 6 to 23, with a score of 1 or 2 in the mobility category as the most sensitive indicator for risk of pressure injury. Lower total scores indicate higher overall risk for developing alterations in skin integrity. Refer to Chapter 50 for further details about Braden scoring.

When a patient has a Braden score of 18 or lower, the nurse uses clinical decision-making skills to implement prevention strategies that address specific patient needs. Prevention measures are nurse-centered interventions that aim to redistribute pressure and include manual turning and repositioning for patients with decreased mobility, chair seat cushions that redistribute pressure, keeping the head of the bed lower than 30 degrees when patients are not at risk for aspiration, and heel protection. Certified wound ostomy continence nurses (CWOCNs) specialize in evaluating risk, recommending prevention and treatment strategies, and teaching patients, families, and staff about pressure injuries in many healthcare settings. See Box 49.2 for the CWOCN's job description.

## Hair Assessment

Color, cleanliness, quantity, thickness, texture, and distribution and lubrication of the patient's hair are evaluated during the skin assessment. Before physical assessment and palpation, the nurse questions the patient about recent or gradual changes in the texture or pattern of hair on all body surfaces. Underlying illness, nutritional deficits, medications, stress, and unhealthy dieting may cause hair loss or textural changes.

Regular and thorough hair hygiene helps to minimize discomfort and skin irritation. If a patient complains of discomfort, the nurse evaluates the area for abnormalities such as lesions, erythema, dandruff, and the presence of lice infestation. When the scalp is assessed, it is important to inspect for irregularly shaped moles or skin growths because patients are not able to independently visualize this body surface.

## Box 49.2 Role of the Certified Wound Ostomy Continence Nurse

### Wound Ostomy Continence Nurses Function in the Following Ways:

- Provide consultation that reflects best practices for managing patients with wounds of various etiologies, urostomies, colostomies, ileostomies, fistulas, and continence problems
- Suggest specialized devices for pressure redistribution to help prevent formation of or minimize deterioration of wounds affected by pressure
- Participate in educating staff, patients, and families about wound, skin care, and ostomy management strategies
- Conduct research to further the body of knowledge related to wound, ostomy, and continence issues

Adapted from Wound Ostomy and Continence Nursing Society. <http://www.wocn.org/>

The quantity, quality, and distribution of hair have a wide range of normal variations, and the nurse focuses on gathering information about any deviations from the individual's usual hair characteristics. For example, decreased amounts of hair and increased dryness of skin on the lower extremities indicate ischemic skin changes usually associated with arterial disease. Although gradual hair loss can be part of the normal aging cycle, many etiologies and medications can contribute to hair loss. Alopecia is the general term used to describe hair loss (Fig. 49.10), and the degree and pattern of loss varies on the basis of etiology (Table 49.12). **Hirsutism** describes excessive male-pattern hair growth in women (Fig. 49.11). An example is a female with male hair patterns on the face, chest, areolae, lower back, linea alba, and buttocks. Causes include ovarian disorders such as polycystic ovary syndrome, adrenal gland disorders, and long-term glucocorticoid therapy that leads to Cushing's syndrome. Because hair is often viewed as a cosmetic feature, the nurse focuses on changes in the pattern and texture of the hair that may be a sensitive subject for the patient.

**FIGURE 49.10** Alopecia secondary to chemotherapy.

**Table 49.12 Causes of Alopecia****Focal (Localized)  
Hair Loss****Etiologies**

- Genetic predisposition
- Scarring
- Postmenopausal state
- Inflammatory disorders
- Localized radiation therapy
- Androgen medications including anabolic steroids, tamoxifen, nortestosterone contraceptive pills

**Global (Diffuse)  
Hair Loss****Etiologies**

- Postpartum state
- Surgery
- High fever
- Nutrient deficiency and unhealthy diets
- High-acuity illness
- Emotional stress
- Radiation therapy to the head
- Heavy metal poisoning
- Medications including angiotensin-converting enzyme inhibitors, anticoagulants, antiparkinsonian and antiseizure agents, beta blockers, birth control pills, histamine blockers
- Chemotherapy including alkylating agents
- Chronic disease states including renal or liver failure, thyroid disease, autoimmune disease (i.e., lupus, inflammatory bowel disease)

**Nail Assessment**

Systemic illness, local infection, or occupational exposures contribute to variations in nail color, shape, consistency, and lesion formation. Because there are many causes for nail abnormalities, the key nursing intervention is to collect a thorough history about the disorder, ascertain whether changes are acute or chronic, and document findings. An interprofessional approach is frequently used to determine the etiology and manage treatment for nail disorders. The color, shape, and consistency of nails, along with the presence and characteristics of lesions, provide important information about the nails and overall health status.

**Color**

The color of the nail beds provides information about perfusion status as well as chronic illness. Normal capillary refill time (CRT) is less than 2 seconds. Common variations in nail bed coloration and their causes are listed in Table 49.13.

**Shape**

A normal nail adheres to the nail bed, is surrounded on three sides by the nail folds, and is slightly convex in shape. Alterations in nail shape often indicate chronic disease states.

**Consistency**

The consistency of the nail should be firm, and the underlying nail bed color should be visible. Overly thick nails are often a result of advanced age, infection, or heredity as well as **onycholysis**, which refers to the nail plate detaching from the nail bed. Additional variations in nail consistency are described in Table 49.13.

**Lesions**

Nail bed and nail fold lesions may be associated with a wide variety of skin conditions (Table 49.14). When nail conditions are present, bacterial or fungal pathogens may exacerbate the condition. Skin cancers such as squamous cell carcinoma and melanoma may become visible under the nail bed or on folds surrounding the nail.

**FIGURE 49.11** Hirsutism of face.**CASE STUDY: EPISODE 3**

Overall, Ms. Bloom's skin has a healthy appearance. All of her nail beds are pale pink and display CRT of less than 2 seconds. She appears to have adequate moisture balance as evidenced by the absence of cracks, excessive dryness, or scabs. Skin, hair, and nails are clean and well-groomed. Hair distribution is appropriate on the basis of age and gender. The rash is located below the neck on her anterior chest wall and measures 6 cm × 8 cm × 0 cm, which correlates to the length times width times depth. The site has erythema with a well-defined border and increased warmth in comparison with surrounding skin. Within

the 6 cm × 8 cm × 0 cm erythematous area, there are scattered, serous-filled, intact vesicles that are localized to the chest. The affected area appears to have increased moisture, but there are no localized signs of infection. Ms. Bloom reports a low-grade fever, pruritus, and burning. The provider orders the collection of a sterile swab culture of a vesicle base to rule out an infectious source...

### Connection Check 49.3

Which clinical finding requires additional investigation by the nurse?

- A. CRT less than 2 seconds
- B. New-onset petechial rash
- C. A macule with symmetrical shape, regular border, and uniform color
- D. Pale or cyanotic nail bed after exposure to cold temperatures

**Table 49.13 Variations in Nail Color, Shape, and Consistency**

#### VARIATIONS IN NAIL COLOR

Color	Significance	
<b>Yellow</b>	Yellow nail syndrome is associated with lymphedema and chronic respiratory diseases	
<b>White (opaque)</b>	Abnormal keratinization of nail matrix that may be caused by cirrhosis, inflammatory bowel disease, or heredity	
<b>Partially opaque nails</b>	Terry's nails, white, ground glass appearance, may be associated with chronic diseases including congestive heart failure, end-stage renal disease, liver disorders, and diabetes mellitus	
<b>Cyanotic</b>	Decreased perfusion, respiratory failure, or cold temperatures

**AGE-RELATED SKIN CHANGES**

The performance of the five basic functions of the skin (protection, temperature regulation, vitamin D metabolism, sensation, and excretion) becomes less efficient as the body ages. In older adults, the skin becomes increasingly fragile, takes longer to heal, and is more prone to age-related skin conditions (Table 49.15).

Structurally, the vascularity of the dermis decreases, which leads to slower healing rates and a thinner dermis. In addition, the cycle of maturation of the epidermis begins to slow by approximately 50%, and this delay interrupts wound contraction. Flattening of the rete ridges weakens the strength of the epidermal-dermal junction, thus increasing the risk for skin tearing even with minor trauma. Collagen and elastin begin to steadily break down, which weakens the tensile strength of the skin. These structural changes cause the skin to function less effectively as a barrier and increases the risk for damage.

In addition to structural changes that affect the skin's protective ability, there are changes that occur in the immune system cells found in the skin. With age, the quantity of Langerhans and mast cells decreases, and this negatively impacts the body's ability to recognize and mobilize an immediate inflammatory response to pathogen invasion. Additionally, fewer active melanocytes increase the risk for sun-related skin damage.

Temperature regulation and excretion become less efficient because of decreased subcutaneous tissue, fewer sweat glands, and reduced vascularity. These changes increase the risk for exposure-related injury such as heat stroke and hypothermia. Older individuals also develop a decreased perception of injury because fewer sensory receptors are present in the skin layers. Hair and nail growth rates decrease as well. See Geriatric/Gerontological Considerations for an overview of specialized skin care for older patients because of their increased susceptibility to complications from alterations in skin integrity.

**Table 49.15 Common Age-Related Skin Conditions**

Condition	Appearance	Description	Medical Management
<b>Xerosis</b>	Skin appears rough and scaly; it may be erythematous and cracked  Frequently located on extremities (Fig. 49.12)	Dry skin that is very uncomfortable. Patients often describe pruritus or burning.	Mild, pH-balanced soaps are used for bathing. Limit bathing time to 10 minutes and use warm water. Twice daily use of moisturizers is encouraged.
<b>Eczema</b>	Erythema, weeping, crusting, scales, and severe pruritus (Fig. 49.13)	Skin inflammation (or dermatitis) that may become chronic with scratching and rubbing	Topical steroids
<b>Psoriasis</b>	Thick, flaky, silvery skin covering circumferential red patches; skin, hair, and nails may be affected (Fig. 49.14)	These lesions emerge from overproduction of epidermal cells. These sites may not be pruritic.	Topical steroids
<b>Herpes zoster (shingles)</b>	Blistering and erythema along a dermatome (Fig. 49.15)	Results from resurgence of varicella virus. Subjective symptoms include burning and pain.	Lidocaine patch to affected area  Antiviral medications

## Geriatric/Gerontological Considerations

### Skin Care Considerations for Older Adults

- Identify risk factors for impaired skin integrity as a result of immobility, chronological age, malnutrition, incontinence, compromised perfusion, immunocompromised status, chronic medical conditions such as diabetes mellitus, spinal cord injury, or renal failure.
- Use mild, pH-balanced soaps for cleansing.
- Limit number of complete baths to two to three per week and alternate them with partial baths. Excessive bathing depletes aging skin of moisture and increases dryness.
- Bathe with warm water (between 90° F [32.2°C] and 105° F [40.8°C]), and limit bathing time to approximately 10 minutes.
- Apply moisturizers twice a day to prevent skin from drying out.
- Avoid skin care products that contain allergens such as lanolin, latex, and dyes.
- When incontinence is present, clean skin immediately after incontinence episode. Use skin barrier creams to shield skin from frequent exposure to moisture.
- During hospitalization, implement skin preservation measures including daily skin moisturizing, assist with frequent repositioning, and consider pressure redistribution devices for older adults with decreased mobility.
- Ensure fluid intake within cardiac and renal limits to a minimum of 1,500 mL per day.

### Connection Check 49.4

The nurse is teaching skin care guidelines to the caretaker of a 79-year-old incontinent female who has a total Braden score of 14 with a score of 2 in the mobility category. What are appropriate educational priorities? (*Select all that apply.*)

- Gently cleanse and dry the skin immediately after an incontinence episode
- Use a toileting schedule to minimize episodes of incontinence
- Aggressively clean the patient's skin after an incontinence episode
- Assist the patient with repositioning at least every 2 hours
- Use diapers for stool and urine containment

## DIAGNOSTIC STUDIES AND NURSING CONSIDERATIONS

### Laboratory Studies

#### Tissue Culturing

When a skin infection is suspected, microscopic examination of the tissue allows for identification of the pathogen. Methods of tissue collection vary depending on the lesion's characteristics but include the swab culture, needle aspiration culture, and biopsy. The method for collection varies depending on the appearance and extent of the affected area. Once the infective organism has been identified, the

**FIGURE 49.12** Xerosis (dermatitis).

**FIGURE 49.14** Psoriasis vulgaris: elbow.

**FIGURE 49.13** Eczema.

**FIGURE 49.15** Varicella-zoster virus infection.

- Biopsy examines deeper layers of the skin for infecting organisms and represents the gold standard for wound culture. Types of tissue biopsy are discussed later in the chapter.

Nurses are responsible for obtaining a swab culture specimen (Box 49.3). Needle aspiration cultures and biopsies require advanced practice skills because of the use of sharp instruments to remove tissue, and these specimens are collected only by an advanced practice registered nurse or healthcare provider.

### **Diagnostic Studies**

In addition to tissue surveillance by way of culturing, additional laboratory and diagnostic evaluations may be ordered to ensure appropriate treatment for patients who are suspected of having a more serious skin infection. These include:

1. Complete blood count (CBC) to evaluate for infection. This test can also help reveal if the infection is an acute occurrence.

culture also determines the appropriate medication for treatment.

- Swab cultures collect fluid from the most superficial tissue layers. Although this process has minimal risk factors for bleeding or additional infection, it represents the least accurate type of culture. Swab cultures identify the correct infecting organism approximately 60% of the time.
- Needle aspiration cultures pinpoint the types of infective organisms that have invaded tissues surrounding the wound bed. This process involves inserting a needle into the periwound to aspirate fluid from surrounding tissues.

### Box 49.3 How to Obtain a Swab Culture (Levine Technique)

1. Evaluate the wound bed to locate a 1-cm<sup>2</sup> area of clean, viable wound tissue.
2. Prepare to use sterile technique and a sterile collection tube to obtain a specimen.
3. Clean the entire wound bed using a nonantiseptic solution such as normal saline to remove surface residue.
4. Moisten the sterile swab with normal saline.
5. Rotate swab with gentle pressure within a 1- to 2-cm<sup>2</sup> area of clean wound tissue for 5 seconds. The goal is to express fluid from the deeper layers of the wound into the entire swab.
6. Place the swab into the sterile container without touching other surfaces on the skin or the tube to reduce the risk of contamination.
7. Label the specimen with patient identifiers, wound site, and time collected.
8. Send the specimen to the laboratory without delay to reduce risk for contamination.

Adapted from Bryant, R. A., & Nix, D. P. (2012). *Acute & chronic wounds: Current management concepts* (4th ed.). St. Louis, MO: Mosby Elsevier.

2. Chemistry screening to evaluate protein status (albumin) as well as the accumulation of waste products in the blood (lactate, blood urea nitrogen, creatinine)
3. Blood cultures to identify whether the organism has entered the circulatory system.
4. Doppler ultrasound to evaluate blood flow through vessels. Skin infections may cause severe soft tissue swelling that occludes blood flow or contributes to clot development.

#### Management

An abnormal value indicates that a skin infection is present, and Table 49.16 provides an overview of common skin infections. Treatment often involves topical and systemic medications; however, surgical tissue debridement may be indicated for severe, rapidly spreading conditions.

#### Fungal Infection

Fungal skin lesions often manifest as erythematous coloration, well-defined edges, scaling, pustules, papules, plaquelike distribution, and satellite lesions (Fig. 49.16). These rashlike lesions may emerge on any moist skin surface, and patients frequently report itching and burning from the affected area.

If pustules are present, an intact pustule should be removed and placed in a sterile container for analysis. The roof of the lesion is inspected for fungal characteristics. Skin scraping may be used in the absence of pustules; however, the test results may not be as accurate. During diagnostic evaluation of a fungal specimen, a potassium hydroxide (KOH) preparation is most frequently used because it partially dissolves the keratin protein so that the fungal cells become perceptible in the specimen.

**Table 49.16** Categories of Skin Infections

Categories	Etiologies
<b>Fungal infections</b>	Candidiasis
	Dermatophytoses (tinea)
<b>Bacterial infections</b>	Folliculitis
	Intertrigo (inflammation on skin surfaces that rub together)
	Abscess
	Cellulitis
	Necrotizing fasciitis
<b>Viral infections</b>	Varicella
	Herpes simplex virus
	Herpes zoster
	Rubella
	Measles
	Human papillomavirus

**FIGURE 49.16** Cutaneous candidiasis.

#### Bacterial Infection

Bacterial skin conditions may range from a mildly uncomfortable pustule on a hair follicle to insidious infections that destroy the skin and fascia of an entire extremity. Because there are many types of bacterial skin infections with a variety of clinical presentations, culture or biopsy is very effective in the identification of the causative organisms. When intact fluid-filled lesions are present, the swabbing technique may be used to absorb aspirate from the wound base of vesicles, pustules, or bullae that may be cultured.

## Viral Infection

Viral skin lesions often have a vesicular appearance and may be highly contagious. The primary method for culturing is gentle scraping of the vesicle base using a scalpel. When the affected area is on a mucous membrane, the site may be swabbed and sent for culture. If viral skin infections are severe, additional diagnostic testing may be indicated.

### Patient Preparation

In preparation for a swab specimen or removal of a blister or pustule, the provider reinforces that the purpose of specimen collection is to assess for tissue infection. Obtaining consent and discussing possible complications are the responsibilities of the healthcare provider. Before the culture is completed, it is essential that the nurse ensures that the patient understands what to expect from the procedure.

Ideally, the specimen is collected before any antiseptic cleansers, topical or systemic antifungal, antibiotic, or antiviral medications are used for treatment. This helps ensure a representative specimen and ultimately helps identify the most effective pharmaceutical treatment. This guideline may not be realistic if the patient is severely ill, and in these cases, the safety of the patient takes precedence over tissue sample collection. Initially, the nurse ensures that the patient is stable before proceeding to specimen collection. A pain management plan must be in place and discussed with the patient before starting the procedure.

### Nursing Implications

Nurses are frequently responsible for educating the patient about the skin condition and cause, treatment, and prevention. Also, nursing staff may be required to collect cultures using the swabbing technique described in Box 49.3.

## Skin Biopsy

Skin biopsy is a key diagnostic tool that allows for microscopic examination of skin conditions or infections. Shave, punch, and excisional biopsies are commonly used techniques, and these techniques differ in the amount and depth of tissue removal. Biopsy is indicated for ulcers and nodules ensuring that all skin layers are scrutinized. When skin biopsy is completed in a timely fashion, it assists with diagnosis as well as identification of an appropriate treatment.

- Shave biopsy is used to collect superficial tissue samples of the epidermis and dermis. A sterile blade is used to remove a small piece of skin tissue, and healing occurs through tissue regeneration.
- A punch biopsy, which is the most frequently used technique, removes a circular, continuous section that contains epidermis, dermis, and upper layers of subcutaneous tissue. The sample is approximately 3 to 4 mm wide, and local analgesia is administered. Closure of the site may require minimal suturing.
- An excisional biopsy removes a relatively large, deep section of tissue. This technique may be used to remove an entire lesion, so sutures, a graft, or even a flap may be required to close the area.

### Significance of Abnormal Values

After a skin biopsy, the specimen is analyzed. Common abnormal diagnoses include skin cancer, benign growths, bacterial or fungal infection, or inflammatory lesions. Table 49.17 provides information about common treatment plans. Removal procedures include excision, freezing with

**Table 49.17 Treatment for Abnormal Biopsy Results**

Laboratory Result	Treatment
<b>Malignant growth:</b> <b>Melanoma</b> <b>Basal cell carcinoma</b> <b>Squamous cell carcinoma</b>	Treatment involves surgical removal of the lesion as well as removal of 5–6 mm of healthy tissue surrounding the lesion to ensure safe margins. Depending on the size and extent of the affected area, surgical removal may be done at one time or over multiple visits.
<b>Benign growth</b>	Lesion may be removed on the basis of patient preference. If the lesion has the potential to become cancerous, the site is excised.
<b>Bacterial infection</b>	Completing a Gram stain of the biopsy helps to determine whether the infective agent is gram-positive or gram-negative. On the basis of this information, broad-spectrum antibiotics are started. When the organism has been isolated, the antibiotic choice may be re-evaluated. Also, a complete blood count, ultrasound, and/or blood cultures may be appropriate to evaluate the systemic response to infection.
<b>Fungal infection</b>	Potassium hydroxide preparation is used to reveal the fungal infection. Depending on the extent of the affected area, systemic antifungal medications may be added to a topical antifungal treatment.
<b>Inflammatory lesions</b>	There are many causes for inflammatory lesions that range from internal sources such as lupus or inflammatory bowel disease to external sources that trigger a contact dermatitis. Treatment must be guided by the underlying etiology. This requires blood work and additional diagnostic testing.

liquid nitrogen (**cryosurgery**), a type of surgery that involves the use of extreme cold to destroy abnormal tissues, laser removal, and topical creams.

### Patient Preparation

When preparing a patient for skin biopsy, the provider ensures that the patient understands what to expect during the procedure. Before the procedure, patients are questioned about recently ingested medications and bleeding abnormalities so that patients with increased risk for bleeding are managed safely. The pain management plan that is appropriate for the type of biopsy being completed is explained, as well as the most common risks associated with this procedure, including infection and scarring.

Before skin layers are removed via biopsy in the severely acute, immunocompromised, and chronically ill patient populations, the individual patient risk factors and goals for care are considered and discussed with the interprofessional team. Ultimately, these surveillance techniques can increase the patient's risk for infection because the process creates a wound bed and provides an entry site for additional pathogens.

### Nursing Implications

Removal of the skin tissue sample is performed by a specially prepared healthcare provider. Nursing responsibilities focus on monitoring and supporting the patient's response to the procedure. After the procedure, the nurse ensures that the patient understands the general biopsy site care instructions (Box 49.4). Depending on the extent and depth of the tissue removed, site care instructions may require individualization.

The comprehensive assessment of the integumentary system provides an overview of the overall health status, as well as specific data related to the status of the skin, nails, and hair. Table 49.18 provides guidelines related to providing care to patients with impaired skin integrity.

### Connection Check 49.5

A patient presents with a new-onset, erythematous rash that contains intact pustules. Subjective symptoms include itching and burning. Which diagnostic evaluation is most helpful in determining the underlying etiology?

- Excisional biopsy
- Skin scraping
- Sterile collection of pustule roof
- Cryosurgery

### Connection Check 49.6

The nurse questions which intervention in the stable patient with the nursing diagnosis "Impaired skin integrity related to draining skin lesions on right lower extremity"?

- Place patient on isolation precautions
- Obtain a swab specimen from wound bed after cleansing with a non-antiseptic solution
- Educate patient about wound and skin treatment regimen
- Administer broad-spectrum antibiotic before obtaining a culture

## Box 49.4 Biopsy Site Care Instructions

- Leave the initial dressing in place for the rest of the day. A small amount of pink or red drainage is normal.
- Change the dressing daily until the site has healed (usually 1–2 weeks). Healing is defined as the absence of open wounds.
- When performing site care, wash and dry your hands. Wash the site with soap and water, then dry thoroughly. Cover with a Band-Aid or dressing and change it daily.
- If erythema, edema, increased pain, or drainage develops, clean the site with hydrogen peroxide and cover it with the dressing. Contact the provider who collected the biopsy for further instructions.
- Showering is permitted the day after the biopsy. While the site is healing, avoid activities that require full immersion in water such as swimming or soaking in a bath.

**Table 49.18 Evidence-Based Practice Guidelines for Impaired Skin Integrity Interventions—cont'd**

Intervention	Rationale
<ul style="list-style-type: none"> <li>● Use a validated risk assessment tool such as the Braden scale to identify individuals at risk for skin breakdown due to pressure</li> </ul>	Targeting variables can focus assessment on particular risk factors and guide prevention and care
<ul style="list-style-type: none"> <li>● Inspect and monitor skin and high-risk areas such as bony prominences at least once a day for color changes, erythema, swelling, warmth, pain or other sign of infection, or changes in sensation</li> </ul>	Systematic inspection can identify impending problems early
<ul style="list-style-type: none"> <li>● Monitor the patient's skin care practices, type of cleansing agent, temperature of water, and frequency of skin cleaning. Cleanse the skin gently with pH-balanced cleansers.</li> </ul>	Cleansing should not compromise the skin
<ul style="list-style-type: none"> <li>● Individualize skin care plan according to the patient's skin condition and needs and preferences</li> </ul>	Avoid harsh cleansing agents, hot water, extreme friction or force, or cleansing too frequently
<ul style="list-style-type: none"> <li>● Monitor the patient's incontinence status and minimize exposure to moisture from perspiration or wound drainage.</li> </ul>	Moisture may contribute to pressure injuries development by macerating the skin
<ul style="list-style-type: none"> <li>● Evaluate for use of support surfaces (specialty mattresses, beds, chair cushion, or other devices)</li> </ul>	Pressure reducing devices limit risk of skin breakdown due to decreased tissue perfusion
<ul style="list-style-type: none"> <li>● Assess nutritional status</li> </ul>	Optimizing nutritional intake, including calories, fatty acids, protein, vitamins is needed to promote wound healing
<ul style="list-style-type: none"> <li>● Interprofessional collaboration should be used for assessment and management</li> </ul>	Collaboration promotes consistency, decreases costs, and reduces errors. The added expertise from all team members benefits not only the patient but the caregivers. Healthcare professionals involved in the care of patients must be willing and able to work together toward positive patient outcomes

## Making Connections

### CASE STUDY: WRAP-UP

On the basis of information gathered in the history and physical assessment, this rash is characteristic of an allergic contact dermatitis brought on by the recent change in the patient's fragrance. The nurse teaches Ms. Bloom to discontinue the new fragrance and explains how the rash may progress. Explaining that the contact with the new spray led to an acute allergic contact dermatitis, the nurse describes that the rash will most likely develop into vesicles opening into erosions that will then crust and eventually flake off.

#### Case Study Questions

- Which skin layers have been affected by Ms. Bloom's allergic contact dermatitis?
  - Dermis only
  - Epidermis only
  - Both epidermis and dermis
  - Subcutaneous tissue
- When a sterile swab specimen is collected, which statement best describes the correct technique?
  - Rotate swab with gentle pressure within a 1- to 2-cm<sup>2</sup> area of nonviable wound tissue
  - Saturate swab with drainage found in the base of the wound
  - Rotate swab with gentle pressure within a 1- to 2-cm<sup>2</sup> area of clean wound tissue
  - Clean the wound with an antiseptic solution before obtaining the specimen
- What information is important to include regarding site care instructions for the healing rash?
  - Clean skin with an abrasive surface to remove dried substances
  - Moisturize the drying rash with emollients to soften and gently remove crusts
  - Manually drain the vesicles
  - Avoid showering while rash persists

4. The nurse recognizes which description as indicative of a vesicle?
  - A. Less than 1 cm in diameter, circumscribed, elevated, serous-filled
  - B. Size varies, circumscribed, elevated, pus-filled
  - C. Less than 1 cm in diameter, circumscribed, elevated, palpable, firm
  - D. Greater than 1 cm in diameter, flat, elevated, firm, rough
5. The nurse correlates which surveillance cell, present in the epidermal layers, as introducing the allergen to the T cells?
  - A. Macrophage
  - B. Merkel cells
  - C. Mast cells
  - D. Langerhans cells

## CHAPTER SUMMARY

Water-resistant keratinocytes form the epidermis, hair, and nails, whereas the dermis contains blood vessels, nerves, immune system cells, dermal proteins, hair follicles, and sweat and sebaceous glands. All of these structures contribute to the integumentary functions of protection, temperature regulation, vitamin D metabolism, sensation, and excretion.

Comprehensive assessment of integumentary function requires collection of the patient's history followed by inspection and palpation. Integumentary assessment varies depending on the patient's presenting complaint. For example, in an ambulatory practice, the assessment may be focused on a new-onset skin condition that is confined to a specific body area, whereas in the inpatient setting with the complications of acute or chronic illness and immobility, the skin assessment should be conducted on all body surfaces at regular intervals in addition to the Braden scale to predict risk for pressure injury.

Depending on the setting and the extent of the skin condition, the history may include demographic data, comorbidities and medication history, family history, diet, and environmental factors such as occupational and sun exposure. The assessment of the skin, hair, and nails often occurs because of a change or deterioration in appearance or function; therefore, gathering the patient's subjective report represents a key assessment component. Important physical assessment guidelines for the skin include color,

temperature, moisture, overall integrity, cleanliness, tissue loss, vascular markings, and lesions. For hair, it is important to observe for cleanliness, quantity, quality, and distribution. In the presence of nail abnormalities, the nurse evaluates for variations in color, shape, consistency, and lesion formation.

Skin changes that occur normally with aging lead to a slow deterioration in overall structure and function of the integumentary system. Specifically, aged skin has decreased vascularity, tensile strength, and immune cell surveillance; slower healing rates; and less-efficient temperature regulation and excretion mechanisms. When these natural skin changes are combined with excessive exposure to chemicals or sun, comorbidities that affect perfusion to skin layers, and medications that have skin-related side effects, serious complications may develop. Potential problems include pain-producing lesions, excessive hair growth or loss, wounds with delayed healing, alterations in the patient's body image, and infection.

Infectious sources may be fungal, bacterial, or viral in origin. Laboratory studies, which may include culture, site biopsy, CBC, chemistry screening, blood cultures, and ultrasound, may be used to identify the pathogen. Treatment varies depending on the extent and severity of the infection or other abnormality such as cancer. Nurses are responsible for collecting swab specimens, managing pain, monitoring the patient during specimen collection, and teaching the patient and family about expectations during the procedure and postprocedure site care. Any technique that requires a sharp instrument to remove the specimen should be completed only by an advanced practice nurse or provider.

Although the body maintains a healthy state, the skin, hair, and nails protect internal structures and support homeostasis. Conversely, during times of prolonged acute and chronic illness, these protective tissues may succumb to skin failure. The white paper published by the National Pressure Ulcer Advisory Panel recognizes that not all pressure injuries are preventable, especially in those at the end of life who are frail. If a terminal pressure injury develops and the healing process cannot be re-established in someone with a terminal illness, at the end of life, or in the critically ill person, then the primary goal should no longer be wound closure. Palliative wound care as a concept is still developing, and it is not restricted to hospice care; nor does it imply that curative treatments should not be implemented and cannot be effective. Instead, the primary goals should shift to symptom management.

# Chapter 50

## Coordinating Care for Patients With Skin Disorders

Catherine Ratliff

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Discussing the epidemiology of disorders of the skin
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Bacterial skin infections
  - b. Herpes simplex
  - c. Fungal infections
  - d. Psoriasis
  - e. Skin trauma
  - f. Pressure injuries
  - g. Skin cancer
  - h. Reconstructive surgery
3. Describing the diagnostic results used to confirm the diagnoses of skin disorders
4. Discussing the medical management of:
  - a. Bacterial skin infections
  - b. Herpes simplex
  - c. Fungal infections
  - d. Psoriasis
  - e. Skin trauma
  - f. Pressure injuries
  - g. Skin cancer
  - h. Reconstructive surgery
5. Describing complications associated with skin disorders
6. Developing a comprehensive plan of nursing care for patients with skin disorders
7. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with skin disorders
8. Describing the process and stages of wound healing

### CONCEPTS

- Assessment
- Cellular Regulation
- Infection
- Medication
- Perfusion
- Promoting Health
- Skin Integrity

### ESSENTIAL TERMS

Abrasion  
Actinic keratosis  
Angiogenesis  
Basal cell carcinoma

Tunneling  
Undermining

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Martin Parker is a 42-year-old man with a 20-year history of T-10 paraplegia from a skiing accident who presents with a left ischial pressure injury measuring 2 cm (L) × 3 cm (W) × 10 cm (D). His wound started about 5 years ago after a furuncle (boil) was opened and drained. He had debridement surgery in the past but was disappointed when this created a larger wound that still has not healed. He has never been told that he has osteomyelitis (bone infection) before. He is currently packing gauze in his wound and changing the dressing one or two times daily. There is undermining of 2 cm from 6 o'clock to 10 o'clock around the wound edge. Wound edges are rolling inward (epibole). The base of the wound is not visible. When probing the wound, the nurse feels exposed, rough bone. Exudate is thick, yellow, and malodorous. The packing in the wound is saturated, as is the secondary dressing over the top of the wound. The periwound skin is intact, and erythema extends greater than 5 cm from the wound's edge. No induration or hardness is palpated along the periwound skin. He has had night sweats over the past three nights but has not taken his temperature.

Mr. Parker has no comorbidities. He is on a strict bowel regimen where he uses an enema every other day to be continent of bowel movements. He catheterizes himself several times a day. He is an accountant and spends much of his time in his wheelchair. He has a pressure-reducing cushion on his wheelchair but does not do his "push-ups" as often as he should. He does not have a specialty mattress at home. Mr. Parker has a very supportive wife...

## INTRODUCTION

The skin is the largest organ of the body and consists of two main layers: the epidermis (outer layer) and the dermis (inner layer). The primary function of an intact epidermis is protection, whereas the main function of the dermis is to provide strength, support, blood, and nutrients to the epidermis. Lastly, the subcutaneous tissue, which is composed of adipose tissue (fat), connective tissue, blood vessels, lymphatic vessels, and nerves, lies beneath the dermis. This layer helps to anchor the dermis to the underlying structures, provides insulation for temperature regulation, and provides cushion-like protection or padding for the skin and underlying structures.

The natural flora on the surface of the skin helps protect against harmful microorganisms. However, penetration of the skin from repeated exposure to environmental hazards,

trauma, or chronic disease weakens the skin's protective function, increases the likelihood of skin breakdown, and places the patient at risk for infection. This chapter focuses on skin infections, selected skin disorders, skin trauma, and skin cancers. Additionally, reconstructive surgery for patients with a history of skin disorders is presented.

## BACTERIAL SKIN INFECTIONS

Skin and soft tissue infections are categorized according to the depth of infection, tissues involved, and interventions necessary to resolve the infection (Box 50.1). The U.S. Food and Drug Administration classifies skin and soft tissue infections as uncomplicated or complicated. Uncomplicated skin and soft tissue infections include superficial **cellulitis** (a diffuse spreading infection of the dermis and subcutaneous tissues; Fig. 50.1), **folliculitis** (inflammation of the hair follicles; Fig. 50.2), impetigo (Fig. 50.3), **furuncles** (boils), simple abscesses, and minor wound infections. These infections usually respond to antibiotic therapy alone or surgical drainage with or without antibiotic therapy. Alternatively, complicated skin and soft tissue infections involve the invasion of deeper tissues by microorganisms, which usually requires considerable surgical **debridement** (removal of dead or infected skin to facilitate healing), as well as infections that occur in the presence of a systemic disease process that may affect the patient's response to therapy. As with most complicated skin and soft tissue infections, necrotizing soft tissue infections are wounds that contain dead, or necrotic, tissue that provides an optimum medium for bacterial growth and require surgical intervention. These infections can involve the dermis and subcutaneous tissues (necrotizing cellulitis), the fascia (**necrotizing fasciitis**), and the muscle. However, it is often difficult to determine the depth and severity of the infection at presentation. Thus, identifying tissue involvement, classifying the infection, and directing treatment can be challenging.

Table 50.1 lists commonly occurring uncomplicated skin and soft tissue infections, the causative organisms, a description of the infection, the presenting clinical manifestations, and the usual treatment. It is important to understand that treatment modalities can change significantly depending on the age of the patient and the strain of bacteria. Additionally, treatment varies for immunocompromised patients or those with other comorbidities.

## Epidemiology

Uncomplicated skin and soft tissue infections occur in many settings, involve different bacteria, and are usually mild to moderate in severity. Most skin and soft tissue infections are caused by gram-positive bacteria such as *Staphylococcus aureus* and *Streptococcus pyogenes*.

**Methicillin-resistant *Staphylococcus aureus* (MRSA)** infections are categorized as either community acquired (CA-MRSA) or healthcare acquired (HA-MRSA), with

## Box 50.1 Superficial Surgical Site Infections

The CDC defines a superficial surgical site infection as meeting the following criteria: infection occurring within 30 days after the operative procedure, involving only skin and subcutaneous tissue of the incision, and the patient has at least one of the following:

- Purulent drainage from the superficial incision
- Organisms isolated from an aseptically obtained culture from the superficial incision or subcutaneous tissue
- Superficial incision that is deliberately opened by a healthcare provider and is culture-positive or is not cultured and the patient has at least one of the following clinical manifestations: pain or tenderness, localized swelling, erythema, or heat (A culture-negative finding does not meet this criterion.)
- Diagnosis of a superficial incisional surgical site infection by the healthcare provider

The CDC defines a deep incisional surgical site infection as meeting the following criteria:

- Infection occurs within 30 or 90 days after the operative procedure, involves deep soft tissues of the incision (e.g., fascial and muscle layers), and the patient has at least one of the following clinical manifestations:
  - Purulent drainage from the deep incision
  - A deep incision that spontaneously dehisces (opens or separates) or is deliberately opened or aspirated by a healthcare provider and is culture-positive or is not cultured and the patient has at least one of the following clinical manifestations: fever (greater than 100.4°F [38°C]) or localized pain or tenderness (A culture-negative finding does not meet this criterion.)
  - An abscess or other evidence of infection involving the deep incision that is detected on anatomical or histopathological examination or imaging study

Organ/space surgical site infections must meet the following criteria:

- Infection occurs within 30 or 90 days after the procedure and involves any part of the body deeper than the fascial/muscle layers that is opened or manipulated during the operative procedure, and the patient has at least one of the following clinical manifestations:
  - Purulent drainage from a drain that is placed into the organ/space (e.g., closed suction drainage system, open drain, T-tube drain, CT-guided drainage)
  - Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
  - An abscess or other evidence of infection involving the organ/space that is detected on gross anatomical or histopathological examination or imaging study

CDC, Centers for Disease Control and Prevention; CT, computed tomography.

**CA-MRSA being more common.** Community-acquired MRSA begins as a localized skin infection from a break in the skin among healthy individuals who have not been hospitalized. Community-acquired MRSA and HA-MRSA are transmitted through direct contact with colonized skin or the surface of a shared item where MRSA is present.

FIGURE 50.1 Cellulitis.

FIGURE 50.2 Folliculitis.

FIGURE 50.3 Impetigo.

Approximately 80% of CA-MRSA cases are uncomplicated skin and soft tissue infections in the form of cellulitis, folliculitis, impetigo, or an abscess.

The risk of MRSA infection after surgery is generally low but affects up to 33% of patients after certain types of surgery. Postoperative MRSA infections can occur as surgical site infections, chest infections, or bloodstream infections (BSIs; bacteremia). The incidence of MRSA surgical site infections varies from 1% to 33% depending on the type of surgery performed and the carrier status of the

**Table 50.1 Uncomplicated Skin and Soft Tissue Infections**

Infection	Causative Organism(s)	Description	Clinical Manifestations	Treatment
<b>Impetigo</b>	MSSA Group A strep	Contagious, localized, inflammatory skin infection	Vesicles, pustules, honey crusted sores on face or extremities without systemic symptoms	Topical mupirocin (Bactroban) ointment  For those with limited lesions
<b>Folliculitis</b>	MSSA CA-MRSA <i>Staphylococcus aureus</i>	Superficial inflammation and infection of hair follicles	Multiple or single pustules with hair follicle in center on any skin bearing hair	Moist heat; topical mupirocin (Bactroban) ointment  Clindamycin 1% lotion or gel; alternatively, benzoyl peroxide 5% wash may be used when showering for 5 to 7 days. Treatment for MRSA usually requires two oral antibiotics.
<b>Furuncle ("boil")</b>	MSSA CA-MRSA	Infection of hair follicle that extends through dermis into subcutaneous tissue and forms a small abscess	Inflammatory nodule with overlying pustule with hair follicle in the center; outbreaks can occur in families or settings with close personal contact (sports); chronic furunculosis with nasal colonization of MRSA	Small: moist heat  Large: incision and drainage and systemic antibiotics  Furunculosis: mupirocin (Bactroban) ointment intranasally
<b>Carbuncle</b>	MSSA	A furuncle that extends into adjacent follicles	Coalescent inflammatory lesion; pus drains from multiple follicles; typically on back and neck	Incision and drainage; systemic antibiotics
<b>Cellulitis</b>	Most commonly: Group A strep  CA-MRSA  MSSA	Diffuse infection of the dermis and subcutaneous tissue; usually occurs through breaks in the skin	Painful, edematous, warmth with poorly demarcated borders of erythema on any part of the body; usually unilateral; lymphadenitis, lymphangitis; fever may be present	Systemic antibiotics
<b>Cutaneous abscess</b>	Polymicrobial	Collections of pus within the dermis and subcutaneous tissues	Painful, fluctuant red nodules surrounded by a ring of erythema	Incision and drainage  Systemic antibiotics

CA-MRSA, Community-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-sensitive *S. aureus*.

individuals concerned. The optimal prophylactic antibiotic regimen for the prevention of MRSA after surgery is not known. There is currently no evidence to suggest that using a combination of multiple prophylactic antibiotics or administering prophylactic antibiotics for an increased duration is beneficial to people undergoing surgery in terms of reducing MRSA infections. Treatment of MRSA infections includes antibiotics that are known not to have resistance against MRSA bacteria. Prevention strategies that have been reported to decrease the rate of surgical site infection include decolonization of *S. aureus* carriers with either

mupirocin ointment alone or in combination with chlorhexidine gluconate baths.

Complicated skin and tissue infections and necrotizing soft tissue infections are usually polymicrobial. In complicated (non-necrotizing) skin and soft tissue infections, gram-positive bacteria such as **methicillin-sensitive *Staphylococcus aureus* (MSSA)** and *S. pyogenes* are isolated about 50% of the time. However, anaerobes and gram-negative bacteria such as *Pseudomonas*, Enterobacteriaceae, and clostridial species can also be cultured. Similarly, aerobic bacteria such as streptococci, enterococci, staphylococci,

and anaerobic bacteria such as *Bacteroides* and *Peptostreptococci* have been cultured out of necrotizing soft tissue infections. The published mortality rate of necrotizing soft tissue infections ranges from 25% to 70%.

Factors influencing the patient's susceptibility to infection include acute or chronic skin ulcerations, fungal infections, venous stasis disease and alterations in venous drainage, obesity, arterial compromise to the skin, lymph node resection, and immunocompromised state. Additional factors that put individuals at risk for necrotizing soft tissue infection, such as necrotizing fasciitis, include diabetes mellitus, trauma, alcohol or injection drug use, and the use of nonsteroidal anti-inflammatory medications because of their immunosuppressant effect.

Methicillin-resistant *S. aureus* infections are frequently associated with poor hygiene, overcrowded living conditions, skin-to-skin contact, sharing of contaminated objects, previous infection with MRSA, and trauma. It is important to understand, however, that CA-MRSA can cause infection in otherwise young and healthy individuals. Inanimate objects are common reservoirs for CA-MRSA. Overcrowded conditions and person-to-person contact potentiate its transmission. Therefore, demographic groups at higher risk of MRSA infections include children, young adults, minorities, low-socioeconomic groups, homosexual men, athletes, prisoners, day-care workers, and tattoo recipients. Methicillin-resistant *S. aureus* typically colonizes in the anterior nares of the patient and can cause recurrent infections in the patient and exposure of others to the bacteria. The prevalence of nasal MRSA colonization in the general population of the United States is 20% to 40%. Up to 80% to 90% of patients with MRSA bacteremia and surgical site infections have nasal colonization of the bacteria.

### Pathophysiology and Clinical Manifestations

Non-necrotizing cellulitis occurs when microorganisms, especially streptococcal and staphylococcal species, find a portal of entry through breaches in skin integrity. Initial presentation of bacterial skin infections can include erythema, warmth, edema, and localized pain. Cellulitis is identified by rapidly spreading erythema, warmth, localized pain, and edema with possible inflammation of regional lymph nodes.

Necrotizing soft tissue infections are very serious, potentially life-threatening infections that spread rapidly and destroy a significant amount of tissue. They can penetrate and spread throughout the dermis, subcutaneous tissues, fascia, and muscle. Necrotizing infections involving the fascia are more common because of the fascia's poor blood supply and limited immune function, which allow pathogens to spread rapidly along the fascial plane. Initially, systemic manifestations of necrotizing soft tissue infections may be mild. However, if they are left untreated, more severe manifestations such as fever, tachycardia, pain that

is disproportionate to physical findings, disorientation, lethargy, and hypotension may signal a worsening, systemic infection. In necrotizing fasciitis, palpation of the erythematous skin can yield firmness to the underlying tissues. Furthermore, necrotizing infections eventually lead to edema and vascular occlusion that causes ischemia, tissue necrosis with resulting loss of feeling to the involved area, and sepsis. The most common sites of necrotizing infections are the abdomen, lower extremities, and perineum. **Fournier's gangrene** is the descriptive name given for necrotizing fasciitis of the genital or perineal area. Table 50.2 describes the clinical manifestations of uncomplicated and complicated skin and soft tissue infections.

## Management

### Medical Management

There are no guideline indications for the duration of skin and soft tissue infection therapy. In general, short-course therapy for uncomplicated skin and soft tissue infection is the standard of care. The treatment duration for complicated skin and soft tissue infection is variable and depends on the patient (influenced by immunological status, comorbidities, age, etc.), the severity of the infection, and the causative agent.

**Table 50.2 Clinical Manifestations of Bacterial Skin Infections**

Uncomplicated SSTIs	Complicated SSTIs
Usually no systemic symptoms	Systemic symptoms: fever (or hypothermia), hypotension, tachycardia, confusion/disorientation, sepsis
Localized signs: erythema/cellulitis, furuncles, pustules, folliculitis, cutaneous abscess, purulent drainage if open wound	Spreading area of cellulitis with swelling of regional lymph nodes
Localized increased warmth to surrounding tissues	Edema, ischemia, tissue necrosis with resulting anesthesia to the involved area
Mild to moderate pain	Moderate pain to pain that is disproportionate with clinical manifestations
No changes in blood work	Blood work: elevated white blood cell count, elevated C-reactive protein
	Later stages: bullae, skin ecchymosis; CT scan shows gas in subcutaneous tissues

CT, Computed tomography; SSTI, skin and soft tissue infections.

## Diagnosis

Patients who present with systemic clinical manifestations of infection require an aggressive approach to management. The initial diagnostic evaluation includes blood culture and sensitivity, complete blood count with differential, serum electrolytes, and C-reactive protein to monitor inflammation and the effects of treatment. Marked abnormalities in these results accompanied by hypotension require immediate hospitalization for fluid resuscitation, surgical evaluation, and the initiation of broad-spectrum systemic antibiotics. Some infectious organisms can produce gas in the subcutaneous tissues. If this is suspected, identification of the gas by computed tomography (CT) scan and immediate surgical exploration and debridement are performed.

Blood cultures, needle biopsies, and punch biopsies are usually not necessary for localized skin and soft tissue infections such as cellulitis. With an infection such as cellulitis, antibiotic therapy directed against staphylococci and streptococci is usually effective. Table 50.1 further summarizes the medical treatment of uncomplicated skin and soft tissue infections.

Nasal colonization of MRSA has been associated with recurrent MRSA skin and soft tissue infections, and there is a high correlation between nasal swab cultures positive for MRSA and wound infections resulting from MRSA. Most systemic antibiotics do not reach adequate concentrations to treat intranasal MRSA. Therefore, patients with MRSA-positive nasal cultures and new or recurrent skin and soft tissue infections resulting from MRSA may be treated empirically with 2% mupirocin (Bactroban) topical ointment to each naris twice daily for 5 days. Some acute care institutions also include bathing patients with a chemical antiseptic.

For hospitalized patients with complicated skin and soft tissue infections (defined as patients with deeper soft tissue infections, surgical/traumatic wound infections, major abscesses, cellulitis, and infected ulcers and burns), in addition to surgical debridement and broad-spectrum antibiotics, empirical therapy for MRSA should be considered pending culture data. For patients with recurrent skin and soft tissue infections, decolonization strategies should be offered in conjunction with ongoing reinforcement of hygiene measures. These strategies may include nasal decolonization with mupirocin twice daily for 5 to 10 days and topical body decolonization regimens with a skin antiseptic solution (e.g., chlorhexidine) for 5 to 14 days or dilute bleach baths.

Patients with open wounds present a slightly different dilemma about whether or not to culture the wound. There is no need to culture a wound in the absence of clinical manifestations of infection, as there can be a plethora of organisms on the surface of chronic wounds. There is a high suspicion for infection if there is necrotic tissue or a foreign body present, the wound is large and deep and has been open for a long time, or the wound is frequently contaminated with stool or urine. In the absence of clinical

manifestation of infection, the quantity of organisms is believed to be the best indicator of infection. Wound tissue is the best specimen for quantitative tissue cultures because it reflects the number of bacterial organisms within the tissue and not on the surface of the wound. A **quantitative tissue biopsy**, an invasive test in which a piece of tissue below the surface of the wound is obtained and sent for quantitative Gram stain and culture, is considered the gold standard in identifying wound pathogens. Infection is present if the quantitative culture is greater than or equal to  $10^5$  colony-forming units per gram of tissue and/or beta-hemolytic streptococci are present. Many practitioners revert to the surface swab culture because it is quick, noninvasive, cost-effective, and less painful to the patient (Box 50.2). Many times, a quantitative swab culture is adequate for the identification and treatment of wound infection, and some investigators report a correlation of findings with tissue biopsy. Wounds that include necrosis or **eschar** (brown or black, thick, leathery, devitalized tissue) require debridement of this tissue to reveal viable tissue for culturing.

## Complications

A major complication of skin and soft tissue infections is the overuse and misuse of systemic antibiotics. Treating infections without guidance from cultures not only puts the patient at risk for side effects from the medications but can also exacerbate the problem of antibiotic resistance. Some providers resort to using antibiotics when some uncomplicated skin and soft tissue infections can be treated simply with warm compresses or incision and drainage without follow-up antibiotics. However, incorrect wound-culturing techniques can lead to further complications, such as misidentification of the virulent bacteria, worsening infection, and bacteremia (bacteria in the bloodstream). It is important that practitioners learn the appropriate technique in performing swab cultures so that patients are not exposed to the wrong antibiotic or put at increased risk of pain and infection with an unnecessary, invasive biopsy.

Complicated soft tissue infections, such as necrotizing soft tissue infection, present another set of complications because it is often not possible to diagnose these infections on initial presentation. An experienced practitioner must use clinical judgment to aggressively guide treatment. Immediate surgical debridement of infected tissue is paramount to the patient's prognosis. Delay in treatment can lead to a significant amount of tissue loss, a multitude of future surgeries, and/or death. Of course, with any invasive procedure, the patient is put at even greater risk of infection with surgical debridement.

## Nursing Management

### Assessment and Analysis

The clinical manifestations observed in patients with bacterial skin infections are related to the bacteria involved, the depth and composition of tissues involved, the temporal association

## Box 50.2 Swab Culture Technique for Wound Cultures

### General Guidelines

1. Debride the wound to access viable tissue if necrosis or eschar is present. Do not culture purulent material, necrotic debris or tissue, drainage, or hard eschar.
2. Thoroughly clean the wound prior to culturing by wiping or irrigating the wound with sterile water or saline to remove surface debris or exudate.
3. Follow standard precautions for infection control according to facility policies for hand hygiene and use of gloves, gowns, masks, eye protection, or face shields depending on any anticipated exposure.

### Prepare Equipment and Supplies

1. Obtain appropriate culture supplies; swab collection and transport systems from the laboratory: two-swab system for aerobes and Gram stains and one-swab system for anaerobes.
2. Gather supplies to clean/prepare the wound, collect the culture, and redress the wound: drape to set up the field, hand sanitizer, gloves, sterile saline (without preservatives), sterile 4 × 4 gauze, and wound dressing.

### Clean and Prepare the Wound

1. Wash hands and apply clean gloves.
2. Remove the soiled wound dressing and discard in an approved receptacle.
3. Remove gloves and wash or clean hands with hand sanitizer.
4. Apply clean gloves.
5. Thoroughly irrigate the wound with sterile normal saline (preservative-free).
6. Wipe the surface of the wound vigorously with sterile 4 × 4 gauze moistened with sterile saline (preservative-free) to remove surface contaminants.
7. Gently blot excess saline from the wound bed with dry, sterile gauze.
8. Assess and measure the wound.
9. Remove gloves and wash hands.

### Obtain Swab Culture

1. Wash or clean hands with hand sanitizer.
2. Apply gloves.
3. Select culture swab for anaerobic specimen. If the wound bed is dry, moisten the swab with the culture medium or sterile saline (preservative-free).
4. Rotate the swab tip over a 1 cm × 1 cm area of viable tissue at or near the center of the wound for 5 seconds, applying sufficient pressure to cause tissue fluid to be expressed from the wound bed.
  - Immediately insert the culture swab into the transport tube or container.
  - Use caution to avoid contaminating the swab or the outside of the transport tube or container.
5. Repeat step 4 to obtain a second specimen for aerobic/Gram stain from the same clean tissue site using the second swab system.
6. Redress the wound.
7. Discard the used supplies in approved receptacles.
8. Remove gloves and wash hands.
9. Label the culture specimen with complete information: date, time, location of wound, site/source of the specimen, reason for the culture, relevant symptoms, antibiotic use, and history of MRSA. Request quantitative processing of the sample.
10. Place the culture in a laboratory biohazard transport bag (or per hospital or facility procedure) and immediately send the specimen to the laboratory (within 2 hours).
11. Document the procedure.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

of clinical manifestation onset and presentation to the health-care provider, existing comorbidities of the patient, and the age of the patient.

Open wounds are always considered contaminated. Microorganisms are present in the contaminated wound, but the body's immune system is able to keep the number of microorganisms at a minimum. A wound infection is

a contaminated wound in which the body's immune system cannot contain the microorganisms, so they continue to multiply. **Exudate** (wound drainage) that contains pus, odor, erythema, inflammation, and increased pain occurs in response to an infection. The characteristics of wound exudate (Table 50.3) denote infection with specific bacteria.

**Table 50.3 Wound Exudate**

Exudate and Characteristics	Significance
<b>Serosanguinous</b> <ul style="list-style-type: none"> <li>● Appears blood-tinged, straw to amber colored, reflecting presence of serum and red blood cells</li> </ul>	<ul style="list-style-type: none"> <li>● Normal during first 48 hours after injury</li> </ul>
<b>Purulent</b> <ul style="list-style-type: none"> <li>● Creamy yellow pus</li> <li>● Greenish-blue with a fruity odor</li> <li>● Beige pus with fishy odor</li> </ul>	<ul style="list-style-type: none"> <li>● Colonization with <i>Staphylococcus</i></li> <li>● Colonization with <i>Pseudomonas</i></li> <li>● Colonization with <i>Proteus</i></li> </ul>

Source: Spear, M. (2012). Wound exudate: The good, the bad, and the ugly. *Plastic Surgical Nursing*, 32(2), 77–79.

### Connection Check 50.1

The nurse in the emergency department is triaging patients. Which patient requires immediate attention?

- A 16-year-old with a laceration that was sutured closed 3 days ago and now has erythema extending 2 cm beyond the suture line
- A 30-year-old patient with an open sacral pressure injury with exposed bone with purulent exudate
- A 48-year-old patient with an indurated, erythematous area on his thigh who is complaining of 10/10 pain and has had a fever for 24 hours
- A 60-year-old patient with diabetes mellitus who has a nail embedded in his foot because he could not feel it in his shoe

### Nursing Diagnoses

- **Acute or chronic pain** related to pressure and edema secondary to the wound infection
- **Impaired tissue integrity** related to the open wound
- **Risk for imbalanced fluid volume** related to fluid loss secondary to the open wound and potential surgical debridement.
- **Risk for infection** related to insufficient knowledge of modes of transmission

### Nursing Interventions

#### Assessments

- Vital signs  
*Hypotension, tachycardia, hyperthermia or hypothermia, disorientation, lethargy, and disproportionate pain can indicate worsening infection or sepsis. Decreased intravascular volume leads to hypotension and tachycardia.*

- Wound and skin  
*It is important to establish a baseline of the appearance of the wound or skin to help guide treatment.*
- Pain  
*Pain disproportionate to the appearance of the wound may indicate underlying infection or tissue damage.*
- Complete blood count (CBC) results  
*An elevated white blood cell count is indicative of an infectious process.*
- Culture results (wound, nares, blood)  
*An appropriately performed swab culture of the wound helps guide antibiotic treatment. There is a high correlation of MRSA colonization of the anterior nares and recurrent MRSA infections. Blood cultures are warranted with systemic clinical manifestations to guide treatment.*
- Nutritional status  
*Adequate nutrition status facilitates wound healing, particularly protein and fluid intake.*

#### Actions

- Administer antibiotics based on culture results.  
*Appropriately treat infections using results from the culture and sensitivity to eliminate infection and decrease the risk of antibiotic resistance.*
- Wound care as prescribed  
*Providing care, including cleansing the wound, dressing changes, and minimizing irritation and pressure, is important to wound healing.*
- Surgical evaluation  
*Surgical evaluation is necessary for complicated skin and soft tissue infections and if a necrotizing infection is suspected to determine the specific treatment required.*

#### Teaching

- Hand washing  
*Hand hygiene greatly reduces the levels of bacteria present on the skin and is the most important factor in preventing the transmission of infection.*
- Wound care  
*Educating caregivers and patients about clinical manifestations of infection and appropriate application and removal of dressings improves clinical management and outcome.*
- Clinical manifestations of infection  
*Early recognition of the clinical manifestations of infection may facilitate earlier treatment, prevent complications, and decrease morbidity.*

### Evaluating Care Outcomes

With the correct antibiotics verified by wound cultures, patients with bacterial skin infections can usually be successfully treated with antibiotics and wound care as needed in the outpatient setting. Care of the patient and family includes teaching about wound care, clinical manifestations of infection, and infection transmission. A rapid and thorough evaluation is essential to a positive prognosis with necrotizing soft tissue infections. Upon initial presentation

and follow-up, a wound or cellulitic area that is causing pain out of proportion to the injury should be immediately referred for a surgical evaluation. With aggressive therapy including surgical debridement and specialized wound care, patients with necrotizing soft tissue infections can recover.

## HERPES SIMPLEX VIRUS

The Greeks first discovered **herpes simplex virus (HSV)** more than 2,000 years ago and used the term *herpes* to describe something “creepy or crawly.” Today, HSV is the most common viral infection diagnosed in developed countries and has become a public health concern. Herpes simplex virus infections exist as two types: type 1 (HSV-1) and type 2 (HSV-2). An HSV-1 infection causes a recurring oral mucosal lesion or “cold sore,” and HSV-2 is the cause of genital herpes (GH). Recently, however, researchers have found an increasing incidence of GH attributed to HSV-1.

### Epidemiology

Both HSV-1 and HSV-2 are common, lifelong viral infections usually acquired and transmitted asymptotically through body fluids or skin-to-skin, skin-to-mucosa, or mucosa-to-mucosa contact. Herpes simplex virus-1 can be transmitted without sexual contact, and orolabial lesions typically occur at a young age most likely because of the sharing of utensils or cups during childhood. Herpes simplex virus-1 infections are usually found on the face, oral cavity, lips, and skin. Herpes simplex virus-2 can cause painful anogenital lesions and is one of the most prevalent sexually transmitted infections (STIs). However, most people infected with HSV-2 do not know that they have it and can shed the virus intermittently within the genital tract. Therefore, most GH infections are transmitted by someone who is asymptomatic or unaware of the presence of the infection. Traditionally, HSV-2 was considered the sole cause of GH; however, recent studies show an increased prevalence of GH attributed to HSV-1, likely because of orogenital sexual contact.

Additionally, HSV-1 and HSV-2 can cause a **herpetic whitlow** (painful lesion on the fingers), which occurs when the herpes virus is introduced through breaks in the skin, commonly on the fingers of healthcare workers. Those with active herpetic lesions on the body are also at high risk. Although both viruses can cause a herpetic whitlow, approximately 60% are thought to be caused by HSV-1.

Between 60% and 95% of all adults are believed to be infected with the HSV-1, and it has been identified as the cause of GH in 71.2% of all subjects. In young adults 18 to 24 years old, HSV-1 was found to be the cause of GH in 79.6% of the cases compared to 31.8% of adults aged 25 years and older. Conversely, HSV-2 was found to be the cause of GH in 66.7% of the cases, compared to 20.6% of adults aged 18 to 24.

The Centers for Disease Control and Prevention reported that 16.2% of people in the United States between

the ages of 14 and 49 are infected with GH. In general, women are twice as likely as men to be infected, and blacks are three times more likely than whites. The prevalence of HSV-2 among African Americans is 41.8%, and more specifically, there is a prevalence of 48% among African American women. These statistics are based on the number of people who tested positive for HSV-2 antibodies, which are present only if the person is infected with the virus. Although not everyone infected with the HSV-2 virus becomes symptomatic, the virus can still be transmitted to others.

Genital herpes infections caused by HSV-1 show slightly different statistics. Positive predictors for genital HSV-1 infections include being white and having receptive oral and anal sex. Herpes simplex virus-1 is more frequently the cause of GH in women, those under 25, and homosexual men. Most likely, this is related to increased orogenital contact. Those in a monogamous relationship for at least 2 months and who participated in orogenital sex were more likely to have HSV-1 as the cause of GH. Conversely, those with multiple partners over 6 months had a greater likelihood of having HSV-2 infections.

### Pathophysiology and Clinical Manifestations

Herpes simplex viral infections can occur on the skin, mucous membranes, central nervous system, and genital tract. There are two phases of reactivity of the herpes virus, primary and secondary infections. A primary HSV infection describes the first time an individual is infected with the herpes virus. Primary infection can occur through direct contact with an individual with HSV who is asymptomatic; is in a prodromal (early) stage of the disease; or has active oral or genital infections, secretions, or lesions. Clinical manifestations of primary infection occur within 2 weeks of viral transmission and can include fever; malaise; myalgias; anorexia; irritability; cervical or inguinal lymphadenopathy; and lesions that can involve the lip, face, mucous membranes of the mouth, pharynx, or genitals. Many times, the primary infection is asymptomatic and can be transmitted unknowingly. Once HSV penetrates the skin or mucous membrane, the virus travels down the peripheral sensory neurons to the ganglia, where it remains dormant until a trigger incites an active lesion.

Secondary (or recurrent) HSV infections occur following an exogenous or endogenous trigger that reactivates the dormant virus. Triggers are individually specific but commonly occur in response to ultraviolet (UV) light exposure, febrile illnesses, and stress, for example. The virus is then transferred from the ganglia back to the initial site of inoculation via the peripheral nerve. Typically, the secondary infection is milder than the primary infection and is usually preceded by a prodrome of a burning, itching, or tingling sensation where the lesion eventually occurs. An area of redness first appears on the lips or genitals followed in about 2 days with the appearance of multiple fluid-filled

vesicles. The pain usually subsides once the vesicles rupture. The number of lesions and the nature of the outbreak depend on the individual's immune status at the time, and in general, genital recurrences occur more frequently than oral recurrences. Recurrences of GH caused by HSV-1 occur less frequently than those caused by HSV-2.

## Management

### Medical Management

#### Diagnosis

Because many primary HSV infections are asymptomatic and lack the classic, painful vesicular lesions, a diagnosis based on clinical presentation alone is nonsensitive and nonspecific. The prognosis and type of clinical counseling a patient needs are dependent on accurate identification of the type of GH infection confirmed by laboratory analyses (HSV-1 or HSV-2). Virological and type-specific serological testing are also available.

Virological testing is appropriate for a patient seeking medical attention because of the presence of **mucocutaneous** (a region of the body where mucosa transitions to skin) lesions or ulcers. Viral culture and polymerase chain reaction (PCR) testing are preferred for the individual with active lesions; however, their sensitivity decreases as the lesions start to heal. Polymerase chain reaction testing is preferred for detecting HSV in spinal fluid. A negative viral culture or PCR test does not negate infection because viral shedding can be intermittent. The cytological Tzanck's smear (examines skin scrapings smeared onto a slide) and cervical Pap smear (examines cervical scrapings smeared onto a slide) are both nonspecific methods of diagnosis, and their results are not reliable.

Serological type-specific glycoprotein G–based assays obtained from capillary or serum blood samples accurately distinguish HSV-1 from HSV-2. These tests are ordered by providers for those patients who have recurrent genital symptoms with negative HSV cultures, a clinical diagnosis of GH without laboratory confirmation, a partner with GH, a person presenting for STI testing with a history of multiple sex partners, persons with HIV, or homosexual men. False-negatives can occur during the early stage of infections because the sensitivities for the HSV-2 antibody can vary and seroconversion can take up to 12 weeks. Although the specificity of the type-specific test is greater than 96%, false positives still occur. Therefore, repeated, confirmatory testing is helpful, especially if GH acquisition is suspected of being recent (within 12 weeks of exposure). Screening for HSV in the general population is not warranted.

The presence of type-specific HSV-2 antibodies implies that the individual acquired GH through anogenital sexual contact, and it is necessary to provide the appropriate education and counseling for individuals who are seropositive for HSV-2. It is more difficult to interpret the serological presence of HSV-1 antibodies because most people who are seropositive for HSV-1 contracted it during childhood and

may be asymptomatic. The presence of HSV-1 antibodies does not distinguish the anogenital form of HSV-1 from the orolabial infection. It is important to understand that individuals with HSV-1 antibodies remain at risk of acquiring HSV-2 and should be offered the same education and counseling to include the natural history of GH, sexual and perinatal transmission, and methods to reduce transmission. Moreover, the sex partners of patients with GH benefit from education and counseling as well.

#### Treatment

The basis of medical treatment of GH is systemic antiviral chemotherapy. Treatment can be directed at first or recurrent episodes as well as daily suppressive therapy, and options need to be discussed with the patient. In counseling patients, it is important to stress that the medications do not eradicate the latent virus. Also, decreased frequency and severity of recurrences are based on continued use of suppressive therapy. Additionally, suppressive therapy has shown to decrease the risk of transmitting HSV-2 to sexual partners. Three antiviral medications, acyclovir, valacyclovir, and famciclovir, tested in randomized trials, have shown clinical benefit in the treatment of GH. Because the bioavailability of IV acyclovir is greater than the oral route, IV acyclovir is utilized for patients with severe disease or those who encounter complications of HSV, such as disseminated infection, pneumonitis, encephalitis, or hepatitis.

#### Complications

One of the most significant complications of HSV infections is its effect on quality of life due to the psychosocial stress of a diagnosis of GH. Patients report feeling isolated, devastated, and embarrassed because of this diagnosis and fear transmitting the virus to others. Infection with HSV-2 is a major risk factor for the acquisition and transmission of HIV as well. Also, because of a loss of skin integrity, open epithelial lesions carry the risk of secondary bacterial infections.

The most devastating time to acquire GH is during pregnancy because the complication of disseminated neonatal herpes carries a mortality rate of up to 30%. Because the viral load is much greater during a primary HSV infection, the greatest risk of maternal transmission occurs among women who acquire a primary infection in the third trimester of pregnancy as opposed to those with recurrent disease. It takes approximately 12 weeks for the neonate to passively acquire maternal antibodies, and when the mother is infected in the final trimester of pregnancy, immunity may not be developed in time to protect the neonate during delivery. Antiviral medications have been shown to be safe for use during pregnancy and should be prescribed for women who contract GH in the first or second trimesters. Cesarean sections are generally recommended for women presenting with primary GH lesions at delivery and in the last 6 weeks of pregnancy because of high viral shedding that can affect the neonate.

## Nursing Management

### Assessment and Analysis

Clinical manifestations of symptomatic primary HSV infections can include fever; malaise; myalgias; anorexia; irritability; cervical or inguinal lymphadenopathy; and painful lesions that can involve the lip, face, mucous membranes of the mouth, pharynx, or genitals. As previously discussed, however, HSV infections can also be asymptomatic.

### Connection Check 50.2

Which statement made by a patient who is currently asymptomatic with an HSV-2 infection indicates the need for more education about the disease?

- “It’s okay to have intercourse with my partner as long as we use a barrier method of protection and I take my antiviral medications.”
- “It’s more likely that I could spread the HSV-2 infection if I have sexual relations when I have open ulcers and pain.”
- “When I get pregnant, I will be certain to tell my gynecologist about my HSV-2 infection.”
- “I understand that I could still transmit the virus if I don’t have symptoms.”

### Nursing Diagnoses

- **Acute pain** related to primary or secondary HSV infections
- **Risk for infection** related to open HSV lesions
- **Deficient knowledge** related to unfamiliarity with safe sex practices and characteristics of HSV transmission
- **Risk for social isolation** related to new diagnosis of HSV genital infection

### Nursing Interventions

#### ■ Assessments

- Pain and fever  
*The prodromal period may include fever, malaise, and headache, and the patient’s understanding of prodromal symptoms may help the patient recognize the onset of an outbreak.*
- Oral cavity lesions (questions about sore throat, dysphagia, anorexia, mouth pain)  
*Oral lesions cause outbreaks that range from painful to severe and even life-threatening to infants, children, and adolescents.*
- Genital lesions  
*The appearance of lesions may provide additional information about the stage of the disease process.*
- Sexual history  
*Understanding the number of partners, use of barrier protection, participation in oral or anal intercourse, dysuria, dyspareunia (painful intercourse), and history of other STIs helps to guide treatment and counseling.*

- Skin and mucous membranes for presence and appearance of lesions  
*Secondary bacterial skin infections can occur with open HSV lesions.*
- Knowledge of HSV and transmission of the virus  
*Patients must understand that HSV-1 can cause genital lesions through orogenital contact and that an individual with genital HSV-1 can still contract HSV-2. Knowledge about transmission increases the likelihood of safe sex practices and may decrease anxiety related to the new diagnosis.*
- Assess serum human chorionic gonadotropin (hCG) levels.  
*To assess for pregnancy*
- Ability to cope with diagnosis of HSV  
*Counseling is warranted because of the psychosocial stress of a new diagnosis of GH.*

#### ■ Actions

- Perform viral cultures and/or serological testing.  
*Viral cultures can be performed on open lesions; serological testing is necessary to differentiate HSV-1 and HSV-2 infections.*
- Administer antiviral medications as indicated.  
*Antiviral medications can decrease the frequency and severity of outbreaks.*
- Administer analgesic medications as indicated and warm sitz baths for comfort.  
*Over-the-counter analgesics and warm water soaks can provide symptomatic relief of pain from open lesions.*
- Collaborate with interprofessional team for psychological support.  
*Counseling is warranted because of the psychosocial stress of a new diagnosis of GH.*

#### ■ Teaching

- Actions of antiviral medications  
*Taking the antiviral medications does not cure HSV and does not reduce the risk of transmitting the virus but may decrease the frequency and severity of outbreaks.*
- Safe sex practices  
*There is a decreased incidence of HSV-2 infections with those who use condoms. Patients should be educated not to have sexual intercourse during an outbreak even with condom use because of the high incidence of transmitting the virus during that time.*
- Considerations related to HSV infection during pregnancy  
*Pregnant women must be educated about the risks of acquiring HSV during pregnancy. Genital herpes acquired during pregnancy includes the complication of disseminated neonatal herpes that carries a mortality rate of up to 30%. Because the viral load is much greater during a primary HSV infection, the greatest risk of maternal transmission occurs among women who acquire a primary infection in the third trimester of pregnancy as opposed to those with recurrent disease. It takes approximately 12 weeks for the neonate to passively acquire maternal antibodies.*

## Evaluating Care Outcomes

To prevent transmission of the virus, it is paramount to teach safe sex practices to individuals with or without an HSV infection, including the use of a condom as well as not engaging in sexual contact during an outbreak. Teenagers and young adults must be made aware of the risk of contracting HSV-1 through orogenital sex. Referring an individual for counseling with a new diagnosis of HSV may be essential in helping him or her cope with feelings of isolation, depression, and anger and can help him or her develop and maintain social and intimate relationships.

## FUNGAL INFECTIONS

Fungal infections in humans are quite common and are caused by two different types of fungi: **dermatophytes** (aerobic fungi) and yeasts. Clinically, the impact of fungal infections ranges from mild to fatal, and the clinical manifestations vary by infection site and depend on the patient's immune response.

### Epidemiology

Fungal infections can spread directly from person to person, through animal contact, or indirectly through contact with inanimate objects that hold skin scales from infected hosts. Dermatophytes are aerobic fungi that infect the stratum corneum (the top, dead layer of the skin) and survive on keratin and therefore cannot survive on mucosal surfaces. Typically, a fungal infection with dermatophytes presents asymmetrically on the patient, affecting one foot or one hand. Because fungal infections proliferate in warm, moist environments, the groin, feet, axillae, and skinfolds are primary places for infection. The Latin word **tinea**, meaning worm, is used to describe fungal infections caused by dermatophytes and precedes the anatomical location of the infection. For example, tinea pedis describes a fungal infection of the foot, or athlete's foot, and tinea capitis involves the head. Synonyms used to describe dermatophyte infections include *dermatophytosis*, *tinea*, and *ringworm*. Table 50.4 describes the diagnosis and treatment of some common fungal skin infections. In the community setting, yeast, or *candidiasis*, most commonly causes oral or vaginal thrush. However, nosocomial invasive fungal or *Candida* infections affecting the critically ill and immunocompromised patients can have devastating consequences.

The incidence and prevalence of fungal infections vary among populations and environmental exposure. Greater than 4 million healthcare visits per year are related to superficial fungal infections, and the most common types are tinea pedis and **onychomycosis** (fungal infection of the nails). The majority of healthcare visits per year are for onychomycosis (23.2%), followed by fungal infections of the skin (20.4%) and, lastly, the feet (18.8%). Generally, risk factors for dermatophytosis include the presence of fungal infections in the family, male gender, farmers and manual laborers, and the use of immunosuppressive medications.

Prevalence rates of tinea pedis range from 25% to 70% over the lifespan, making it the most commonly occurring dermatophyte infection, especially among athletes. Onychomycosis has been shown to be more prevalent with advancing age, likely because of decreased vascular flow, difficulty in grooming nails and maintaining foot hygiene, frequent nail injuries, and diabetes. Approximately 72% of those older than 45 are affected, and it is more frequently found among men, likely because of men's greater participation in manual labor and sports, which require tight-fitting shoes. Fungal scalp infections are found more frequently among those of lower socioeconomic status.

*Candida*, or yeast, causes a broad range of infections that range from those easy to treat in an outpatient setting to significant and fatal infections that occur among the acutely sick and critically ill populations. Three out of four women will experience a vulvovaginal yeast infection, and half of all women will have more than one in a lifetime. Risk factors include tight-fitting or synthetic-fiber clothing, douching too frequently, and contamination with bacteria from the rectum because yeast thrives in warm, moist environments on the skin and mucous membranes of the gastrointestinal tract and vagina. These infections are usually treated with an over-the-counter antifungal medication (such as Monistat) for 1 to 7 days.

The more significant *Candida* infections that occur among hospitalized patients may be related to the medical treatment of other diseases or infections. In the United States, 12% of all hospital-acquired bloodstream infections (BSIs) are caused by *Candida*. This may be due to several factors, including increased empirical use of antimicrobials; a large population of immunocompromised patients due to cancer, organ transplants, and chemotherapy; an increase in survival of the sickest patients; and invasive procedures. Additional risk factors include *Candida* colonization, renal failure, severity of illness, and the need for total parenteral nutrition. Among intensive care unit (ICU) patients, mortality rates of *Candida* BSIs range from 38% to 75%. The increasing incidence of hospitalizations involving candidemia has led to longer lengths of hospital stay and additional costs.

### Pathophysiology and Clinical Manifestations

Dermatophytes, which reproduce by the formation of spores, cause superficial cutaneous fungal infections and do not spread beyond the epidermis. Found living in soil, on animals, and on humans, dermatophytes are aerobic fungi that feed on the dead keratin of the skin, hair, and nails. Areas that are occluded, such as the toe spaces, are most at risk of infection, and an identifiable characteristic of dermatophyte infections is an active, raised border. Yeasts, on the other hand, multiply by budding and thrive in warm, moist environments on the skin and mucous membranes of the gastrointestinal tract and vagina. Fungal infections may present as scaling rashes, plaques, vesicles, or pustules. Table 50.4 reviews common fungal infections and their clinical manifestations.

(Text continued on page 1111)

Table 50.4 Common Fungal Infections

Name	Site	Clinical Manifestations	Diagnosis	Medical Management
<i>Tinea capitis</i>	Scalp	<ul style="list-style-type: none"> <li>● Scaling of scalp, alopecia, broken hair at scalp line</li> </ul>	<ul style="list-style-type: none"> <li>● Physical findings: scaling, alopecia, pruritus</li> <li>● KOH microscopy</li> </ul>	<ul style="list-style-type: none"> <li>● Oral antifungals to penetrate hair shafts Example: terbinafine (Lamisil)</li> <li>● Topical antifungal medications, such as itraconazole, terbinafine, and fluconazole</li> </ul>
<i>Tinea corporis</i>	Body	<ul style="list-style-type: none"> <li>● Annular patches or plaques with advancing, raised border and central clearing</li> </ul>	<ul style="list-style-type: none"> <li>● Clinical appearance</li> <li>● KOH microscopy A fungal culture, used as an adjunct to KOH for diagnosis, is more specific than KOH for detecting a dermatophyte infection. If clinical suspicion is high, yet the KOH result is negative, a fungal culture should be obtained.</li> </ul>	<ul style="list-style-type: none"> <li>● Topical antifungals for infections</li> <li>● Topical azoles (i.e., ketoconazole, clotrimazole, miconazole, and allylamines) (i.e., terbinafine)</li> <li>● Topical therapy should be applied to the lesion and at least 2 cm beyond this area once or twice a day for at least 2 weeks.</li> </ul>

**Tinea cruris (jock itch)**

Groin

- Sharply delineated, symmetrical red to reddish-brown plaques with central clearing; border with pustules or vesicles; pruritic; scrotum spared
- Evaluate feet because the same dermatophyte causes tinea pedis.
- Differentiate from *Candida intertrigo*, which does not have central clearing.

- Topical antifungal (terbinafine [Lamisil], butenafine [Lotrimin])
- Topical antifungal agents of the imidazole or allylamine family

**Tinea faciei**

Face

- Annular rash with raised margins
- Pruritus
- Clinical appearance  
Tinea faciei is the most frequently misdiagnosed entity among cutaneous fungal infections. The atypical clinical features support the separation of this disease from tinea corporis.

- Topical antifungals (butenafine [Lotrimin], clotrimazole [Mycelex])
- Topical antifungal agents (i.e., ciclopirox and terbinafine)

- KOH microscopy  
The surface scrapings are obtained from the border of the lesions where the more severe inflammatory reaction occurs and where more fungal elements are present.

Continued

Table 50.4 Common Fungal Infections—cont'd

Name	Site	Clinical Manifestations	Diagnosis	Medical Management
<i>Tinea pedis</i>	Feet	<ul style="list-style-type: none"> <li>Maceration of interdigital skin of feet</li> <li>Diffuse dry scaling of soles of feet</li> </ul>	<ul style="list-style-type: none"> <li>Clinical appearance</li> <li>KOH microscopy if needed</li> </ul>	<ul style="list-style-type: none"> <li>Keep feet dry and ventilated.</li> <li>Topical antifungal (terbinafine [Lamisil])</li> <li>Severe: oral antifungal</li> </ul>
<i>Tinea versicolor (pityriasis versicolor)</i>	Upper chest, back, upper arms	<ul style="list-style-type: none"> <li>Scaly patches of different colors (erythematous, hypo- or hyperpigmented)</li> </ul>	<ul style="list-style-type: none"> <li>Wood's lamp</li> <li>KOH microscopy</li> </ul>	<ul style="list-style-type: none"> <li>Topical antifungals (terbinafine [Lamisil] or ketoconazole [Nizoral])</li> <li>Selenium sulfide shampoo (Selsun Blue)</li> <li>Oral "azole" antifungals for resistant or recurrent infections</li> <li>Over-the-counter (OTC) remedies include clotrimazole (Lotrimin, Mycelex) and miconazole (Lotrimin). Another OTC option is selenium sulfide shampoo 1% (Selsun Blue) or 1% ketoconazole shampoo (Nizoral).</li> </ul>
<i>Onychomycosis (tinea unguium)</i>	Nails	<ul style="list-style-type: none"> <li>Yellow, brittle, thick nails with subungual hyperkeratosis</li> </ul>	<ul style="list-style-type: none"> <li>Clinical appearance</li> <li>KOH microscopy</li> </ul>	<ul style="list-style-type: none"> <li>Topical antifungals effective with debridement</li> <li>Oral antifungals (terbinafine [Lamisil], itraconazole [Sporanox], fluconazole [Diflucan])</li> <li>Topical therapy: <ul style="list-style-type: none"> <li>Ciclopirox olamine 8% nail lacquer solution</li> </ul> </li> </ul>

- Efinacozole 10% topical solution (the first FDA-approved topical triazole for toenail onychomycosis)
- Tavaborole 0.5% topical solution, an oxaborole solution (boron-containing compound)
- Topical treatments may be useful to prevent recurrence in patients cured with systemic agents.

Oral therapy:

- Terbinafine
- Itraconazole

Nonpharmacological approaches include the following:

- Laser treatment
- Photodynamic therapy
- Mechanical, chemical, or surgical nail avulsion
- Chemical removal with a 40%-50% urea compound used with very thick nails
- Removal of the nail plate as an adjunct to oral therapy

- Oral antifungal liquids (swish and swallow) or lozenge such as Nystatin
- May be either treated topically (i.e., nystatin) or ingested in liquid form (i.e., flucanazole)

- Creamy white plaques on erythematous mucous membranes
- Thick white coating of tongue, inner cheeks, inner lips, or gums

Mouth:  
tongue, inner cheek (buccal mucosa), inner lip, and occasionally gums (gingiva)

**Oral thrush (oropharyngeal candidiasis)**

## Management

### Medical Management

#### Diagnosis

The diagnosis of tinea infections is usually made with a focused history, physical examination, and potassium hydroxide (KOH) microscopy, but sometimes Wood's lamp examination, fungal culture, or histological tissue evaluation is necessary to confirm the diagnosis. Potassium hydroxide microscopy, which has a 76.5% sensitivity and an 81.6% negative predictive value, makes it more sensitive than a fungal culture. To perform KOH microscopy, the scraping of skin from the affected area is placed on a slide and viewed through a microscope after adding a drop of 10% to 20% KOH solution. The presence of hyphae confirms the diagnosis. A Wood's lamp examination that uses a UV light held close to the skin in a darkened room is helpful in diagnosing tinea versicolor. This fungus fluoresces a pale yellow to white. Otherwise, a Wood's lamp usually is not helpful in diagnosing fungal infections because there is a declining number of infections that still fluoresce under UV light. Table 50.4 provides additional detail regarding diagnoses of fungal infections.

#### Treatment

Antifungal agents are the primary agents used to treat fungal infections, and Table 50.4 provides an overview regarding the medical management of common fungal infections. Healthcare providers often prescribe ineffective antifungal therapies because of a lack of knowledge of the medications and incorrect diagnoses. Not every antifungal medication is the same, and what is an appropriate treatment for one infection may not be for another. Therefore, research recommends better healthcare provider education concerning the diagnosis, management, and prevention of fungal skin infections.

#### Prevention

Generally, the prevention of fungal skin infections requires avoidance of the causative factors, which include wearing tight shoes for prolonged periods, moisture and perspiration, contact of surfaces with bare skin, and sharing of contaminated personal items. Meticulous hand washing and eliminating the sharing of personal items are the primary methods of preventing infection transmission. For hospitalized patients, prevention of superficial fungal infections can be achieved by keeping skinfolds dry and clean, frequent turning of bed-bound patients to enhance airflow, and timely cleansing and drying of incontinence and wound exudates.

#### Complications

Complications of fungal infections occur when they are not treated promptly and are allowed to proliferate, especially in the critically ill and immunocompromised patient. Prompt diagnosis of *Candida* infections in an

ICU is difficult because of the time needed for finalization, thus delaying treatment and increasing the risk of mortality. Because of the high mortality rate of an invasive *Candida* infection, many prediction tools have emerged. For example, the *Candida* colonization index requires the acquisition of surveillance cultures from multiple patient body sites a few times per week up to daily while the patient is in the ICU. The *Candida* colonization index is the ratio of the number of body sites that grow the same species of *Candida* divided by the number of body sites tested. A *Candida* colonization index of 0.5 identifies patients who are colonized and are at great risk of developing invasive candidiasis. This guides clinicians to promptly treat patients at greatest risk with antifungal medications and reduce morbidity from candidemia. Other risk identification scales consider admitting diagnoses, use of corticosteroids or other immunosuppressive medications, antibiotic use, parenteral nutrition, and the presence of an invasive central venous catheter.

### Connection Check 50.3

A mother brings in her 8-year-old child because of a new rash of annular patches, raised borders, and central clearing. What should be done first?

- Obtain a scraping of the rash for KOH microscopy.
- Explain to the mother that this is probably tinea corporis and an antifungal ointment will successfully treat it.
- Obtain a focused history to include medications, activities in which the patient partakes, and any history of skin disorders or fungal rashes.
- Explain to the mother that the rash will subside on its own.

### Nursing Management

#### Assessment and Analysis

Nursing assessment and care of the skin are crucial in the diagnosis and treatment of fungal skin infections. Clinical manifestations include rashes, plaque formation, pustules, and vesicles. Patients at increased risk require enhanced surveillance because of immunocompromise, alterations in skin integrity, and obesity (particularly with moist skinfolds), which increase the risk of fungal infections.

#### Nursing Diagnoses

- **Impaired comfort** related to fungal skin infections as evidenced by pruritus
- **Risk for infection transmission** related to colonization of fungus as diagnosed by rash, KOH microscopy, and/or cultures
- **Risk for impaired skin integrity** related to moisture on skin secondary to incontinence and diaphoresis

## Nursing Interventions

### ■ Assessments

- Assess skin, paying close attention to creases and moist environments and noting any treated or untreated fungal infections.

*Particular attention needs to be given to creases and moist environments. Macerated skin from moisture and a dark environment support successful penetration and proliferation of fungi. A patient with tinea pedis many times will have tinea cruris because of contamination when putting on clothing. The development of skin and eye lesions is sometimes the only clue to finding that the cause of sepsis is a Candida infection.*

- Pruritus

*Pruritus is a side effect of some fungal infections and can exacerbate skin breakdown.*

- Current and recent medications

*Antibiotic use increases the risk of fungal infections.*

- Liver function

*Oral antifungal agents can cause liver damage, requiring the assessment of liver function results.*

- Health history

*Assessment of the history of fungal infections may help identify colonization; certain populations are more susceptible to fungal infections (see Epidemiology section).*

### ■ Actions

- Meticulous hand washing before and after patient contact  
*Hand washing is the most important way to decrease the transmission of fungi.*

- Perform cultures as needed.

*Surveillance cultures in an ICU can identify the risk of Candida bloodstream infections and decrease morbidity and mortality.*

- Administer antifungal medications as prescribed.

*Prompt treatment with the correct antifungal medications can decrease morbidity and mortality. Applying antifungal medications appropriately treats the infection and alleviates symptoms such as pruritus.*

- Cleanse incontinent episodes as soon as they occur and keep the perineum as dry as possible; change moist bed linens and gowns.

*Fungal infections thrive in dark, moist environments.*

- Separate skinfolds with gauze or other dressings and keep dry to decrease the risk of intertrigo.

*Intertrigo is caused by skinfolds rubbing together and **maceration** (soft, white skin secondary to constant exposure to moisture) of moist tissue, allowing invasion of fungi.*

- Meticulous cleanliness and application of antifungal medications

*In the presence of infection, cleanliness decreases the proliferation of infection and increases healing.*

### ■ Teaching

- Avoid tight-fitting clothes, shoes, and communal washing (wear shower shoes).

*Women with tight-fitting clothes are more susceptible to vulvovaginal Candida infections. Tight-fitting shoes hold*

*the web spaces between toes closed, increasing temperature and moisture. The transmission of fungi can occur from inanimate objects.*

- Clinical manifestations of fungal infections  
*Understanding the clinical manifestations will allow for prompt treatment.*

- Complete antifungal infection medications as prescribed.

*The complete eradication of the fungal infection requires the patient to complete the entire course of antifungal medications. Stopping the medications once clinical manifestations are gone may lead to recurrent infection.*

## Evaluating Care Outcomes

Treating fungal infections in the community has a high success rate as long as the correct antifungal medication is prescribed. Educating the patient about clinical manifestations and causes of fungal infections can decrease occurrences and the severity of the infection. For the hospitalized patient, keeping the skin and skinfolds dry and cleaning incontinence episodes as soon as they occur is an appropriate goal to decrease the incidence of fungal infections. The healthcare provider must keep in mind that critically ill and immunocompromised patients with a fungal infection of the skin are at high risk of developing a bloodstream infection that could prove to be fatal. Therefore, close monitoring of the patient's status, including vital signs and blood work, is essential in his or her care.

## PSORIASIS

**Psoriasis** is a lifelong inflammatory disorder characterized by exacerbations and remissions of raised, scaling, erythematous plaques usually seen on the extensor surfaces of the body. Although there is no cure for psoriasis, there is a variety of treatments available that can control symptoms.

## Epidemiology

Psoriasis is an immune disorder that causes chronic inflammation of the skin characterized by thick, raised red patches covered with silvery, flaking scales. Essentially, the etiology of psoriasis is unknown. Infections, medications, stress, trauma, and hormonal changes are some of the things that can aggravate the disease. Patients with psoriasis fare better in warmer climates with sun exposure because UV radiation kills rapidly proliferating skin cells.

It is difficult to establish the true incidence and prevalence of psoriasis because not everyone seeks medical help for the disease. In previous studies, psoriasis was found to affect as many as 7.5 million people, or about 2% of the population. Its prevalence varies with ethnicity, and it is less common in people of Asian or African descent. Seventy-five percent of patients in some studies reported a moderate to severe form of the disease with plaques affecting 3% or more of the total body surface area. Men and women are equally likely to develop psoriasis, and the mean age of

onset is 28, with a range of 15 to 35 years. Onset of psoriasis before age 30 is linked with more severe cutaneous manifestations, serious psychosocial impact, and a family history of the disease. Up to 30% of those with psoriasis develop psoriatic arthritis, a complication that causes inflammation, pain, and stiffness of the joints.

## Pathophysiology and Clinical Manifestations

Although the cause of psoriasis remains unknown, current research suggests that it results from an interaction of multiple genes, the immune system, and environmental influences (see Genetic Connections: Psoriasis). Epidermal thickness with increased vascularity and increased inflammation are the main pathological aspects of psoriasis. New epithelial cells are continually made in the basal layer of the epidermis, and it takes approximately 28 days for these new cells to reach the surface of the skin and shed. In psoriasis, this process is accelerated for unknown reasons, and more skin cells are made than are actually shed, and these cells form the scaly plaques on the surface of the skin. Also, the dermal capillaries become tortuous and dilated (Fig. 50.4), causing the red appearance of the skin under the scaly plaques, and these abnormal capillaries are the last aspect of psoriasis to resolve after treatment. Although psoriasis can occur anywhere on the body, psoriatic plaques are most often seen on the elbows, knees, legs, palms, soles of the feet, scalp, trunk, and face. There are several forms of psoriasis including plaque, guttate, and erythrodermic.

## Genetic Connections

### Psoriasis

The occurrence of psoriasis is multifactorial. Genetic, age, behavioral, and environmental factors are associated with the development of the disease. In at least 30% of cases, a genetic predisposition is recognized. Research demonstrates that monozygotic (identical) twins have a higher concordance rate for psoriasis (70%) as opposed to dizygotic (fraternal) twins (20%). Seventy-one percent of children with psoriasis have a positive family history of the disease, and in families where both parents have the disease, psoriasis is found among half of the siblings. Therefore, it is important to ask about family history of a patient who presents with clinical manifestations of psoriasis.

The most common type of psoriasis is plaque psoriasis, affecting approximately 80% to 90% of those with the disease. Patients with this type of psoriasis present with well-circumscribed, thick, reddened papules or plaques, often covered with silvery scaling flakes. In guttate psoriasis, small

FIGURE 50.4 Psoriasis.

plaques 2 to 10 mm in diameter appear in a centripetal distribution (starting from the face and extremities and moving toward the trunk). Many times, this is the initial presentation of psoriasis in children. Up to 33% of patients with guttate psoriasis eventually develop chronic plaque psoriasis. *Erythroderma*, another form of psoriasis, can involve most or all of the skin. Erythroderma can occur when psoriatic plaques become confluent and extensive or may be an indication of unstable psoriasis exacerbated by infection, medications, or corticosteroid withdrawal. This may lead to the skin's inability to thermoregulate, causing hypothermia and heart failure.

Psoriasis is not always limited to the skin. Psoriatic arthritis (PsA) is a common manifestation of psoriasis, and there is evidence to suggest that there is a genetic component to PsA. It is believed that the genetic susceptibilities of the host interact with environmental and other random factors to precipitate the disease. Psoriatic arthritis usually involves the joints of the hands and spine. Additionally, nail involvement is common and presents as pitting, *onycholysis* (lifting of the nail away from the nail bed), and splinter hemorrhages under the nail.

## Management

### Medical Management

#### Diagnosis

There are no laboratory tests specific for psoriasis. Plaque psoriasis is usually diagnosed on the basis of a patient's clinical manifestations. However, some forms of psoriasis mimic other skin disorders, such as bacterial and fungal infections, making it sometimes necessary for a dermatologist to perform a skin biopsy for a definitive diagnosis. If PsA is suspected, serum inflammatory markers such as C-reactive protein and an erythrocyte sedimentation rate (ESR) usually are elevated. Rheumatoid factor usually is not found in PsA, and this can help differentiate PsA from rheumatoid arthritis.

#### Treatment

Because there is no cure for psoriasis, the goal in treating this disorder is to reduce the clinical manifestations, control

the disease, and improve quality of life. Therefore, it is important to complete a thorough skin assessment to note the location and extent of the lesions, as well as to ascertain what the patient's goals of treatment are. There are several therapies available, including topical creams and ointments and UV light therapy, as well as systemic medications (Table 50.5).

**Safety Alert** Phototherapy for psoriasis requires exposure to UVA (long wave ultraviolet A) or UVB (short wave ultraviolet B) light rays and needs to be performed in a controlled environment under the clinical expertise of a dermatology provider. Medications such as antibiotics and over-the-counter supplements can sensitize the patient to phototherapy, causing burning of the skin and increasing the patient's risk of skin cancer.

## Complications

In addition to the side effects of medications, patients with psoriasis are at high risk of developing other diseases (i.e., cancer, cardiovascular disease, Crohn's disease, diabetes, metabolic syndrome, uveitis, and liver disease). It is important to understand the patient's risk of developing these comorbidities when counseling patients and considering therapies to manage the disease. As previously mentioned, PsA occurs in approximately 30% of those individuals diagnosed with psoriasis. Those with PsA experience pain, soft tissue swelling, and limitations in movement for 6 weeks or longer, and this can be a debilitating consequence of psoriasis.

Research demonstrates an increased risk of malignancy among patients with psoriasis. Non-melanoma skin cancer; lymphoma; and cancer of the lung, larynx, pharynx, liver, pancreas, female breast, penis, vulva, bladder, and kidney are among the most common malignancies found to develop. **Basal cell carcinoma** (abnormal, uncontrolled cancer cells in the skin's basal cells) and **squamous cell carcinoma**

**Table 50.5** Treatments for Psoriasis

Treatment	Rationale
<b>Topicals</b>	
<ul style="list-style-type: none"> <li>Moisturizing ointments, gels, creams</li> <li>Coal tar: creams and shampoos</li> <li>Corticosteroids</li> <li>Vitamin D analogues (calcipotriene, calcitriol)</li> <li>Retinoids (vitamin A)</li> <li>Salicylic acid (in combination with other topical therapies)</li> </ul>	<ul style="list-style-type: none"> <li>For mild to moderate psoriasis: moisturizing plaques minimize scaling, decrease itching, keep the skin hydrated</li> <li>Suppresses cell division and decreases inflammation; applied twice daily</li> <li>Fast acting; decrease inflammation and itching; vasoconstrictive to decrease redness; prevent formation of new lesions</li> <li>Inhibit proliferation of keratinocytes to decrease plaque formation; added benefits if used with topical corticosteroids</li> <li>Diminish proliferation of keratinocytes and decrease inflammation</li> <li>Decreases scaling and softens plaques</li> </ul>
<b>Phototherapy</b>	
<ul style="list-style-type: none"> <li>Narrow-band ultraviolet therapy (NB-UVB) phototherapy</li> <li>PVA photochemotherapy: uses oral psoralens to sensitize cells to ultraviolet A (UVA) radiation; can be combined with other therapies</li> </ul>	<ul style="list-style-type: none"> <li>Inhibits cellular turnover and downregulates local immune system function; treatments measured in seconds of exposure; has synergistic effect when used with methotrexate</li> <li>Same effects as NB-UVB but also penetrates dermis to decrease inflammation</li> </ul>
<b>Biologics</b>	
<ul style="list-style-type: none"> <li>Immunomodulatory medications (e.g., Humira, Enbrel, Remicade)</li> </ul>	<ul style="list-style-type: none"> <li>Inhibit the effects of immune system components; for moderate to severe psoriasis in individuals who have not responded to other therapies; require careful monitoring for serious side effects</li> </ul>
<b>Traditional systemic medications</b>	
<ul style="list-style-type: none"> <li>Methotrexate, cyclosporine, acitretin</li> </ul>	<ul style="list-style-type: none"> <li>Inhibits the enzyme involved in rapid cell growth; requires careful monitoring</li> </ul>

(cancer cells that arise from the flat squamous cells that make up the epidermis) seem to be related to the treatment exposures during phototherapy. In addition to therapy-related malignancies, patients with psoriasis who choose to smoke or consume large quantities of alcohol have a greater risk of developing cancers of the oral cavity, esophagus, liver, pancreas, lung, kidney, and breast.

Research also suggests that patients with psoriasis may be at greater risk of developing cardiovascular disease. This may be related to the chronic inflammation of psoriasis that results in high levels of circulating oxidants, which stimulate the formation of atherosclerotic lesions in blood vessel walls. Therefore, prudent monitoring of cardiovascular risk factors such as obesity, increased cholesterol and triglycerides, and hypertension should occur in patients with psoriasis.

Some forms of psoriasis are associated with recent streptococcal infections among patients who complained of sore throat symptoms 1 to 2 weeks prior to the psoriatic eruption. Additionally, patients with psoriasis are at increased risk of systemic infections, mainly related to the immunosuppressant therapies used to treat the disease. Therefore, immunizations against influenza and pneumonia are highly recommended.

Lastly, psoriasis can have a significant impact on an individual's quality of life. Depression leading to suicidal ideation occurs in more than 5% of those with psoriasis. Studies confirm that worry and anxiety occur in more than 30% of patients with psoriasis, and interpersonal difficulties affect every aspect of relationships. Persistent stress occurs when patients practice avoidance behavior because they believe they are being judged on the basis of physical appearance due to this skin disorder. Not only does this stress and worry have a negative impact on the success of treatment, but it can further exacerbate the disease. Therefore, it is essential to consider not only the physical but also the psychosocial implications of psoriasis when caring for these patients.

### Connection Check 50.4

An 18-year-old with psoriatic plaques on the elbows, knees, and legs has been successfully treated with a combination of therapies including phototherapy. Because the patient is an avid soccer player and expects to receive a college scholarship next year, which information is the most important aspect to teach at this time?

- The importance of knowing the clinical manifestations of PsA (soft tissue swelling, limitations of movement) because as many as 30% of those who have psoriasis develop PsA
- The importance of adhering to the medication regimen
- The importance of finding a support group to help cope with stress and anxiety that can develop as a response to treatment and can exacerbate the disease
- The importance of using sunscreen while outside

## Nursing Management

### Assessment and Analysis

Psoriasis significantly affects the quality of life of the individual patient and the family. The effects of the disease are not necessarily proportionate with the extent of the disease on the individual. Psoriasis can lead to psychosocial stress, poor self-esteem, financial worries, increased pain and discomfort, and infection. A baseline skin assessment is necessary to identify the location, quality, and amount of plaques and areas of infection and to evaluate the effectiveness of treatment. Clinical manifestations of psoriasis include thickening of the epidermis related to silver-white scales over red, circumscribed, thickened plaques. Patients with psoriasis are at higher risk of developing non-melanoma skin cancer and PsA that can lead to impaired mobility and restrict activities of daily living. More than 50% of patients diagnosed with psoriasis complain of physical pain as well as physical irritation and itching.

Because there is a high rate of psoriasis within families, it is important to obtain a detailed family history from those patients presenting with clinical manifestations of psoriasis. Assessment also focuses on conditions that increase the risk of psoriasis, including immunocompromise or immunosuppression and impaired skin integrity. Because of the skin changes associated with psoriasis, patients often manifest issues around personal appearance, leading to an increased risk of depression, anxiety, obsessive behavior, and difficulty expressing emotions such as anger. Depression and low self-esteem are associated with psoriasis and can be so debilitating that patients contemplate suicide. Pathological anxiety and worry occur because of the effects of avoidance behavior. Stress and anxiety have deleterious effects on the response to treatment and can exacerbate the disease.

### Nursing Diagnoses

- **Impaired skin integrity** related to chronic skin inflammation and pruritus
- **Chronic pain** related to chronic skin inflammation, psoriatic plaques, and arthritis
- **Disturbed body image** related to altered appearance secondary to thick, scaling plaques on the skin

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Vital signs can be affected by infection (increased temperature, increased heart rate, decreased blood pressure with sepsis).*
- **Pain**  
*Patients with psoriasis have increased levels of discomfort, pain, and itching associated with inflammation of the skin.*
- **Skin**  
*Baseline and ongoing skin assessments help guide and evaluate the effectiveness of treatment; skin infections are noted with erythema, increased warmth, and purulent drainage.*
- **Mood, affect**  
*Mood and affect are a reflection of emotional well-being.*

## Actions

- Administer ordered medications.  
*The specific actions of medications, although they do not cure psoriasis, minimize symptoms and may minimize exacerbations.*
- Monitor for side effects of treatments.
- Topical preparations  
*Staining of skin, hair, nails, and clothes can occur with topical treatments.*  
*Skin atrophy can occur with prolonged use of topical corticosteroids.*  
*Disease can worsen after discontinuing strong topical corticosteroids.*  
*Increased serum calcium levels and photosensitivity may occur with vitamin D analogues.*  
*Skin irritation may occur with retinoids.*  
*Systemic toxicity may occur if used in conjunction with oral salicylates.*
- Phototherapy  
*Itching, burning, erythema, stinging, increased risk of skin cancer, abdominal fullness, flulike symptoms, nasal congestion*
- Biologics (immunomodulatory medications such as Humira, Enbrel, and Remicade)  
*Infections, injection site reactions, rash, tuberculosis, cancers of the bladder or skin, neurological reactions, hypertension, malignancies, fever, chills*
- Traditional systemics (methotrexate, cyclosporine, acitretin)  
*Infection, fever, chills, nausea, infertility, photosensitivity, severe allergic reactions, difficulty breathing, liver or kidney damage, hypertension, hair loss*
- Provide emotional support  
*Low self-esteem may occur on the basis of patients' sense of altered body image because of plaques.*
- Referral to counseling for psychosocial dysfunction  
*Psoriasis can have a negative impact on quality of life, leading to high levels of anxiety, depression, anger, and possibly suicidal thoughts.*
- Administer analgesics as ordered for control of pain.  
*Some patients require analgesic medication for the pain caused by psoriasis.*
- Encourage patient and family to join a psoriasis support group.  
*Local support group information and many online resources are found on the National Psoriasis Foundation Web site ([www.psoriasis.org](http://www.psoriasis.org)). Support groups can help patients cope with the disease.*

## Teaching

- Proper hand washing before and after application of topical medications  
*To avoid staining and unnecessary absorption of medications as well as diminish the transmission of bacteria*
- Clinical manifestations of adverse reactions to specific therapies  
*Explanations of adverse reactions helps the patient understand the treatments.*

- Signs of skin infection (purulent drainage, erythema, increased warmth)  
*Understanding the clinical manifestations allows for more timely treatment.*
- To limit the amount of sunlight exposure while taking systemic therapies  
*Photosensitivity can occur in response to systemic therapy.*
- For phototherapy: daily examination of skin to look for signs of overexposure (erythema, tenderness on palpation, blisters)  
*Phototherapy should be held and reevaluated because of the increased risk of skin cancer, pain, and infection if patients experience signs of overexposure.*

## Evaluating Care Outcomes

Address emotional and psychological stress because physical clinical manifestations have proven to be crucial in the management of psoriasis. Providing emotional support, allowing the patient to verbalize concerns, and referral to the appropriate providers and support groups can improve overall quality of life. Educating the patient and family about medication side effects, including frequent skin assessment during phototherapy, is essential for the patient's health and safety.

## Connection Check 50.5

The nurse correlates the use of KOH testing with the definitive diagnosis of which skin disorder?

- Bacterial infections
- Herpes simplex
- Fungal infections
- Psoriasis

## SKIN TRAUMA

Traumatic injuries to the skin are the result of external sources and are classified as acute wounds. There are many types of traumatic skin injuries, including lacerations, abrasions, excoriations, friction blisters, skin tears, pressure injuries, and burns. Pressure injuries are discussed in more detail later in this chapter, and burns are discussed in Chapter 51.

## Epidemiology

### Laceration

A **laceration** is a break in the skin caused by penetration of a sharp object or high **shearing forces** that exert a diagonal force on the skin, causing damage. The wound edges of abrasions may be smooth or jagged. Lacerations are superficial (near the skin surface) or extend into the deeper tissues such as the nerves, muscle, bone, or tendon. Lacerations that are superficial and do not involve the underlying tissues are usually treated in the primary healthcare provider's office.

## Abrasion

**Abrasions**, occurring as a result of friction and shear from external forces, are usually minor injuries involving only the epidermis. Some abrasions involve part or all of the dermis. An example of an abrasion is a grazing or scraping injury to the skin of the knee of a patient who fell on concrete. Minor abrasions do not usually require treatment by healthcare personnel, leading to difficulty in determining incidence and prevalence rates because these injuries are not consistently reported.

## Excoriation

An **excoriation** is a superficial abrasion. It can be self-induced through repetitive scratching and is usually linear in appearance. Excoriations are commonly seen in disorders of the skin that cause pruritus (itching), such as insect bites, scabies, dermatitis (inflammation of the skin from an allergic reaction), and chicken pox (varicella-zoster virus). The term *excoriation* is also used to describe the loss of epithelium in response to prolonged exposure to urine and feces in an individual who is incontinent. Urine and feces alter the pH of the skin, causing it to become more alkaline, which supports bacterial proliferation, leading to skin breakdown in the perineal area, also known as incontinence-associated dermatitis (IAD). More than 200 million people worldwide are affected by urinary incontinence. Approximately 35% of the older adults in acute care facilities and 41% of those in long-term care facilities experience IAD.

## Friction Blisters

Friction blisters commonly occur on the feet of long-distance runners or on individuals with poor-fitting shoes, as well as on the palms of athletes who play racquet sports. Friction is a force that is applied parallel to a surface, resulting in a rubbing motion. This causes the cells of the epidermis to

separate, and increased hydrostatic pressure causes plasma-like fluid to accumulate between the cells. Moisture on the surface increases the risk of blistering. Most commonly, blisters occur on the feet and palms where the skin is thick; however, blisters can occur on other parts of the body because of the external forces of friction and shear. Up to 39% of marathon runners experience friction blisters on the feet.

## Skin Tears

**Skin tears** are traumatic wounds usually caused by minor trauma that primarily affect older adults. Minor trauma in this population includes injuries involving wheelchairs (25%), bumping into objects (25%), transfers (18%), falls (12.4%), and tape removal. In the United States, more than 1.5 million skin tears occur among institutionalized older adults. Approximately 80% of these skin tears occur on the upper extremities, whereas other common areas include the lower extremities, back, and buttocks. In addition, premature infants who have immature skin, as well as individuals who are critically ill, are also at risk of developing skin tears. Payne and Martin developed a skin tear classification scale that assists in the diagnosis and treatment of skin tears (Table 50.6). The Skin Tear Audit Research (STAR) Classification System, which was developed in Australia, is another skin tear classification system that includes three categories and two subcategories of skin tears.

## Pathophysiology and Clinical Manifestations

The explanation of the pathophysiology of skin trauma and the acute wound must include a discussion of the structure and function of the skin, a definition of wound tissues, wound healing, and the influence of age. There are many functions of the skin, including protection from bacterial invasion and external elements; perception of the environment through

**Table 50.6 Payne–Martin Skin Tear Classification**

Category	Description
<b>Category I</b>	Skin tear without tissue loss: The epidermal flap either completely covers the dermis or covers the dermis to within 1 mm of the wound margin.  Ia: Linear type  Ib: Flap type
<b>Category II</b>	Skin tears with partial tissue loss  IIa: Scant tissue loss: Partial-thickness wound in which less than or equal to 25% of the epidermis flap is lost and greater than or equal to 75% of the dermis is covered by the flap.  IIb: Moderate to large tissue loss: Partial-thickness wound in which greater than or equal to 25% of the epidermal flap is lost and greater than or equal to 25% of the dermis is exposed.
<b>Category III</b>	Skin tears with complete tissue loss: Epidermal flap is absent.

Adapted from Payne, R., & Martin, M. (1993). Defining and classifying skin tears: Need for a common language. *Ostomy Wound Management*, 39(5), 16–26.

the senses of touch, pain, temperature, and pressure; retention of water; absorption; thermoregulation; immune surveillance; and metabolism of vitamin D. However, once the surface of the skin is breached, homeostasis is disturbed, and skin functions become less effective. Aging can impact wound healing because of structural changes of the skin (see Geriatric/Gerontological Considerations).

## Geriatric/Gerontological Considerations

### Wound Healing

The functions of the skin and its ability to heal are significantly affected by the aging process. Epidermal thinning occurs with aging and makes the skin more susceptible to external mechanical forces such as friction, shear, trauma, and moisture. The rete ridges are epidermal finger-like projections that reach and “lock” into the dermal layer. With aging, the rete ridges flatten between the dermal-epidermal junction, making it more susceptible to tearing injury from external shearing forces. Additionally, aging skin is a less effective barrier against water loss and infection because the dermis thins by about 20% and causes a decrease in the number of dermal cells, blood vessels, nerves, and collagen. Older adults are also subject to loss of subcutaneous tissue, which results in loss of the insulating properties and mechanical protection of the skin. This leads to alterations in sensation, thermoregulation, and moisture retention in the skin of older adults, making them more susceptible to traumatic injuries such as skin tears, excoriations, and pressure injuries.

A cascade of healing is set into motion in response to traumatic injury of the skin. **Partial-thickness** skin loss describes a wound where damage extends through the epidermis and into the dermis but not through the dermis. This can be a shallow laceration, abrasion, or excoriation. Because the hair follicles originate in the dermis, not all of them are destroyed in a partial-thickness wound. Each hair follicle is surrounded by epidermal cells that proliferate and migrate along the wound bed within the first 24 hours of injury. Repair of the dermis takes longer because **neovascularization** (growth of new blood vessels) must occur while collagen fibers build to help contraction of the wound and full re-epithelialization.

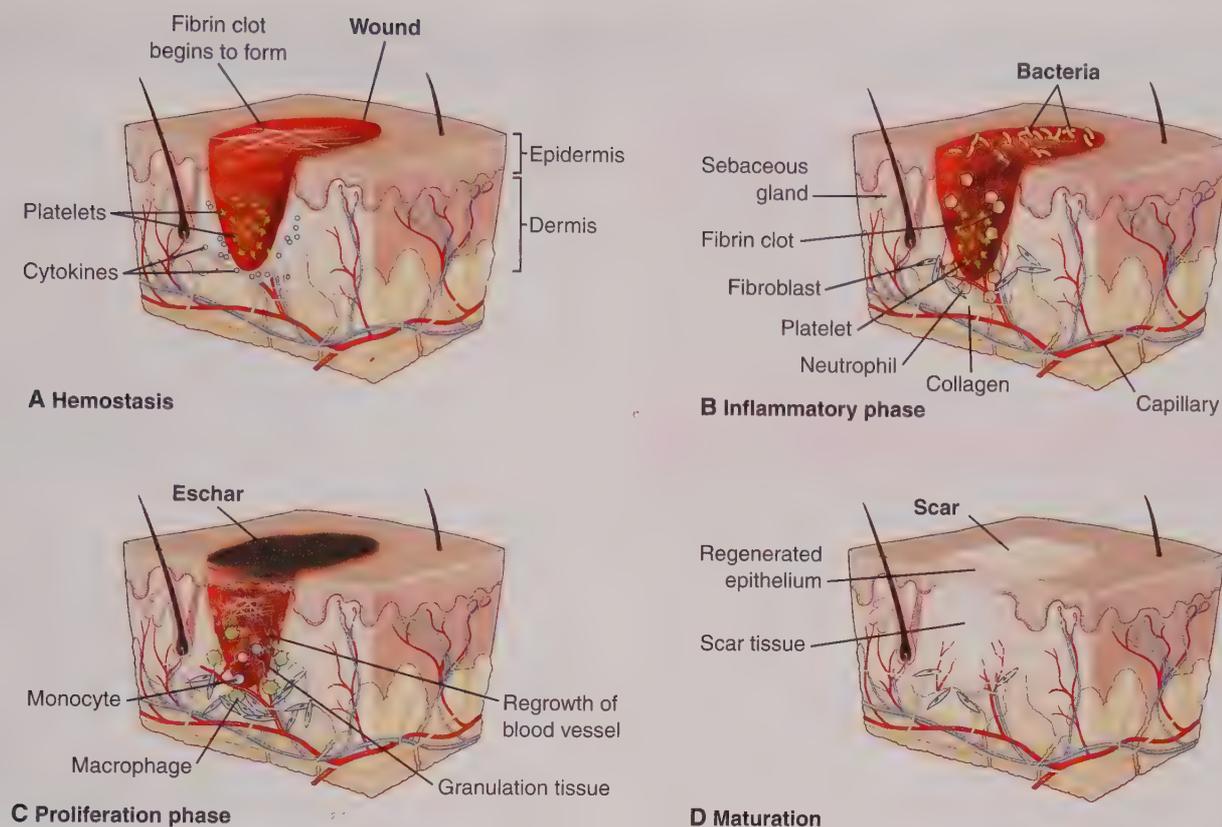

**Full-thickness** skin trauma involves the epidermis, dermis, subcutaneous tissues, and possibly muscles, tendons, or bones and can occur as a result of a deep laceration or ulcer. The four **phases of wound healing** are initiated when a full-thickness injury occurs. The four phases of wound healing are hemostasis, inflammatory, proliferative, and maturation (Table 50.7; Fig. 50.5). After the immediate injury, platelets and other clotting factors are activated and aggregate to form a clot, stopping hemorrhage at the site

**Table 50.7 Four Phases of Wound Healing**

Phase	Actions
<b>Hemostasis (immediate)</b>	<ul style="list-style-type: none"> <li>Activation of platelets and clotting factors</li> <li>Fibrin deposition</li> <li>Platelet release of cytokines</li> <li>Fibroblasts activate production of collagen</li> </ul>
<b>Inflammatory (from 24 hours to 2 weeks)</b>	<ul style="list-style-type: none"> <li>Surrounding vasculature begins to “leak” in response to mast cells.</li> <li>Neutrophils phagocytize bacteria and remove foreign material.</li> <li>Fluid escapes into the wound and causes edema.</li> <li>Macrophages remove additional bacteria, residual foreign bodies, and necrotic tissue.</li> <li>Macrophages secrete growth factors and cytokines that activate the synthesis of collagen and lay down extracellular matrix.</li> </ul>
<b>Proliferative</b>	<ul style="list-style-type: none"> <li>Angiogenesis</li> <li>Epithelialization</li> <li>Fibroplasia with formation of granulation tissue</li> <li>Collagen deposition</li> <li>Wound contraction</li> </ul>
<b>Maturation (up to 2 years)</b>	<ul style="list-style-type: none"> <li>Decreased fluid within wound</li> <li>Decreased metabolic rate</li> <li>Reorganization of collagen fibers</li> <li>Continued collagen synthesis and degradation</li> </ul>

of blood vessel damage as part of the hemostasis phase. Fibrin is deposited in the wound and functions as a provisional matrix to stabilize the wound site. Then, platelets release cytokines, which initiate the wound-healing process and play a key role in the progression of the wound-healing cycle. The cytokines recruit additional cells such as fibroblasts that activate the production of collagen, which is essential in repairing the extracellular matrix.

The main function of the inflammatory phase of wound healing is to remove debris within the wound. This phase begins within the first 24 hours after injury and can last up to 2 weeks for an acute wound. In response to mast cells, the surrounding vasculature begins to leak neutrophils (white blood cells) into the area of injury to phagocytize bacteria and remove foreign materials. Along with the neutrophils, fluid also escapes into this area and causes swelling. Additionally, monocytes attracted to the wound site become macrophages and are stimulated to remove any additional bacteria, residual

**FIGURE 50.5** Four phases of wound healing. A, Hemostasis. B, Inflammatory. C, Proliferative. D, Maturation.

foreign bodies, and necrotic tissue. Lastly, macrophages secrete growth factors and cytokines that activate fibroblasts, which synthesize collagen and lay down the extracellular matrix. The clinical characteristics of the inflammatory phase include edema, erythema, heat, and pain. The wound bed during this phase may have visible necrotic (dead) tissue.

The third phase of the wound-healing cycle is the proliferative phase. The four major steps of this phase are **angiogenesis** (growth of new blood vessels from previously existing ones), epithelialization, granulation (growth of new tissue), and collagen deposition with tissue formation. During the proliferative phase, the number of macrophages decreases and fibroblasts proliferate, secreting collagen to replace the provisional fibrin matrix and provide a strong extracellular matrix. While the macrophages are synthesizing collagen, keratinocytes emerge to help with re-epithelialization. Endothelial cells are activated to initiate angiogenesis, which increases blood supply to the new tissue. As the capillary bed is laid down, the wound fills with **granulation tissue** and appears beefy red, shiny, and granular. During this time, the metabolic rate of the tissue is higher and requires adequate nutrition and oxygenation to properly heal the wound.

In the maturation or remodeling phase, which is the final phase of wound healing, granulation tissue matures into a scar. There is decreased fluid within the wound, decreased metabolic rate and cell densities, and an increase and reorganization of collagen fibers, resulting in increased tensile strength of the wound. Collagen synthesis and degradation continue during this phase for up to 2 years. Still, the tensile strength of the

scar tissue becomes only 80% of that of normal tissue, making it more susceptible to tissue breakdown and trauma.

### Connection Check 50.6

The nurse is admitting a patient to the unit who is a paraplegic and has a history of healed sacral pressure injuries, verified by the large scars on the sacrum. What action should the nurse take first?

- Apply a moisturizing lotion to the sacrum.
- Place a dressing such as a silicone foam dressing over the scars.
- Place the patient in a sitting position to keep pressure off the sacrum.
- Help the patient choose the most nutritious foods on the menu.

### Connection Check 50.7

In completing a skin assessment, the nurse correlates erythema, redness, and warmth with which phase of wound healing?

- Hemostasis
- Inflammatory
- Proliferative
- Maturation

## Management

### Medical Management

Medical management of skin trauma begins with a thorough wound and medical history, including immunization status. Tetanus is a potentially life-threatening disease that can occur following penetrating injury with an object contaminated with *Clostridium tetani* bacteria. The expected length of immunity to the *C. tetani* bacteria following immunization is 10 years. Therefore, tetanus toxoid is indicated if the last immunization was greater than 10 years prior to the traumatic injury, unless the patient is allergic. Evaluation of the patient's overall health status, including nutritional status, vascular status, immune status, blood pressure, and smoking, is essential. Additionally, local findings such as wound perfusion, tissue viability, infection, and exposure to external mechanical forces are considered. A wound can contain many different types of tissues over the course of healing, and an understanding of the types of wound tissues guides treatment decisions. Table 50.8 explains the different types of wound tissue.

Adequate blood supply to an extremity and ultimately to the wound is needed for healing to occur. Disease states such as diabetes mellitus, peripheral vascular disease, anemia, arteriosclerosis, and cardiopulmonary disorders can affect the blood, oxygen, and nutrient supply to an acute wound. The ankle-brachial index (ABI) is the ratio of the systolic blood pressures obtained at the ankle and in the arm and is a sensitive, noninvasive indicator of arterial perfusion to the lower extremities. For example, an ankle systolic blood

pressure of 120 and a brachial systolic blood pressure of 132 would be reported as an ABI of 0.91 (120/132). The ABI is interpreted as follows:

- Greater than 1.3: abnormal, usually related to calcification of vessel wall
- 0.9 to 1.3: normal
- Less than or equal to 0.9: lower extremity arterial disease
- 0.6 to 0.8: borderline perfusion
- Less than or equal to 0.5: severe ischemia
- Less than or equal to 0.4: critical limb ischemia

A wound on an extremity with an ABI of less than 0.8 may have a prolonged course of healing. Therefore, endovascular procedures are indicated with severe ischemia to improve blood supply to the affected limb. Similarly, hypotension can significantly affect healing of the acute wound. Smoking and hypothermia should be avoided while healing to maximize blood flow to the wound.

Nutritional status is another important indicator of wound healing and should be incorporated into the treatment plan to promote wound healing and decrease the length of treatment. The Nutrition Screening Initiative reported that as many as 40% to 60% of hospitalized adult patients in the United States are either malnourished or at risk of malnourishment. Malnutrition can prolong the inflammatory phase of wound healing by decreasing fibroblast proliferation, collagen formation, and angiogenesis. Unfortunately, the biochemical data on which many clinicians still rely, such as serum albumin and prealbumin levels, can be significantly

**Table 50.8 Definition of Tissue Types**

Tissue Type	Definition
<p><b>Granulation tissue</b></p> 	<p>Red/pink moist granular tissue composed of new blood vessels</p> <p>Healthy, healing tissue</p>
<p><b>Hypergranulation tissue</b></p> 	<p>Hyperplasia of granulation tissue recognized by its friable red appearance usually in response to a prolonged inflammatory phase</p>

**Table 50.8** Definition of Tissue Types—cont'd**Tissue Type****Definition****Necrotic tissue**

Dead or avascular or devitalized tissue

**Eschar**

Thick, leathery, devitalized tissue; black or brown; hard, soft, or boggy  
Loose or firmly attached to wound bed

**Slough**

Soft, moist devitalized tissue that may be white, yellow, tan, green  
May be loose, stringy

**Macerated tissue**

Softened tissue in response to prolonged exposure to moisture

affected by numerous confounding factors, including hydration status, medications, alterations in metabolism, and inflammation, making them an unreliable reflection of nutritional status.

Nutrition screening uses valid and reliable tools to quickly ascertain an individual's risk of malnutrition, and

the anthropometric measurements of weight, height, and body mass index (BMI) are utilized as part of these tools. Additionally, significant unwanted weight loss and any significant recent illnesses are also indicators utilized in some nutrition screening tools (see Chapter 55 for the Malnutrition Universal Screening Tool [MUST] from the British

Association of Parenteral and Enteral Nutrition; referral to a nutritionist for a complete nutritional assessment is initiated when an individual scores 2 or higher on the MUST).

The immune status of a patient plays an important role in the ability to heal. For patients with immune deficiencies such as AIDS, treatment with prophylactic antibiotics is considered. If possible, immunosuppressant medications, such as steroids, should be weaned to the lowest possible dose. When it is not possible to wean patients from steroids, providers use high doses of vitamin A to counteract the steroids' detrimental effects. Vitamin A works by boosting

the immune response and enhancing the early inflammatory phase of wound healing.

Identifying infection is another important part of wound management, and culturing a wound by surface swab or punch biopsy assists with antibiotic selection and guides treatment. The surgical management of a traumatic wound involves debridement (removal) of necrotic (dead) tissue to decrease the bioburden (bacteria living on the wound surface) of the wound, thereby decreasing the risk of infection. Table 50.9 provides an overview of the different methods of debridement.

**Table 50.9 Overview of Debridement Methods**

Method	Considerations	Contraindications
<p><b>Surgical/sharp</b> Necrotic tissue is removed using a scalpel, scissors, forceps, or curette.</p>	<p>Urgent need for debridement</p> <p>Highly selective</p> <p>Rapid results</p> <p>Pain unless the patient has neuropathy; analgesia often needed</p> <p>Risk of hemorrhage/complications</p> <p>Cost; use of special equipment</p> <p>Requires patient consent</p> <p>Requires special training and expert comfort level (including anatomical knowledge)</p> <p>Must distinguish between necrotic and healthy tissues</p> <p>Can be done bedside</p> <p>May require the need for operating room and systemic anesthetics for extensive procedures</p> <p>Anticoagulant therapy</p>	<p>Malignant wounds</p> <p>Patients with clotting/bleeding abnormalities</p> <p>Ischemic tissue</p> <p>Unstable patient status</p> <p>Underlying dialysis fistula, prosthesis, or arterial bypass graft</p> <p>Caution with wounds involving hands and face</p> <p>Caution with immunocompromised patients</p>

Source: Kirshen, C., Woo, K., Ayello, E., & Sibbald, R. (2006). Debridement: A vital component of wound bed preparation. *Advances in Skin and Wound Care*, 19(9), 511-512.

Controlling or eliminating external factors, such as exposure to urine and feces, and decreasing the mechanical forces of friction and shear are necessary in the healing and prevention of traumatic skin injury. Cleansing incontinent episodes as soon as possible and using moisture barrier creams such as zinc pastes can reduce the exposure of the perineal skin to the detrimental effects of urine and feces. Shearing exerts a diagonal force on the skin, causing an opposing motion of the internal tissue layers against bone, leading to damage to deeper structures such as blood vessels, muscle, and subcutaneous fat. Friction, on the other hand, inflicts a parallel force on the skin, damages the superficial layers, and occurs when one surface slides across another. Keeping the head of the bed at less than 30 degrees minimizes the forces of friction and shear by limiting the ability of the body to “slide down” the surface of the bed. Friction also plays a role in the development of traumatic foot blisters, which can be minimized with properly fitting

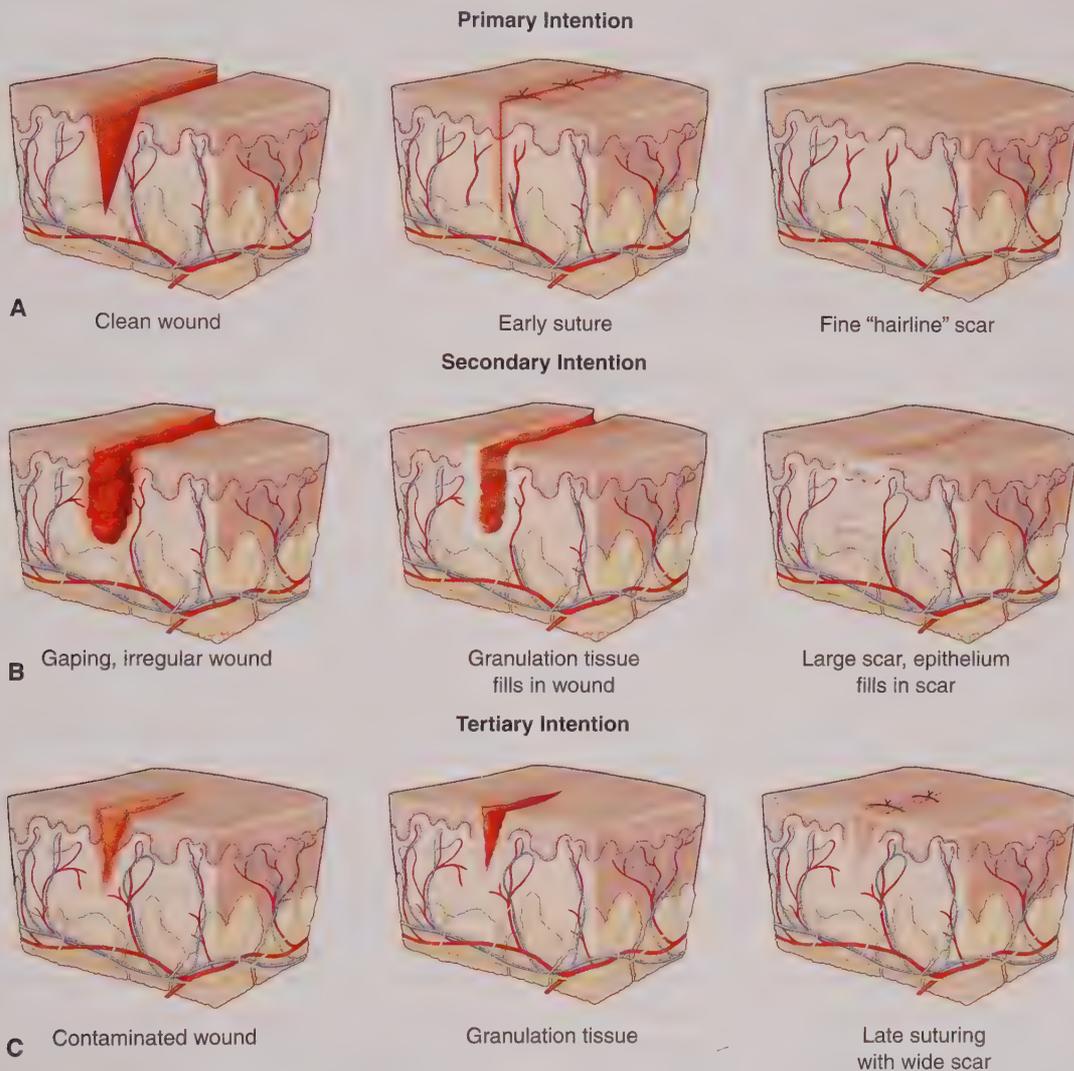

shoes, appropriate socks, and utilization of gel soles in the shoes.

### **Surgical Management**

Surgical approaches to the management of traumatic skin injuries vary depending on the nature of the wound itself. There are three different surgical closure approaches: primary intention, secondary intention, and tertiary intention (Table 50.10; Fig. 50.6). Prior to wound closure, necrotic tissue must be removed because it provides a medium on which bacteria can multiply, leading to infection. **Primary intention** is the approach used with typical surgical incisions with well-approximated edges that are closed with sutures or staples. With **secondary intention**, the wound is left open and allowed to fill with granulation tissue. Often, these wounds are packed with gauze and changed daily. The healing process with secondary intention can be slow, and scar tissue is more pronounced. **Tertiary intention** often

**Table 50.10** Types of Wound Closure

Intention (Closure)	Unique Characteristics	Key Points
<b>Primary</b>	Clean, minimally contaminated 6–8 hours old	May close with tape, staples, sutures, glue
<b>Secondary</b>	Animal bites Abscess cavities, ulcers	No sutures Delayed skin coverage, grafts
<b>Tertiary</b>	Too contaminated to close	Must clean, debride, and observe 4–6 days before suturing

**FIGURE 50.6** Types of wound closure. A, Primary intention. B, Secondary intention. C, Tertiary intention.

uses skin grafts for wound closure, after a period of observation following initial surgical debridement.

### Complications

As with any breach in the integrity of the skin, patients with traumatic skin injuries are at high risk for infection. Clinical manifestations of infection include increasing erythema,

increased temperature of surrounding tissues, odor, purulent drainage, increased swelling, increased pain, and fever. Depending on the depth of the injury, an individual can be at further risk of damage to underlying structures of muscle, tendon, bone, and nerve, requiring deep lacerations to be explored down to the wound bed to determine the involvement of these structures. Additionally, pain from a

traumatic skin injury can range from mild to severe and must be treated accordingly. Lastly, scarring from skin injuries that are on the face or other apparent surfaces can be psychologically traumatic and can affect self-image and interpersonal relationships.

## Nursing Management

### Assessment and Analysis

Specific assessments include the overall health and nutritional status, skin integrity, mobility, and hydration status of the patient. In addition to a comprehensive physical assessment, the nurse examines and documents the characteristics of the actual area of skin trauma, as well as the surrounding tissue. Assessment of color, temperature, edema, and erythema provides important data about perfusion to the wound area, and any signs of drainage may indicate infection. When managing the patient with a traumatic skin injury, the nurse must consider associated patient factors; environmental factors; and the knowledge base of the patient, family, and nursing staff.

### Nursing Diagnoses

- **Impaired skin integrity** related to effects of mechanical irritants of friction, shear, or excoriation secondary to exposure to urine and stool
- **Acute pain** related to the wound secondary to traumatic skin injury
- **Risk for infection** related to the wound secondary to traumatic skin injury
- **Risk for body image disturbance** related to the wound secondary to traumatic skin injury
- **Risk for imbalanced nutrition** related to increased metabolic rate secondary to the open wound

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Fever, tachycardia, and hypotension are indications of infection.*
- Pain  
*Pain occurs related to pressure in the wound area, as well as potential exposure of nerve endings. Rate the patient's pain on a scale of 0 to 10 to guide pain management.*
- Nutritional status  
*Perform a nutritional screening assessment during the patient's initial visit to ascertain the risk of malnutrition and need for referral to a nutritionist; adequate nutrition is needed for wound healing. Prealbumin and albumin levels may provide data about the overall nutrition status. The MUST score is effective in guiding nutritional assessment and management.*
- Skin  
*Conduct a baseline skin assessment, including measurement of wounds, to guide treatment and evaluation of interventions; observe for clinical manifestations of infection (increased erythema, temperature, swelling, increased pain, odor, purulent drainage).*

- Peripheral vascular status  
*Wounds need adequate perfusion to heal, and cool, pale skin is indicative of decreased perfusion.*
- Fluid volume status  
*Adequate perfusion is dependent on ideal fluid volume status. Dehydration can exacerbate alterations in skin integrity.*

#### ■ Actions

- Perform wound care as prescribed (including cleansing and using appropriate dressings).  
*Cleansing decreases the bacterial burden, and moist wound-healing products support adequate healing.*
- Administer pain medications as prescribed.  
*Nerve endings can be exposed in open wounds, causing pain.*
- Administer antibiotics as prescribed.  
*Antibiotics are administered in accordance with the culture and sensitivity results to lower the bacterial count and support healing.*
- Referral to a nutritionist as needed  
*A nutritionist can recommend types and amounts of foods that can promote wound healing.*
- Referral for vascular evaluation with documented decreased perfusion  
*Wounds need adequate perfusion, oxygen, and nutrients to heal; a vascular surgeon may be able to perform reperfusion procedures to increase blood flow to the wound.*
- Provide emotional support.  
*Body image disturbance can occur with a traumatic skin injury.*

#### ■ Teaching

- Proper positioning  
*Keeping the head of the bed at less than 30 degrees decreases the risk of friction and shear; older adults are more prone to the effects of friction and shear because of a flattened dermal-epidermal junction.*
- Need to cleanse incontinence as soon as possible and use moisture barrier creams  
*Urine and feces decrease the pH of skin, which supports bacterial proliferation; barrier creams minimize the effects of urine and feces on perineal tissue.*
- Minimize objects on the floor, and maintain the bed in the lowest position.  
*Minimizing objects on the floor in patients' rooms and keeping beds in the lowest position decrease the risk of falling and traumatic skin injuries.*
- Importance of nutrition and examples of nutritious foods to eat (increased protein intake)  
*Wounds require adequate nutrition to heal.*
- Utilize mobility aids as prescribed, and ask for assistance.  
*Minimizing falls reduces the risk of traumatic skin injuries.*

### Evaluating Care Outcomes

Acute traumatic wounds usually heal without consequence. Educating the patient and family about the clinical manifestations of infection is important in managing wounds. Additionally, because aging skin is at even greater risk of

trauma, awareness of potential environmental hazards can minimize traumatic injuries. Ensuring that wheelchairs are in good repair, floors are clear from clutter, beds are kept in their lowest position, and patients are positioned with the head of the bed at less than 30 degrees when possible are ways to minimize environmental risks. Lastly, evaluating and maximizing nutrition for a patient with an open wound supports wound healing.

### Connection Check 50.8

Which position is best to reduce the risk of skin tears in an immobile, older adult patient?

- In a side-lying position
- Foot of the bed elevated to no greater than 15 degrees
- In a chair with feet on the floor
- Head of the bed elevated no greater than 30 degrees

## PRESSURE INJURIES

**Pressure injuries** are a common health problem among individuals who are physically limited or bedridden. A pressure injury is localized damage to the skin and underlying soft tissue, usually over a bony prominence or related to a medical or other device. The injury can present as intact skin or an open ulcer and may be painful. The injury occurs as a result of intense and/or prolonged pressure or pressure in combination with shear. The tolerance of soft tissue for pressure and shear may also be affected by microclimate, nutrition, perfusion, comorbidities, and the condition of the soft tissue.

Ultimately, the nurse's goal is to limit pressure and shearing to prevent pressure injury development. However, for the patient with an existing pressure injury, the goals are wound management and the prevention of further tissue breakdown and infection.

### Epidemiology

Pressure injuries are a significant clinical issue that spans across all ages and all healthcare settings. In the United States, the 2.5 million people treated annually for pressure injuries in acute care facilities are three times more likely to be transferred to a long-term care facility. Of those people treated annually, as many as 60,000 may die from complications. **Most pressure injuries occur in individuals over age 65.** However, people of all ages are susceptible to pressure injuries depending on comorbid conditions such as diabetes, dementia, malnutrition, and immobility.

The prevalence of pressure injuries in the United States is estimated to be 10% to 18% in acute care facilities, 2.3% to 28% in long-term care, and up to 29% in home care. The incidence of pressure injuries is estimated to be 0.4% to 38% in acute care, 2.3% to 23.9% in long-term care, 0% to 17% in home care, and 0% to 6% in rehabilitative care. The Agency for Healthcare Research and Quality (AHRQ)

continuously monitors and studies the incidence, significance, complications, and costs associated with the management of patients with pressure injuries, and the National Pressure Ulcer Advisory Panel (NPUAP) serves as the source for public policy, education, and research to support improved patient outcomes.

Not only is the cost of treating pressure injuries exorbitant, but they also significantly affect the patient's quality of life. Estimates indicate that the annual cost of treating pressure injuries in the United States runs between \$9.2 billion and \$15.6 billion. This includes increases in length of stay and treatment regimens related to infection, pain, support surfaces, and decreased functional ability. **Pressure injuries increase the risk of mortality in the older adult population and those in ICUs by 25% to 33%.** In patients admitted to the hospital with pressure injuries as the primary admission diagnosis, the mortality rate is 1 in 25 patients, whereas admissions with pressure injuries as a secondary diagnosis has a death rate of 1 in 8 patients.

Factors that increase a patient's susceptibility to the development of pressure injuries are multifactorial and include the following:

- Impaired or decreased mobility and decreased functional status with exposure to increased forces of pressure and shear
- Increased age
- Comorbid conditions such as end-stage renal disease, anemia, or diabetes mellitus
- Use of steroids
- Impaired blood flow as in atherosclerosis or lower extremity peripheral arterial disease
- Cognitive impairment
- Urinary or fecal incontinence
- Undernutrition, malnutrition, and deficits in hydration
- History of previous pressure injuries because the tensile strength of scars over healed pressure injuries is diminished and prone to repeated breakdown
- Terminal illness

Pressure injuries are an added burden to caregivers and are viewed by laypeople as preventable. Although pressure injuries are not always the result of improper care or poor-quality care, their development not only casts a negative reflection on the institution in which the patient stays but is also viewed as clinical negligence that may lead to litigation. Pressure injuries are a major litigation issue across healthcare settings, and judgments as high as \$312 million for a single case have been awarded.

### Pathophysiology and Clinical Manifestations

The discussion of the pathophysiology of pressure injuries must include an explanation of the extrinsic factors of pressure and shear that lead to development. Pressure is exerted when tissue is compressed between the surface on which the patient lies and the bony prominences of the body. This

causes a decrease in capillary blood flow, leading to decreased perfusion of a localized area of the body, potentiating tissue ischemia and death. On average, intracapillary pressure is estimated at 32 mm Hg, whereas pressure exerted on a localized area of the body from a hard surface can reach up to 300 to 500 mm Hg depending on weight and surface area exposed. Lying flat in bed causes pressures of 50 to 94 mm Hg to be exerted on the heels, sacrum, and scapulae. This level of pressure exceeds the pressure necessary to keep the capillaries open (32 mm Hg), causing ischemia of the tissues. The intensity of the pressure and the duration of time that the skin is exposed to that pressure inversely correlate to pressure injury. In other words, a pressure injury can develop in less time with a higher intensity of pressure or in a longer period of time with a lesser degree of pressure. Therefore, the use of pressure-redistribution surfaces and frequent repositioning of the patient are equally important. Pressure-related tissue damage is not only associated with the surface involved but also the type of tissue involved. The epidermis and the dermis can withstand a lengthier exposure to ischemia without incurring irreversible damage. Therefore, tissue injuries related to pressure may be first manifested in the muscle and subcutaneous fat and characterized by a change in the color, temperature, or consistency of intact skin.

Most pressure injuries occur over bony prominences; however, they can occur on any body surface or related to a medical or other device. Commonly, the occiput (back of the head), ears, scapulae, sacrum and coccyx, ischium and buttocks, greater trochanters of the hips, and the heels of the feet are affected. An individual who sits for prolonged periods of time is exposed to higher pressures in the coccyx and ischial areas (and possibly the heels or even the lateral surfaces of the feet if a wheelchair is not adjusted to the patient's body). In the lying positions, the scapulae, sacrum, greater trochanters, heels, occiput, and ears are typically affected. Kyphosis of the spine can also lead to increased pressure and tissue breakdown on the back. Wrinkles in bed-sheets or pads beneath the patient can increase pressure and potentiate the development of a pressure injury. Medical device-related pressure injuries result from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury should be staged using the staging system. For example, a pressure injury can occur on the external nares related to the presence of a nasogastric tube or on the glans of the penis due to pressure exerted from an indwelling urinary catheter. Mucosal membrane pressure injury is found on mucous membranes with a history of a medical device in use at the location of the injury. Due to the anatomy of the tissue, these ulcers cannot be staged.

Further complications of pressure include reperfusion injury, impaired lymphatic function, and mechanical deformation of cells. With ischemia, affected tissues reduce their metabolic needs to reduce further damage caused from hypoxia. During reperfusion of this ischemic area, the

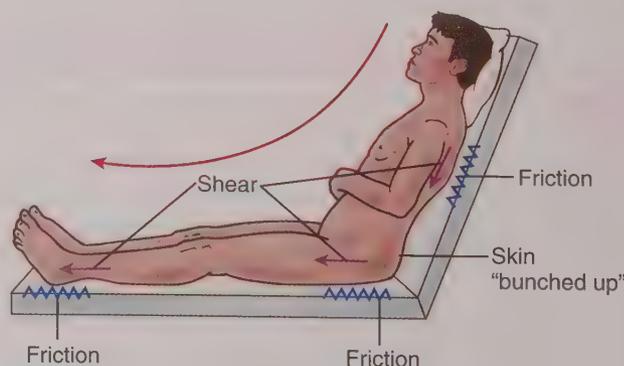

oxygenated blood carrying white blood cells to the area releases inflammatory factors in response to the injury. These inflammatory factors include free radicals, which lead to further cell damage. Lymphatic function is impaired during ischemia, which leads to an accumulation of metabolic waste products, further potentiating tissue death. Lastly, alterations of tissues and cells related to pressure cause cellular membranes to rupture, leading to irreversible tissue damage.

In addition to pressure, the extrinsic forces of shear also play a role in the development of pressure injuries. Shearing forces exert a diagonal impact, and the damage occurs internally in response to the opposing motions of bone and subcutaneous tissues (Fig. 50.7). Shear and pressure usually occur together, causing significant damage first to muscle and subcutaneous tissues and later to skin. The collagen and elastic fibers of the skin increase tensile strength and make it less susceptible to shearing forces. Shear occurs when an older adult, for example, slides down in bed or while sitting up in a chair. When this occurs, blood vessels in the dermis become contorted, diminishing blood flow and perfusion, leading to ischemic damage to the tissues. Keeping the head of the bed at less than 30 degrees and minimizing the amount of time the patient is kept in a chair can diminish the effects of shear. Additionally, increased moisture from incontinence and perspiration causes maceration and inflammation, increasing the risk of skin breakdown. Utilizing draw sheets; cleaning incontinence episodes as soon as they happen; utilizing barrier ointments on the perineal skin; and maintaining dry, clean sheets or surfaces can diminish the damaging effects of moisture.

### Connection Check 50.9

The nurse recognizes that pressure injury is most probable in which areas in the patient positioned in a supine position? (Select all that apply.)

- A. Occiput
- B. Nares
- C. Behind the knees
- D. Sacrum
- E. Heels

**FIGURE 50.7** Shearing forces and friction that can damage skin.

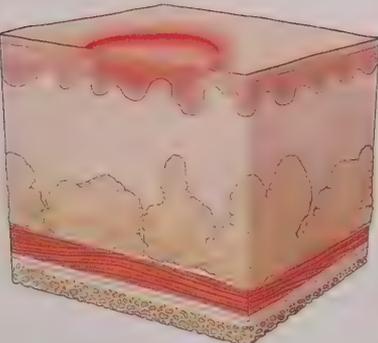

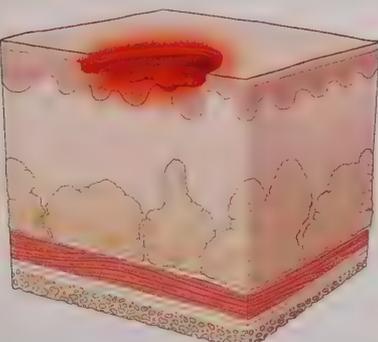

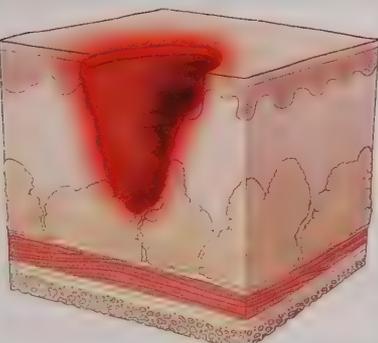

Historically, there are four stages of pressure injuries. However, in 2007, the NPUAP revised its classification to include two additional categories: unstageable injuries and deep tissue injury. The NPUAP redefined the definition of pressure injuries during the NPUAP 2016 Staging Consensus Conference. Table 50.11 presents the pressure injury staging system.

## Management

### Medical Management

Admission to any care setting requires a thorough head-to-toe physical examination, including meticulous evaluation of the patient's skin as well as a wound history. Skin and risk assessments are conducted upon admission and at regular

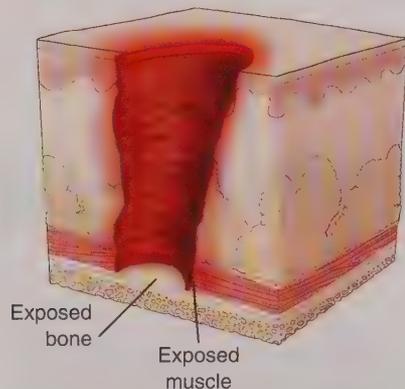

**Table 50.11 Pressure Injury Classification**

Stage/Category	Description	
<p><b>Stage 1</b></p> 	<p><b>Non-blanchable erythema of intact skin</b></p> <p>Intact skin with a localized area of non-blanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.</p>	
<p><b>Stage 2</b></p> 	<p><b>Partial-thickness skin loss with exposed dermis</b></p> <p>Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, and moist and may also present as an intact or ruptured serum-filled blister. Adipose (fat) and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage (MASD), including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARS), or traumatic wounds (skin tears, burns, abrasions).</p>	
<p><b>Stage 3</b></p> 	<p><b>Full-thickness skin loss</b></p> <p>Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an unstageable pressure injury.</p>	

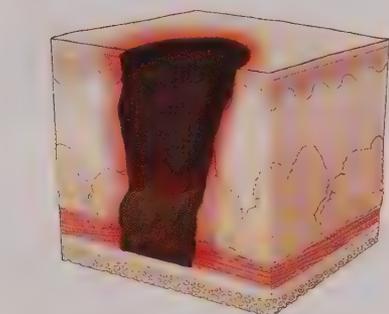

Continued

**Table 50.11 Pressure Injury Classification—cont'd****Stage/Category****Description****Stage 4****Full-thickness skin and tissue loss**

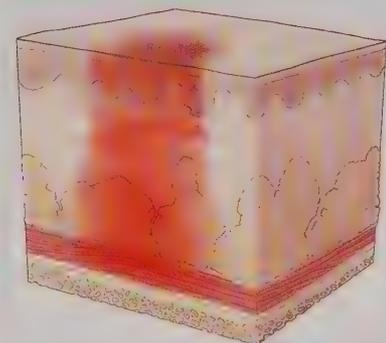

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss, this is an unstageable pressure injury.

**Unstageable****Obscured full-thickness skin and tissue loss**

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

**Deep tissue pressure injury (DTPI)****Persistent non-blanchable deep-red, maroon, or purple discoloration**

Intact or non-intact skin with localized area of persistent non-blanchable deep-red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood-filled blister. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone–muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full-thickness pressure injury (unstageable, Stage 3 or Stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatological conditions.

intervals according to the institution's policies, with documentation placed in the patient's chart. Although there are no specific regulations mandating a minimum standard for skin assessments, the Centers for Medicare and Medicaid Services recommended five key parameters to be addressed: temperature, moisture-balance status, color, turgor, and integrity. Any evidence of pressure on the body of the patient admitted to a healthcare facility must be documented as part of the admission skin assessment, or the institution can be held legally responsible for its development and may not receive reimbursement for its treatment. When skin integrity is compromised on admission, a licensed provider must document its etiology and description in the patient's record.

Pressure injury risk assessments are important in identifying patients at greatest risk of pressure injury development. The **Braden scale**, the most widely utilized pressure injury risk assessment tool, guides clinicians in medical management decisions to modify treatment parameters and reduce a patient's pressure injury risk. A score of 15 to 18 = mild risk, 13 to 14 = moderate risk, 10 to 12 = high risk, and 9 or below = very high risk. Decisions regarding support surfaces, nutrition, and the need for physical and occupational therapy, for example, are protocols that can be initiated on the basis of the Braden scale (Fig. 50.8; Box 50.3) score (dependent on institution policy).

### Support Surfaces

To diminish the effects of pressure, attention to the surface on which the patient lies and/or sits is essential to pressure injury treatment. Various redistributing surfaces are used in pressure injury prevention and treatment, including overlays, mattresses, integrated bed systems, and chair cushions. The goal of these support surfaces is to redistribute pressure, reduce shear, and control heat and humidity (microclimate). Because of a lack of consistent recommendations about support surfaces for the prevention and management of pressure injury, in 2015 the Wound, Ostomy and Continence Nurses Society developed an algorithm for support-surface selection to assist clinicians in selecting support surfaces. This is thought to be the first evidence-based algorithm that provides clinical guidelines for support-surface selection based on individual patient needs (see Evidence-Based Practice).

**Safety Alert** It is important to maintain regular turning schedules, proper positioning, and the use of lift sheets for reduction of friction and shear for patients at risk for pressure-related injury, even if they are on a redistributing support surface. Additionally, nurses must be educated about the specifications of each surface. For example, placing too many linens on surfaces that provide pressure redistribution through inflation and deflation of the mattress may obstruct airflow and reduce the efficacy of the support surface.

## Evidence-Based Practice

### Selecting Support Surface for Pressure Injuries

The use of support surfaces is an effective intervention for the prevention and treatment of pressure injuries. Because of a paucity of evidence to guide healthcare professionals in the selection of support surfaces, the Wound, Ostomy and Continence Nurses Society (WOCN) led the development of an evidence-based and consensus-based algorithm. A task force of clinical experts was assembled to review the literature around the use of support surfaces to manage pressure injuries, to develop specific recommendations for the algorithm, to draft the algorithm, and to establish the face validity of the tool. Based on the work of the task force, 20 "key opinion leaders" reviewed the draft algorithm, reached consensus on the supporting evidence, and revised the draft and evaluated its content validity. The results demonstrated a strong content validity index (CVI) for the algorithm, which is thought to be the first evidence-based algorithm to guide clinical decisions about the implementation of support surfaces in the management of pressure injuries. It is the hope of the WOCN that this algorithm is used in facilities across the United States to provide additional data about the effectiveness of this tool.

McNichol, L., Watts, C., Mackey, D., Beitz, J., & Gray, M. (2015). Identifying the right surface for the right patient at the right time: Generation and content validation for the algorithm for support surface selection. *Journal of Wound, Ostomy and Continence Nursing*, 42(1), 19–37.

Pressure-redistributing support surfaces are a type of durable medical equipment used for patients with pressure injuries. A major distinction between support surfaces is that some are powered and others are nonpowered. They are categorized into the following three groups, and insurance coverage is based on the specific type of surface prescribed:

- **Group 1 support surfaces** are generally designed to either replace a standard hospital or home mattress or as an overlay placed on top of a standard hospital or home mattress. These are static surfaces that do not require electricity. Products in this category include mattresses, pressure pads, and mattress overlays (foam, air, water, or gel) and are meant to disperse pressure over a larger area. These are appropriate for patients at risk of developing a pressure injury or those with a stage 1 or 2 pressure injury. For Medicare reimbursement of Group Support 1 surfaces, the following criteria must be met:
  - The patient is completely immobile or has limited mobility (i.e., cannot independently make changes in body position significant enough to alleviate pressure).

## Braden Scale for Predicting Pressure Sore Risk

Patient's name \_\_\_\_\_ Evaluator's name \_\_\_\_\_ Date of Assessment \_\_\_\_\_

<b>Sensory Perception</b> Ability to respond meaningfully to pressure-related discomfort	<b>1. Completely Limited</b> Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation  OR limited ability to feel pain over most of body.	<b>2. Very Limited</b> Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness  OR has a sensory impairment which limits the ability to feel pain or discomfort over 1/2 of body.	<b>3. Slightly Limited</b> Responds to verbal commands, but cannot always communicate discomfort or the need to be turned  OR has some sensory impairment which limits ability to feel pain or discomfort in 1 or 2 extremities.	<b>4. No Impairment</b> Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.	
<b>Moisture</b> Degree to which skin is exposed to moisture	<b>1. Constantly Moist</b> Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	<b>2. Very Moist</b> Skin is often, but not always moist. Linen must be changed at least once a shift.	<b>3. Occasionally Moist</b> Skin is occasionally moist, requiring an extra linen change approximately once a day.	<b>4. Rarely Moist</b> Skin is usually dry, linen only requires changing at routine intervals.	
<b>Activity</b> Degree of physical activity	<b>1. Bedfast</b> Confined to bed.	<b>2. Chairfast</b> Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	<b>3. Walks Occasionally</b> Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	<b>4. Walks Frequently</b> Walks outside room at least twice a day and inside room at least once every two hours during waking hours.	
<b>Mobility</b> Ability to change and control body position	<b>1. Completely Immobile</b> Does not make even slight changes in body or extremity position without assistance.	<b>2. Very Limited</b> Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	<b>3. Slightly Limited</b> Makes frequent though slight changes in body or extremity position independently.	<b>4. No Limitation</b> Makes major and frequent changes in position without assistance.	
<b>Nutrition</b> Usual food intake pattern	<b>1. Very Poor</b> Never eats a complete meal. Rarely eats more than 1/3 of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement  OR is NPO and/or maintained on clear liquids or IV's for more than 5 days.	<b>2. Probably Inadequate</b> Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement  OR receives less than optimum amount of liquid diet or tube feeding.	<b>3. Adequate</b> Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) per day. Occasionally will refuse a meal, but will usually take a supplement when offered  OR is on a tube feeding or TPN regimen which probably meets most of nutritional needs.	<b>4. Excellent</b> Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.	
<b>Friction and Shear</b>	<b>1. Problem</b> Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures or agitation leads to almost constant friction.	<b>2. Potential Problem</b> Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	<b>3. No Apparent Problem</b> Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair.

Total Score

FIGURE 50.8 The Braden scale.

### Box 50.3 Braden Scale Scoring

Mild risk:	15 to 18
Moderate risk:	13 to 14
High risk:	10 to 12
Very high risk:	9 or below

- The patient has a pressure injury of any stage on the trunk or pelvis.
- The patient has at least one of the following conditions:
  1. Impaired nutritional status
  2. Fecal or urinary incontinence
  3. Altered sensory perception
  4. Compromised circulatory status
- *Group 2 support surfaces* are generally designed to either replace a standard hospital or home mattress or as an overlay placed on top of a standard hospital or home mattress but are powered surfaces (require electricity or battery). Products in this category include the active support surface, integrated bed system, nonpowered, overlay, powered, reactive support, and replacement mattress. Most of these products allow the nurse to adjust the air mattress supportive pressure by alternating the inflation and deflation of air cells, which is recommended for patients with stage 3 and 4 pressure injuries. Additionally, low-air-loss mattresses are similar to air-permeable pillows that remain inflated and have a drying effect on tissues. The use of these mattresses is recommended for patients with stage 1 or 2 injuries who are not improving on static surfaces and for patients with stage 3 and 4 pressure injuries. For Medicare reimbursement of group support 2 surfaces, the following criteria must be met:
  - The patient has multiple stage 2 pressure injuries located on the trunk or pelvis that have failed to improve over the last month, and the patient has been on a comprehensive injury treatment program for at least the past month (minimum of 30 days) that included each of the following:
    1. Use of an appropriate group 1 support surface
    2. Regular assessment by a nurse, physician, or licensed healthcare practitioner
    3. Appropriate turning and positioning
    4. Appropriate wound care
    5. Appropriate management of moisture/incontinence
    6. Nutritional assessment and intervention consistent with the overall plan of care
  - The patient has large or multiple stage 3 or 4 pressure injuries on the trunk or pelvis.
  - The patient had a recent myocutaneous flap or skin graft for a pressure injury on the trunk or pelvis (surgery within the past 60 days), and the

patient has been on a group 2 or 3 support surface immediately prior to a recent discharge from a hospital or nursing facility (discharge within the past 30 days).

- *Group 3 support surfaces* are complete bed systems, known as air-fluidized beds, which use the circulation of filtered air through silicone beads. These systems are considered dynamic surfaces and require electricity. Air-fluidized (or high-air-loss) mattresses contain silicone-coated beads that liquefy with the infusion of air into the bed, which reduces moisture and has a cooling effect. These support surfaces are indicated for stage 3 and 4 pressure injuries or for patients with multiple pressure injuries. Group 3 support surfaces are covered only if the patient is bedridden or chair-bound with stage 3 or stage 4 pressure injuries that would require institutionalization without the use of an air-fluidized bed. Additionally, the patient must have been treated conservatively for at least a month without progression of wound healing that included repositioning to relieve pressure over bony prominences (usually every two hours) and the use of a group 2 support surface.

### Connection Check 50.10

A 78-year-old patient fractured a hip 1 week ago and is now being admitted to a rehabilitation facility for physical therapy because of difficulty ambulating. During the admission skin assessment, the nurse notes an area of nonblanchable erythema on the sacrum. What is the nursing priority at this time?

- Order a redistributing mattress for the patient's bed.
- Consult the nutritionist for a complete nutritional assessment.
- Perform and document the admission skin and risk assessments.
- Apply a hydrocolloid dressing over the area to protect it from further trauma.

### Nutrition

Adequate nutrition plays a significant role in healing pressure injuries, and patients require supplementary nutritional support (Table 50.12). Appropriate amounts of calories, protein, fluids, vitamins, and minerals are necessary for tissue repair and the prevention of pressure injuries. Evaluating a patient's nutritional status with the use of a nutrition screening tool is done on the patient's first visit to any healthcare setting, and a referral to a nutritionist is generated for those deemed to be at risk. Decreased collagen formation and fibroblast proliferation are effects of undernutrition and protein-energy malnutrition that prolong the inflammatory phase of wound healing. Undernutrition, a deficiency in energy and protein, can be reversed solely with the administration of nutrients and significantly impacts the body's

**Table 50.12 Nutritional Assessment Relevant to Pressure Injuries**

Nutritional States	Definition and Characteristics
<b>Undernutrition</b>	Protein and energy deficiency Consequences can be reversed completely with the administration of nutrients. Contributing conditions include increased dependence on others for eating, decreased oral intake of food and fluids, unintentional weight loss, and aging.
<b>Protein-energy malnutrition (PEM)</b>	Wasting with excessive loss of lean muscle mass Results from untreated undernutrition and can be reversed with administration of nutrients Increased morbidity and mortality
<b>Cachexia</b>	Loss of muscle and weight loss with or without loss of fat mass Is a metabolic syndrome associated with underlying illnesses
<b>Hypermetabolism</b>	Increased metabolic rate causing an increased need for calories in response to trauma, severe illness, infection, or pressure injuries, for example Energy pulled from glycogen stores first, then visceral protein stores Results in anorexia, muscle wasting, decreased nitrogen retention, impaired albumin synthesis

Data from Posthauer, M. E., Banks, M., Dorner, B., & Schols, J. M. G. A. (2015). The role of nutrition for pressure ulcer management: National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, and Pan Pacific Pressure Injury Alliance white paper. *Advances in Skin & Wound Care*, 28(4), 175–188.

ability to heal and fight infections. Hypermetabolism, which occurs as a result of trauma, severe illness, or infection, utilizes calories rapidly. The body compensates for insufficient energy during a hypermetabolic state by stealing energy from visceral protein stores to maintain organ functioning. As a result, anorexia, muscle wasting, decreased nitrogen retention, and impaired albumin synthesis occur.

Box 50.4 includes recommendations from the NPUAP's white paper on the role of nutrition in pressure injury management.

### Wound Care

Pressure injury wound assessment includes staging the injury; evaluating wound tissues, the topography of the wound, and wound exudate; and measuring wound dimensions. Wound measurements are performed on admission and at intervals according to institutional policies. Measurements must include length (head to toe), width (widest perpendicular to the length), and depth (measured at 90 degrees to the wound surface). A circumferential assessment for **undermining** (tissue destruction or pressure injury extending under the wound edges, making the injury larger at its base than at the skin surface) and inspection and measurements of **tunneling** (a passageway under the skin surface that is also known as a sinus tract that results in dead space that can increase the risk for abscess formation) are included in each wound assessment.

The selection of wound-care products is based on the characteristics of the wound (wound type, tissue type, exudate characteristics, location, and bacterial profile) as well as patient-related factors (activity level, compliance, caregiver, and level of consciousness). Primary wound dressings

are applied directly to the wound bed, and their removal should not be traumatic in order to avoid damage to new granulation tissue. Secondary dressings are applied over the top of primary dressings and serve to protect the wound and to secure the primary dressing. Table 50.13 presents the different types of wound dressings available. (Refer to Table 50.8 for the definitions of different tissues found in wounds and Table 50.9 for debridement methods.)

### Debridement

Wound debridement removes necrotic tissue, reducing the risk of infection and facilitating healing. There are many different types of wound debridement, including surgical, autolytic, mechanical, maggot, and enzymatic (see Table 50.9). Necrotic tissue within the wound bed impairs granulation tissue development and keeps the wound in the inflammatory phase of wound healing. If conservative measures such as local wound care, including conservative debridement methods (autolytic, mechanical, maggot, and enzymatic), are not successful in removing the necrotic tissue, surgical/sharp wound debridement may be warranted. Surgical/sharp debridement can occur in an inpatient setting, outpatient setting, or operating room, depending on the extent and goals of debridement, and requires anesthetic medications (local or general). Healing by secondary intention or reconstructive flap surgery may be required following surgical debridement of pressure injuries.

A comprehensive wound assessment and physical examination are necessary to evaluate for any potential contraindications to surgical/sharp debridement. Because wound healing requires adequate oxygenation, wounds with poor

## Box 50.4 National Pressure Ulcer Advisory Panel Advisory Panel White Paper Recommendations

### Macronutrient Requirements:

- **Energy:** Energy (kilocalories) is provided by the macronutrients of carbohydrates, fats, and protein. Increased energy is needed to overcome the effects of a hypermetabolic state that is created by pressure injuries. Carbohydrates are the main source of fuel for collagen synthesis. Thirty to 35 kilocalories per gram of body weight per day is recommended for patients with pressure injuries.
- **Protein:** All phases of wound healing require adequate amounts of protein for collagen synthesis, fibroblast production, and cell multiplication. The recommended daily allowance (RDA) of protein for healing wounds is 1.2 to 1.5 g per kilogram of body weight. Higher levels of protein in older adults can potentiate renal disease and cause dehydration.
- **Amino acids:** Amino acids are the precursors to protein. The amino acids of arginine and glutamine are essential during periods of stress such as pressure injury healing.
- **Fluids:** Vitamins, minerals, glucose, and other minerals rely on fluids for bodily dispersion. Fluid needs are individualized according to health status and healing needs. Therefore, the nutritionist evaluates and calculates each patient's needs. It is important to monitor fluid status by observing mucous membranes, skin turgor, weight, urine output, and serum sodium. Also, fluid need calculations must include the loss of fluids with heavily exuding wounds.

### Micronutrient Requirements:

The need for micronutrients increases with pressure injuries.

- **Ascorbic acid (vitamin C):** Ascorbic acid is essential in collagen formation, capillary strength, immune function, and tissue repair and regeneration. If the patient is unable to consume the RDA of vitamin C by ingesting fruits and vegetables, vitamin supplementation is initiated.
- **Zinc:** Zinc is needed for collagen formation and protein synthesis. A patient with prolonged poor dietary intake and highly exuding pressure injuries is at risk for zinc deficiency. Zinc supplementation should not exceed 40 mg per day and should only be given to those who show signs of zinc deficiency, including loss of appetite, abnormal taste, impaired immune function, and impaired wound healing. Too much zinc can impair healing and inhibit the effects of copper, possibly causing anemia.
- **Copper:** Copper is essential for collagen cross-linking and red blood cell formation. If the diet does not contain adequate foods rich in copper (nuts, seafood, whole grains, legumes), providing a multivitamin with 100% of the RDA of copper is sufficient.

Adapted from Posthauer, M. E., Banks, M., Dorner, B., & Schols, J. M. G. A. (2015). The role of nutrition for pressure ulcer management: National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, and Pan Pacific Pressure Injury Alliance white paper. *Advances in Skin & Wound Care*, 28(4), 175–188.

perfusion due to peripheral vascular disease should not be debrided unless surgical revascularization occurs first. Additionally, patient-centered concerns, such as pain and postdebridement expectations, must be addressed and consent given prior to any invasive procedure.

### Comorbidities

The Braden scale addresses the extrinsic factors of pressure, friction, and shear, as well as mental status, mobility, nutrition, and incontinence, all of which contribute significantly to the development of pressure injuries. However, the medical management of comorbid diseases such as peripheral vascular disease, diabetes, congestive heart failure, incontinence, and end-stage renal disease must be optimized for successful wound healing to take place.

### Complications

As with any open wound, infection is the main complication. Assessing for local clinical manifestations of wound infections (erythema, increased warmth, swelling, increase in injury size or depth, increased pain, purulent exudate, and odor) should occur on a regular basis. Swab cultures can be helpful, but punch biopsies with culture can help identify bacteria in deeper tissues such as muscle and bone (osteomyelitis). If osteomyelitis is suspected, evaluation with x-ray, computed tomography (CT) scan, or magnetic resonance imaging (MRI) is recommended. If the bone is exposed, the patient is diagnosed clinically with osteomyelitis, making further scanning unnecessary at that point to confirm infection. Imaging may be necessary to observe the structural integrity of a joint. C-reactive protein levels and ESRs are elevated with infection and inflammation. As infection and inflammation are treated, these values decrease, making them important indexes to assess the effectiveness of treatment. Patients who are immunocompromised and/or have extensive wounds are at greater risk of infection. Therefore, vigilant monitoring for systemic clinical manifestations of infection (fever, increased white blood cell count) helps to identify bacteremia (bacteria in the blood) or sepsis (systemic infection).

Pressure injuries on the sacrum, coccyx, ischium, and trochanters are at risk of fecal and urine contamination in a patient who is incontinent. Depending on the severity of the injury and potential surgical interventions, a temporary diverting colostomy may be recommended to avoid contamination of the site with feces and/or urine until the injury or surgical site is completely healed. Once healing is complete, the temporary colostomy can be re-anastomosed at the patient's request.

In addition to the obvious physical manifestations of pressure injuries, a patient may also experience body image disturbances related to a chronically open wound. Lifestyle changes related to the pressure injury, such as changes in employment status, can put a financial strain on the family and interpersonal relationships. Caregivers can feel overwhelmed because of the physical and psychosocial needs of the patient with a pressure injury. Lastly, the chronic pain of an open wound can lead to feelings of hopelessness and fear.

Table 50.13 Types of Wound Dressings

Product Category	Description	Function	Appropriate Use	Advantages	Disadvantages
<b>Alginate</b>	Composed of calcium alginate (seaweed component)	Forms a gel-like substance when coming into contact with exudate; provides hemostasis	Moderate to heavy exudate	Painless removal; exudate management; moldable to wound surface; maintains moist environment	Most wound dressings are expensive, but topical dressing selection is based on wound characteristics and dressing functions; wound must be moist for gelling to occur and for avoidance of traumatic removal. Require secondary dressing
<b>Collagens</b>	Pads, gels, or particles of collagen; usually derived from bovine or porcine sources; usually contain cellulose or alginate for absorption	Promote deposition of collagen; stimulate granulation tissue	As primary dressing in minimal to heavily exuding wounds; can pack into tunnels	Absorbent, nonadherent; usually dissolve in wound bed; moldable	Require secondary dressing
<b>Nonadherent contact layers</b>	Thin, nonadherent sheets placed in wound bed	Protection of wound bed; covering of topical ointments when applied to wound bed	Primary dressing for protection of wound bed and to keep topical ointments in contact with wound bed (and not absorbed by outer dressing)	Are porous and allow exudate to pass through for absorption on other dressings; protect new granulation tissue; can be applied over topical ointments	Not recommended for dehydrated wounds or viscous exudate; require secondary dressing
<b>Foams</b>	Semipermeable, nonadherent, absorptive dressing made of open-cell, medical-grade expanded polymer	Absorption; maintain moist environment; insulate wound	Moderate to heavy exudate Absorption of minimal to heavy exudate, nonadherent	Nonadherent; waterproof outer layer; provide bacterial barrier; good for hypergranulation	Will dry out wounds without enough exudate; not for autolytic debridement
<b>Hydrocolloids</b>	Composed of carboxymethylcellulose, gelatin, pectin, elastomers, and adhesives that are hydrophilic and turn into a gel when exudate is absorbed	Debridement, absorption, protection; occlusive wafer-type dressing; can be adhesive or nonadhesive	To protect intact or newly healed skin from further exposure to friction and shear; scant to minimal exudate; to assist in debridement of necrotic tissue	Provide autolysis with necrotic wounds; are moldable; extended wear times; good bacterial barrier	Can dislodge with friction and shear or with heavy exudate; not for use on infected wounds

<b>Hydrogels</b>	Contain mostly water in a polymer gel base; come in gel or sheet form	Provide moisture; can absorb small amounts of exudate	Autolytic debridement of necrotic tissue/eschar; Stage 3 or 4 pressure injuries	Cooling and soothing to patient; provide hydration to promote autolytic debridement	Not for heavily exuding wounds; will hydrate if not covered (consider using a contact layer between hydrogel and secondary dressing); can cause maceration
<b>Hydrofibers</b>	Consist of highly absorptive, soft, woven fiber layers (made from sodium carboxymethylcellulose)	Interact with wound exudate to form gel	To absorb moderate to heavy exudate; partial to full thickness; can use in infected, necrotic, or granulating wounds	Nonadherent; highly absorptive; easy application and removal; good for packing deep wounds	May require a secondary dressing
<b>Semipermeable films</b>	Thin sheets of polyurethane with an adhesive	Act as a clear covering over wound or intact skin	Shallow wounds with minimal to no exudate; can be placed over bony prominences for protection from mechanical trauma	Transparent nature allows wound/skin inspections; can be used as a secondary dressing; bacterial barrier  Act as a semiocclusive; also allows the exchange of gases, vapors; <i>not for infected wounds</i>	Nonabsorptive; adhesive can damage healthy skin
<b>Gauze</b>	Usually a cotton or synthetic mesh of fibers  Also antimicrobial gauze sponges and dressing rolls	Absorption; mechanical debridement	Used for packing deep wounds, mechanical debridement, primary or secondary dressings; delivery of topical agents	Inexpensive	Can cause mechanical trauma to granulation tissue upon removal; painful removal; decreases temperature of wound; frequent dressing changes
<b>Hydrofera Blue</b>	Bacteriostatic dressing (made of Hydrofera polyvinyl alcohol sponge, methylene blue, gentian violet)	Highly absorptive dressing that absorbs bacteria-laden exudates away from the wound bed and physically binds endotoxins to the dressing	Used with diabetic ulcers, postsurgical incision sites, large abrasions, burns, and trauma wounds  Protects against infection by inhibiting the growth or reproduction of bacteria  Protects wounds from harmful microorganisms	Does not inhibit the activity of enzymatic debriders  Absorption capacity superior to many silver-impregnated dressings and equal to that of high-absorbency foams	

All of these dressings are expensive except for gauze. This is not an all-inclusive list; there are many other products.

## Nursing Management

### Assessment and Analysis

The treatment of pressure injuries is multifactorial and requires an interprofessional approach to patient care that includes nursing, medicine, nutrition, social work, physical and occupational therapies, and pain services. The nurse's role is critical in the treatment and prevention of pressure injuries. It is essential to assess and accurately document the findings of the skin, wound, and risk assessments in the patient care record. In addition to following wound-care protocols of the institution, the nurse must also recognize the clinical manifestations of local and systemic infections.

The assessment of the patient with pressure injuries requires the nurse to complete a thorough skin assessment, along with an evaluation of nutritional status, fluid volume status, and activity and mobility. In the patient presenting with an existing pressure injury, detailed and consistent documentation of the wound appearance is required to monitor for signs of healing or deterioration.

### Nursing Diagnoses

- **Impaired skin integrity** related to trauma secondary to exposure to pressure, friction, and shear
- **Acute and/or chronic pain** related to skin trauma, wound infection, and/or wound treatment
- **Imbalanced nutrition, less than body requirements**, related to hypermetabolic state secondary to the open wound
- **Depression** related to sense of loss as evidenced by forced lifestyle changes (loss of job, strained relationships) secondary to non-healing pressure injury
- **Risk for infection** related to the open wound

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Vital signs reflect systemic status related to infection and hydration status. An elevated temperature may be indicative of infection. With sepsis, tachycardia and hypotension may also develop.*
- **Pain**  
*Pressure injuries may cause pain because of edema and pressure in the area, as well as the exposure of nerve endings with large wounds.*
- **Functional assessment**  
*A functional assessment provides data on the patient's mobility status, how many hours/day the patient sits or lies down, and typical activities of daily living (including type of work). It is also important to ask what kind of bed and/or wheelchair surface the patient uses.*
- **Skin**  
*Admission skin and risk assessments identify patients at risk of developing pressure injuries and those who already have existing signs of pressure.*

- **Pressure-prone areas**  
*Depending on positioning, different areas are at increased risk for pressure and decreased perfusion. Patients who are supine are at increased risk of pressure to the occiput, scapulae, sacrum, ischium, and heels.*
- **Risk assessments (Braden scale)**  
*Admission assessments identify which patients are refusing treatment and provide the basis of their refusal, help define initial care approaches, and provide documentation, which must occur every 48 hours in acute care, weekly in long-term care, and on every home-care visit.*
- **Wounds**  
*Wound assessments should include location, injury stage, wound measurements (length, width, depth), tissue type, the presence of infection, exudate, and a description of periwound skin.*
- **Nutritional status**  
*The AHRQ recommends nutrition screening upon patient admission with referral to a nutritionist if found to be at risk of malnutrition. Wound healing requires increased protein, nutrients, and hydration.*
- **Past medical history**  
*History of previous pressure injuries increases the risk of new injury, as well as potentially resulting in delayed wound healing.*
- **Serum albumin and prealbumin**  
*Nutritional status is important to skin integrity and wound healing. Decreased serum albumin and prealbumin may indicate nutritional deficits.*
- **Blood values of C-reactive proteins and ESRs**  
*These values are elevated in infection and inflammation and are good indexes to monitor resolution.*

#### ■ Actions

- **Positioning to decrease pressure on bony prominences**  
*Skin breakdown starts to occur within 2 to 6 hours of the onset of pressure. Repositioning is essential for the immobile patient to reduce pressure over bony prominences and pressure injury risk. Reassessment of pressure-prone areas during repositioning helps to guide repositioning treatment plans.*
- **Keep the head of the bed at 30 degrees or less.**  
*Keeping the head of the bed at 30 degrees or less decreases the effects of shearing forces by minimizing the patient sliding down in the bed.*
- **Utilize draw sheets to reposition the patient.**  
*Draw sheets decrease the effects of friction by not allowing the patient's skin to be dragged along the surface of the bed.*
- **Control moisture, and cleanse the patient immediately after incontinence.**  
*Urine and feces irritate the epidermis, increasing susceptibility to skin breakdown.*
- **Apply moisture barrier ointment to skin subject to incontinence.**  
*Increased moisture on the skin causes maceration, increasing susceptibility to skin breakdown.*
- **Obtain appropriate bed surfaces.**  
*Bed surfaces should be selected according to the patient's clinical presentation and to redistribute pressure.*

- **Wound care: cleansing, dressings**  
*Wound care should be done according to wound-dressing recommendations and clinical evaluation; wound dressings should be chosen according to the needs of the wound.*
- **Documentation of wound progression with each dressing change or at least weekly**  
*Wound documentation provides the status of the effectiveness of therapies and can guide further treatment decisions.*
- **Nutritionist referral**  
*Nutritionists develop a diet plan specific to meet the needs of the patient with open pressure injuries.*
- **Administer antibiotics as prescribed for infections.**  
*Infection inhibits wound healing.*
- **Physical therapy/occupational therapy referrals**  
*Rehabilitation therapies maximize a patient's functional status to allow the patient to be an active participant in his or her care.*
- **Provide emotional support to the patient, and refer to social work if needed.**  
*Patients with a chronic wound can experience a decreased quality of life as a result of depression.*
- **Provide emotional support to caregivers, and refer to social work if needed.**  
*Caregivers can experience role strain when caring for a person with a chronic illness.*

### ■ Teaching

- **Importance of turning and repositioning**  
*Patient and family compliance increase with teaching about the relationship between the lack of movement and pressure injury development.*
- **Nutritional requirements**  
*Adequate wound healing requires adequate nutrition. The patient needs to consume an adequate intake of proteins and carbohydrates.*
- **Importance of adequate fluid intake**  
*Fluid status is associated with normal skin turgor, and dry, scaly skin increases the risk for loss of skin integrity.*
- **Clinical manifestation of infection**  
*Early recognition of infection is important to minimize the risk of systematic involvement.*

### Evaluating Care Outcomes

Prevention of pressure injuries is an important nursing intervention, and surveillance and assessment of risk factors contribute to decreasing the incidence. Pressure injury diagnosis, management, treatment, and prevention require an interprofessional approach to care. Initial and consistent ongoing skin assessment is crucial to the management of pressure injuries. It is essential to include the patient, family, and caregivers in the treatment plan. Careful assessment of risk factors, skin, wound, and nutrition guide the clinical decision-making process. Uncomplicated wound healing and prevention of further tissue damage are the ultimate goals in treating pressure injuries.

## CASE STUDY: EPISODE 2

Mr. Parker undergoes extensive wound debridement to remove necrotic tissue and bone. Initially, he does not want to undergo reconstructive surgery for fear of a larger wound that will not heal. Advanced wound-care products applied by highly specialized nurses are used to attempt wound closure by secondary intention.

After 1 year without wound closure, Mr. Parker and his wife decide that he will undergo debridement and myocutaneous flap reconstructive surgery for his ischial pressure injury. He does well perioperatively and is transferred to a rehabilitation hospital, where a low-air-loss mattress is used along with complete avoidance of lying or sitting on the surgical site for 4 weeks. A small area of the incision dehisces. However, with local wound care and continued off-loading of the site over the next 2 weeks, the area heals...

## SKIN CANCER

The most common form of cancer in the United States is skin cancer. The most common types of skin cancers are categorized into two groups, **melanoma** and non-melanoma.

### Epidemiology

Non-melanoma skin cancers include basal cell and squamous cell carcinomas. **Actinic keratoses** are atypical keratinocytes found in the epidermis and represent the most common form of precancerous lesions. Approximately 2.2 million people are diagnosed each year with a form of non-melanoma skin cancer in the United States. Furthermore, basal cell carcinomas are the most common form of cancer occurring in human beings, accounting for approximately 75% of all diagnosed skin cancers. In contrast, melanoma skin cancers account for less than 2% of all diagnosed cancers in the United States each year but account for the vast majority of skin cancer deaths. Both basal cell and squamous cell carcinomas have a higher incidence among the solid organ transplant population, most likely because of immunosuppression therapy. In the United States, men are diagnosed with melanomas of the skin at a higher rate. The overall lifetime risk for being diagnosed with melanoma is about 2.4% (or 1 in 40) for whites, 0.1% (or 1 in 1,000) for blacks, and 0.5% (1 in 200) for Hispanics.

Ultraviolet damage to the DNA of keratinocytes increases with extended time in the sun and is a major contributing factor to the development of skin cancers. Therefore, there is an increased risk of developing melanoma with advancing age because of prolonged sun exposure over time. Melanoma

is currently the most common cancer affecting women aged 25 to 29 and the second most common cancer diagnosed in women aged 30 to 34. Use of tanning salons is a causative theory of the development of this cancer among these age groups. Survival rates associated with melanoma skin cancer are dependent on the staging of the cancer, which reflects tumor depth, early recognition, and treatment directly related to prognosis. Actinic keratosis is diagnosed in more than 10 million people per year worldwide and represents the most common skin condition treated by dermatologists. The cumulative effect of sun exposure correlates with an increased incidence of actinic keratosis. Therefore, the incidence of actinic keratosis increases after age 40. About a quarter of these lesions regress spontaneously, but 0.1% to 10% develop into squamous cell carcinomas. Individuals with less melanin (e.g., those with fair skin; blond or red hair; and blue, green, or gray eyes) are more prone to developing actinic keratosis. Additionally, the chances of having this type of cancer are greater with increased proximity to the equator.

The main modifiable risk factor associated with skin cancers and premalignant lesions is exposure to UV radiation (Box 50.5), with those who spend much time in the sun (either for work or for pleasure) at greatest risk. Although people with fair skin are at greatest risk, darker-skinned populations still carry a risk of developing skin cancers (see Genetic Connections: Skin Cancer). Additionally, occupational exposure to some carcinogens can increase the risk.

## Genetic Connections

### Skin Cancer

The genetic risks for the development of melanoma of the skin include skin type, number of nevi and having atypical nevi, and having a family history of skin cancer.

## Pathophysiology and Clinical Manifestations

Ultraviolet radiation from sunlight is composed of UVA and UVB rays. Ultraviolet radiation is the main cause of all types of skin cancers. Ultraviolet B rays do not penetrate deep into the skin and are responsible for sunburns that occur from prolonged periods in the sun. Ultraviolet B rays cause direct damage to DNA within the skin cells, whereas UVA rays penetrate deeper into the skin and are responsible for indirect damage that disrupts the cellular membranes. Researchers hypothesize that UV radiation energy is absorbed by the DNA of the epidermal cells and mediates immune suppression, leading to the development of cancerous cells.

## Box 50.5 Patient Education for Skin Cancer Prevention

The American Cancer Society recommends the phrase “slip, slop, slap . . . and wrap” to remember ways to reduce the risks of getting skin cancer (slip on a shirt, slop on sunscreen, slap on a hat, and wrap on sunglasses to protect the eyes and skin around the eyes).

- Limit time spent in the sun between the hours of 10 a.m. and 4 p.m. when UV rays are strongest.
- Wear clothing to protect as much of the skin as possible. If light can be seen through the clothing, then UV rays can still get through. Some companies are now making lightweight fabrics that provide UV ray protection.
- Use sunscreen with an SPF of at least 30, applied thickly. Sunscreens do not provide total protection.
  - An SPF of 30 means that you are exposed to 1 minute of UV radiation for every 30 minutes spent in the sun.
  - Reapply often for best protection (at least every 2 hours and more frequently with swimming).
- Wear a hat with at least a 2- to 3-in. brim to protect the eyes, ears, forehead, nose, and scalp.
- Wear sunglasses that block UVA and UVB radiation to decrease your chances of eye disease.
- Avoid tanning beds.
- Be especially diligent in using these guidelines in protecting children.
- Examine your body (front and back) monthly, and keep a map of your current skin spots; seek medical advice if any lesion has the following characteristics (ABCDE):
  - A: Asymmetry
  - B: Border irregularity
  - C: Color variation (areas of brown, tan, black, blue, red, white, or any combination)
  - D: Diameter is greater than 6 mm
  - E: Elevation or enlargement of the lesion

SPF, Sun protection factor; UVA, ultraviolet A; UVB, ultraviolet B.

### Actinic Keratosis

Actinic keratoses are considered precancerous lesions. Formed by atypical keratinocytes (epidermal squamous cells), they proliferate in the epidermis. Without treatment, they evolve into squamous cell carcinoma.

- **Clinical features:** Skin-colored to reddish-brown macules, papules, or plaques; range from a few millimeters up to 2 cm; usually occur as multiple lesions
- **Body distribution:** Sun-exposed areas (particularly cheeks, temples, forehead, anterior and posterior neck, ears, backs of hands, and forearms)
- **Clinical course:** May begin as erythematous, scaly plaques that exfoliate with toweling off or the rubbing of clothes during the day; induration at the base, cutaneous horn, ulceration, or pain may indicate transformation to squamous cell carcinoma.

### Squamous Cell Carcinoma

Squamous cell carcinoma (Fig. 50.9) is mostly attributed to cumulative exposure to UVB rays over an extended period of time and is a cancer that arises from epidermal squamous cells (keratinocytes). These atypical squamous cells intermix with the normal squamous cells and can invade the underlying dermis (Fig. 50.10). Squamous cell carcinomas can cause significant damage to adjacent tissue and can metastasize within a few months. Many times, actinic keratoses are within or adjacent to the squamous cell carcinomas.

- **Clinical features:** Crusted papules and plaques that can become indurated and ulcerated. Larger lesions can become painful and bleed. Also, squamous cell carcinomas can arise from chronically open wounds, burn scars, or leg ulcers because of chronic inflammation.
- **Body distribution:** Sun-exposed skin, especially the top of the head, neck, and lips
- **Clinical course:** Can invade fatty tissue beneath the dermis and spread via the lymph nodes to other parts of the body (although this is not that common); recurrence rate within 3 years is 18%.

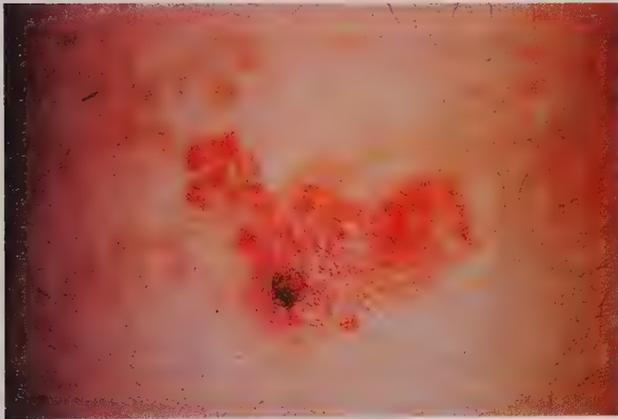

FIGURE 50.9 Squamous cell carcinoma.

### Basal Cell Carcinoma

Basal cell carcinomas (Fig. 50.11) arise from the basement membrane of the epidermis. Although these are rarely metastatic, they can significantly damage adjacent tissue secondary to large excisions and damage vital structures.

- **Clinical features:** Pearly, translucent, flesh-colored papules; superficial **telangiectasias** (broken blood vessels) are usually visible; may have rolled edges or ulcerations
- **Body distribution:** Sun-exposed areas, especially head, neck, and trunk
- **Clinical course:** Usually not metastatic but can become locally invasive; recurrence rate after excision is 44% in 3 years.

### Malignant Melanoma

The most serious of all skin cancers are malignant melanomas (Fig. 50.12) that originate from melanocytes found in the basement membrane of the epidermis. There are several different stages of malignant melanomas, depending on the thickness and depth of the tissue.

- **Clinical features:** Appearance can follow the ABCDE rule (see Box 50.5):
  - A: Asymmetric appearance
  - B: Irregular borders
  - C: Variation of color (brown, black, tan, blue, red, white, or any combination)
  - D: Diameter greater than 6 mm
  - E: Elevation or an evolving, enlarging, and changing existing lesion
- **Body distribution:** Anywhere on the body, especially where there are existing moles; upper back, lower legs, soles of feet, and palms of hands in dark-skinned individuals
- **Clinical course:** Favorable outcome if diagnosed and treated early; rapid metastasis can occur; 5-year survival rate of 91% and 10-year survival rate of 89%

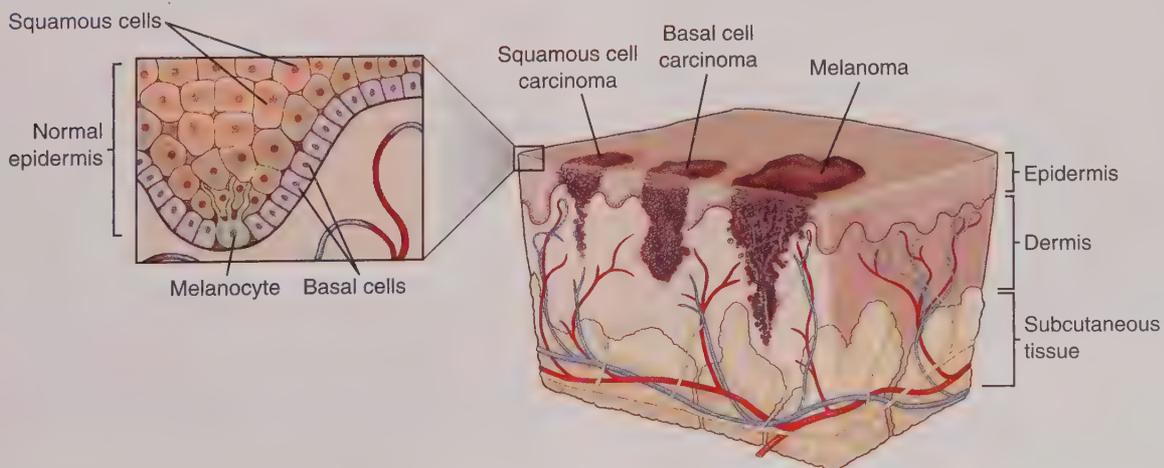

FIGURE 50.10 Atypical squamous cells intermix with the normal squamous cells and can invade the underlying dermis, causing squamous cell carcinomas, basal cell carcinomas, and melanomas.

**FIGURE 50.11** Basal cell carcinoma.

**FIGURE 50.12** Malignant melanoma.

### Connection Check 50.11

Which individual is at greatest risk for developing skin cancer?

- A fair-skinned, blue-eyed teenager who works outside in the summers, uses sunscreen with sun protection factor (SPF) of 50, and wears long-sleeved dark shirts
- A woman with a medium to dark complexion who applies sunscreen once in the midmorning and afternoon while she is playing tennis
- A 10-year-old child who plays outside in the early morning and late afternoons and uses SPF 30
- A surfer who wears a wet suit with long sleeves and legs and applies sunscreen to his face periodically throughout the day

## Management

### Medical and Surgical Management of Non-melanoma Skin Cancers

Management of non-melanoma skin cancers is dependent on size, location, recurrence risk factors, age, and the patient's current state of health.

### Surgical Excision

Skin cancers with well-defined margins (surrounding structures are not involved) can be treated with surgical excision. In 95% of the cases of low-risk tumors, excision of the tumor with a 4-mm (millimeter) margin is successful. Not only does surgical excision provide a high cure rate, but also the cosmetic results of surgical excision are preferred over radiotherapy. Excised tissue is sent for biopsy.

### Curettage and Electrodesiccation

The curettage and electrodesiccation treatment method is appropriate for low-risk, smaller lesions. After the patient receives a local anesthetic, a sharp curette (or scoop) is used to scrape away friable tumor tissue until the firm base of the tumor is felt by the surgeon. Electrodesiccation denatures the proteins in the dermis and destroys the tumor's base. This method can minimize damage to surrounding tissues, and three treatment sessions are usually needed for complete removal. Successful outcomes are operator dependent. Healing is by secondary intention, cosmetic results are good, and the method is cost-effective.

### Mohs' Micrographic Surgery

Considered the "gold standard" for the treatment of non-melanoma skin cancers, Mohs' micrographic surgery is a highly specialized surgical approach completed only by surgeons specifically trained in this procedure. The surgeon excises horizontal sections of the tumor, leaving a minimal margin of normal tissue. Each layer of tissue is histologically examined by frozen section and microscopically analyzed during surgery. Excision continues until all residual tumor is removed. This allows the surgeon to explore all of the margins to reduce the risk of incomplete excision or removal of too much tissue, possibly causing unfavorable cosmetic outcomes.

### Photodynamic Therapy

This is a noninvasive procedure that applies light therapy following an application of a topical photosensitizing agent. After an incubation period during which the photosensitizing agent accumulates in the tumor, the tumor is exposed to a light source that reacts with the agent to destroy cancer cells. Up to 20% of patients experience "severe" pain during the procedure. Following photodynamic therapy, the patient may experience burning, itching, crusting, scaling, and erythema at the site. Although cosmetic results are similar to those of surgical excision, patients are inconvenienced by a 4- to 5-hour procedure during which any scales or crusting must be removed prior to applying the photosensitizing agent. Photodynamic therapy is advantageous for patients who are poor surgical candidates because of other comorbidities or for those who have large or multiple lesions that can be treated at one time.

## Cryotherapy

Liquid nitrogen is used for cryotherapy. It creates temperatures between  $-50^{\circ}\text{F}$  ( $-45.6^{\circ}\text{C}$ ) and  $-60^{\circ}\text{F}$  ( $-51.1^{\circ}\text{C}$ ), which freeze the vasculature, leading to cell death and tissue destruction. The freezing of the tissues is nonselective, and the microcirculation becomes impaired, causing pain that usually requires local anesthesia. As the tissues thaw, patients experience increased tenderness. In the days following the procedure, the patient may experience blistering and sloughing at the site, requiring local wound care. **Slough** is soft, moist devitalized tissue that may be white, yellow, tan, or green. Healing occurs with minimal scarring.

## Radiotherapy

Radiotherapy is appropriate for use in patients who are poor surgical candidates because of their health or the site and extent of the tumor. In cases of aggressive squamous cell carcinoma, radiotherapy is an additional treatment following surgical excision. Radiotherapy is external-beam radiation delivered in fractionated doses from an x-ray machine. It is contraindicated for previously irradiated areas and some non-melanoma skin cancers. Because of side effects, such as alopecia, skin atrophy, and the development of telangiectasias, it is recommended that this therapy not be used on patients under 50 years of age.

## Topical Chemotherapy

Topical chemotherapy with 5-fluorouracil is used in the treatment of multiple actinic keratoses or for superficial widespread basal cell carcinoma that would take multiple surgical procedures for complete removal. This therapy occurs over several weeks, and the lesions become inflamed, begin to crust, drain, and eventually erode away. Patients are educated about the appearance of the lesions during therapy and that post-therapy cosmetic results are usually effective.

## Medical and Surgical Management of Malignant Melanoma

Treatment of malignant melanomas consists of excision with a 5-mm margin of unaffected tissue and biopsy, including a sentinel lymph node (the first lymph node to which cancer is likely to spread) biopsy. The outcome of treatment depends on the staging of the tumor and lymph node involvement. Tumors confined to the epidermis have a better prognosis postoperatively. With positive lymph nodes, a complete lymphadenectomy is indicated.

Metastatic melanoma is incurable, having a median survival of 7.5 months following initial diagnosis. Immunotherapy with interferon alpha and interleukin-2 provides a treatment option, although with only modest benefits. The desired effect of immunotherapy is to stimulate the antitumor response of the immune system and inhibit tumor growth and metastases. Further research is under way to develop more effective therapies for the treatment of metastatic melanoma.

## Connection Check 50.12

What should the nurse teach the patient to expect during and following cryosurgery for the removal of a basal cell carcinoma?

- "You may experience some discomfort during and immediately after the procedure. Local wound care may be required because of minor skin sloughing in the next few days."
- "You will not have any pain with this procedure and need to see your provider only if complications develop."
- "You may experience some discomfort during the procedure, but there is no follow-up care required."
- "You will receive a local anesthetic just prior to the procedure. In the next few days, you may experience burning and itching at the site."

## Complications

In addition to the physical complications of the treatments, the psychosocial aspects of skin cancers can have far-reaching effects on both the patient and family. The impact of the diagnosis of melanoma does not necessarily correlate with the stage and severity of the prognosis. Many times, patients are angry with themselves for not finding the cancerous lesion earlier or for not changing their lifestyle to reduce the risk of melanoma. Also, there may be financial concerns for the families during treatment. Patients with melanoma respond well to a straightforward approach of honesty and clarity in diagnosis and prognosis discussions and prefer to be involved in the decision making and treatment plans. Anxieties about treatment progress and risk of recurrence are diminished with regular follow-up and education. Research demonstrates that patients with melanoma may benefit from the support of a psychological healthcare professional.

## Nursing Management

### Assessment and Analysis

Thorough assessment and history-taking skills are essential in identifying risks for skin cancers. Physical changes in the appearance of skin, as well as a review of risk factors and exposures, are important to an accurate diagnosis and treatment plan. Clinical manifestations are associated with the type of cancerous lesion. Care for the patient following medical or surgical interventions includes psychosocial support and an understanding of community resources.

### Nursing Diagnoses

- **Alterations in body image** related to altered pigmentation, scarring, and surgical excisions secondary to skin cancer
- **Acute pain** related to treatments for skin cancer
- **Risk for infection** related to treatments for skin cancer

- **Fear** related to the threat to well-being secondary to diagnosis of skin cancer

## Nursing Interventions

### ■ Assessments

- **Skin**  
*Recent changes in size, color, or sensation in moles, birthmarks, or scars are significant signs potentially related to skin cancer. Significant sunburns with blistering are risk factors for skin cancer. Spending prolonged periods of time in the sun during peak sun intensity increases the risk of skin cancer. Regular use of sunscreen is important to assess. Skin that has sustained significant injury in the past is more prone to skin cancer development.*
- **Work history**  
*Work environments that require outdoor work increase exposure to the effects of UV radiation.*
- **Family and personal history**  
*A risk factor of skin cancer includes a positive family history.*
- **Psychosocial history**  
*Skin cancers can provoke fear related to the diagnosis and prognosis.*

### ■ Actions

- Provide pain medication as prescribed for postprocedural pain.  
*Some treatments of skin cancer involve surgical excision or topical therapies that can disrupt the skin, causing pain.*
- Provide emotional support.  
*A diagnosis of skin cancer can evoke fear and concern over alterations in body image, prognosis, and finances.*
- Refer to social work or psychologist  
*Skin cancers can provoke fear related to the diagnosis and prognosis, and referral for counseling is indicated.*

### ■ Teaching

- **Limit sun exposure.**  
*Exposure to the sun is directly related to the development of skin cancer. There are specific actions that can minimize exposure, including the application of sunscreen and wearing hats and long sleeves, as well as limiting exposure during the times when the sun is brightest.*
- **Sunscreen use**  
*The SPF of sunscreen should be at least 30 (with an explanation that SPF 30 means the patient is fully exposed to harmful UV rays for 1 minute of every 30 minutes in the sun). Sunscreen should be applied thickly and reapplied at least every 2 hours or more frequently if swimming or exercising.*
- **Skin self-examinations**  
*Skin self-examinations should be performed monthly, looking at both anterior and posterior surfaces as well as the top of the head, soles of the feet, and palms of the hands.*
- **Wound care for postoperative incisions or effects of other skin cancer treatment**  
*Education about proper wound care decreases the risks of infection and promotes healing.*

- Information about different types of skin cancer  
*Because not all skin cancers have the same prognosis, education about the specific types of skin cancer may alleviate concerns.*
- Providing patients and families with contact information for local chapters of the American Cancer Society  
*Support groups can help patients cope with a new diagnosis of skin cancer.*

## Evaluating Care Outcomes

Treatment for skin cancers begins with teaching about risks and ways to prevent the development of skin cancers. Certainly, the prognoses of actinic keratosis, basal cell carcinomas, and most squamous cell carcinomas are much better than those for patients with malignant melanoma. Education for patients treated for actinic keratosis and basal carcinomas includes an explanation of prognosis as well as ways to decrease risk factors. Emotional support and connecting the patient and his or her family with appropriate community resources significantly helps the patient with a new diagnosis of melanoma.

## RECONSTRUCTIVE SURGERY

Reconstructive surgery is performed by a plastic/reconstructive surgeon following trauma, surgical debridement of a wound, excision of cancerous lesions, or repair of congenital defects (such as a cleft lip or palate) to repair or improve functional deficits.

## Epidemiology

More than 5 million reconstructive surgeries are performed each year in the United States. There are two distinct groups of patients who require reconstructive surgery: those who need surgery because of congenital defects or disfiguring birthmarks and those who need surgery because of trauma, excisions of tumors, infections, or chronic wounds.

The most common reconstructive surgeries performed by plastic surgeons were for cancer reconstruction and wound repair and closure. Tumor removal and repair accounted for approximately 90% of these reconstructive procedures. Additional reconstructive surgeries include scar revision, laceration repair, dog bite repair, hand surgery, burn care, breast reconstruction, and microsurgery.

## Pathophysiology

The plastic surgeon performs primary closure of the wound with minimal scarring if the edges of the wound are fairly straight. For wider wounds, surgical debridement and healing by secondary or tertiary intention may be required. Healing by tertiary intention includes the use of skin grafts, myocutaneous (skin, subcutaneous tissues, and muscle), fasciocutaneous (skin, subcutaneous tissues, and fascia), and free muscle flaps.

## Management

### Medical Management and Complications

Medical management of the postoperative reconstructive surgical wound involves diligent assessment skills. As with any surgery, reconstructive surgery runs a high risk of infection. A close assessment of the surgical site and donor sites of skin grafts and free tissue transfers for erythema, increased warmth, purulent drainage, approximation of the incision line, swelling, increased pain, and local lymphadenopathy is essential. For flaps and free tissue transfer, hematoma formation, induration, and signs of decreased vascularity are indications that may require further surgical interventions. Additionally, attention to frequent laboratory values such as CBC values and serum electrolyte panels is essential in monitoring for hemorrhage, fluid and electrolyte imbalances, and infections. Antibiotics may be ordered prophylactically for initial treatment; however, culture and sensitivity information must be evaluated and antibiotic therapy targeted to treat any identified pathogens. Lastly, nutrition must be optimized for healing to occur.

### Nursing Management

#### Assessment and Analysis

Nursing care of the patient undergoing reconstructive surgery extends from the preoperative to the postoperative periods. The nurse focuses on diligent assessment of the wound as well as any graft sites and is attentive to signs of infection, decreased perfusion, and delayed wound healing. Additionally, elevations in white blood cell count must be reported to the provider. Fluid and electrolyte status, as well as nutritional intake, are also important parameters to follow in the patient after reconstructive surgery. Wound care, psychosocial needs, pain management, and astute assessment skills are critical in managing the reconstructive surgical patient.

#### Nursing Diagnoses

- **Acute pain** related to injury/inflammation at surgical and donor sites
- **Risk for infection** related to the surgical incision or open wound
- **Risk for ineffective peripheral tissue perfusion** related to failure of microvascular anastomoses of the flap
- **Risk for imbalanced nutrition (less than body requirements)** related to hypermetabolic state of wound healing
- **Risk for deficient fluid volume** related to hypermetabolic state of wound healing, fluid loss during surgery

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Elevated temperature and heart rate may be indicative of infection.*
- Pain  
*Postoperative pain is likely after reconstructive surgery because of the debridement, surgical exploration, and reanastomosis.*

*Uncontrollable pain may indicate complications, including inflammation, infection, dehiscence, and rejection.*

- Baseline and ongoing wound/surgical incision assessments  
*Assessment of the wound/surgical incision is necessary for evaluation of infection, perfusion, bleeding, and potential graft rejection.*
- Intake and output  
*The surgical patient is at risk for fluid volume deficit related to blood loss and increased metabolic demands that increase insensible fluid loss.*
- CBC  
*Because the postoperative patient is at risk for hemorrhage, the patient is assessed for decreases in hematocrit and hemoglobin, and elevated white blood cell counts are indicative of infection.*
- Serum electrolytes  
*The postoperative patient is at risk for dehydration that can lead to elevated serum sodium levels and third spacing that requires monitoring of albumin levels.*
- Medication history  
*Anticoagulants and antiplatelet medications must be stopped several days before surgery to avoid excessive bleeding.*

##### ■ Actions

- Administer pain medications according to prescriptions.  
*Pharmacological pain interventions are essential for the management of moderate to severe pain.*
- Assist patient in identifying alternative methods of pain control to supplement medications: distraction, imagery, relaxation, application of heat and cold.  
*Alternative methods of pain control can give the patient a sense of self-control and active participation in his or her care.*
- Obtain nutrition referral for nutrition assessment.  
*The hypermetabolic state of wound healing requires supplementation of protein, energy, carbohydrates, fluid, and vitamins and minerals.*
- Obtain a specialty bed if reconstruction was for a pressure injury.  
*Specialty beds can reduce the effects of pressure on the new flap. Pressure can compromise blood flow to the flap and cause more tissue destruction.*
- Position patient so that he or she is not lying on the newly reconstructed surgical area.  
*Positioning the patient appropriately can reduce or eliminate pressure on the surgical area.*
- Provide emotional support to the family/caregivers.  
*Caregivers can experience anxiety and apprehension about their abilities to provide care to the patient.*

##### ■ Teaching

- Importance of following prescribed diet  
*The hypermetabolic state of wound healing requires supplementation of protein, energy, carbohydrates, fluid, and vitamins and minerals.*

- Clinical manifestations of infection and decreased tissue perfusion to patient and family  
*Rapid and early assessment for infection or decreased tissue perfusion of the flap is essential to prevent further injury, including graft failure.*
- Expected progression of healing  
*Anxiety can be diminished if the patient and family/caregivers understand what to expect.*
- Wound care  
*Patients with wounds healing by secondary intention require wound care throughout the wound-healing process.*
- Appropriate methods of off-loading, such as push-ups while sitting in the wheelchair and repositioning while lying down  
*Wheelchair push-ups (patient lifting body weight up off of wheelchair surface) every 15 minutes and repositioning while lying down every 2 hours diminish the effects of pressure.*

### Evaluating Care Outcomes

The patient undergoing reconstructive surgery has many needs during the perioperative period. Success rates of skin grafts, muscle flaps, and free tissue transfer flaps can be tenuous and vary by the location of the flap, health status of the patient, presence of preoperative infections such as osteomyelitis, and postoperative care. Patients undergoing debridement with closure by secondary intention need dressing changes throughout the healing phase and will likely go home with an open wound. The patient and family/caregivers require support to help them meet the physical and psychosocial demands of wound healing and the prescribed course of treatment. The goal of treatment is a well-healed wound and improved functional status of the patient.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Parker's wife has been his advocate and support throughout his hospitalization and treatment. She diligently makes certain all of the necessary therapies are in place and that he is adhering to orders. Mr. Parker receives nutrition counseling and physical and occupational therapies while in the rehabilitative hospital, helping him to maintain his upper-body strength, which is needed for transfers in and out of bed and his wheelchair. Also, he adheres to the recommendation of doing "push-ups" (paraplegic patients in wheelchairs should lift their bodies off the surface of the wheelchair cushion every 15 minutes). He has a pressure-redistributing cushion on his wheelchair and a specialty mattress in his home. He is able to return to work and lives a full life without an open wound, something he has not done for more than 6 years.

### Case Study Questions

1. The nurse is preparing to admit Mr. Parker to the rehabilitation unit following his hospital stay for his myocutaneous flap surgery. Which action should be the priority in preparing for his arrival?
  - A. Having his favorite food available to help him maintain a healthy nutritional status
  - B. Having a bed available for his wife to spend the night
  - C. Having the appropriate mattress on his bed to redistribute pressure
  - D. Having advanced wound dressings for highly exuding wounds available
2. Which priority should be implemented early in the treatment plan for Mr. Parker?
  - A. Maintaining upper-body strength
  - B. Performing full passive range-of-motion exercises to his lower extremities three times daily
  - C. Maintaining his contact with work e-mail to facilitate his eventual return to work
  - D. Getting out of bed to his wheelchair and going outside
3. In what position is Mr. Parker at least risk of increasing pressure to the ischial muscle flap?
  - A. Lying on his left side
  - B. Lying on his right side
  - C. Sitting up in bed at a 60-degree angle
  - D. Sitting up in bed at a 45-degree angle
4. The nurse is teaching Mr. Parker about wound healing. Which statement by him indicates that the teaching was effective?
  - A. "I will deeply massage my muscle flap daily to increase circulation and speed healing."
  - B. "I will make sure I get a mattress overlay at home so that I don't need to worry about changing positions during the night."
  - C. "I will be sure to increase my intake of lean meats and proteins."
  - D. "I will go on a diet when I'm discharged because I've gained so much weight over the past few years."
5. Which activity could compromise the healing of Mr. Parker's new flap? (*Select all that apply.*)
  - A. Smoking
  - B. Wheelchair "push-ups"
  - C. Incontinence
  - D. Participating in physical therapy
  - E. Increased fluid intake

## CHAPTER SUMMARY

The skin is the largest organ of the body and serves important functions in relation to protection, sensation, and temperature regulation. Specific functions include protection from bacterial invasion and external elements; sensation of the environment through the senses of touch, pain, temperature, and pressure; retention of water; absorption; thermoregulation; immune surveillance; and metabolism of vitamin D. Disorders of the skin may be related to local damage or trauma or indicative of systemic disease.

Skin infections may be bacterial, viral (herpes simplex), or fungal in origin, and each has characteristic clinical manifestations. Treatment is based on identifying the specific pathogen and administration of targeted antibiotics and other therapies. Patients with skin infections may also manifest issues related to stigma and body image disturbance because of the skin infections, requiring sensitivity by the healthcare team.

Similar to patients with skin infections, patients with psoriasis may also have concerns related to body image because of the chronic nature of this disorder. Psoriasis is a lifelong inflammatory disorder that is characterized by exacerbations and remissions of raised, scaling, erythematous plaques usually seen on the extensor surfaces of the body. Although there is no cure for psoriasis, there are various treatments available that can control clinical manifestations.

Traumatic injuries to the skin are the result of external sources and are classified as an acute wound. There are many types of traumatic skin injuries, including lacerations, abrasions, excoriations, friction blisters, skin tears, pressure injuries, and burns. Clinical manifestations vary depending on the size and depth of the trauma as well as injury to underlying structures, including blood vessels, muscles, and bones. Wound healing is important in reestablishing skin integrity and has four phases—hemostasis, inflammatory, proliferative, and maturation—and each phase has specific clinical manifestations that reflect whether the healing is proceeding normally.

Patients in many healthcare settings are at risk for damage to the skin related to pressure, and because of the complexity and cost in the treatment of complicated pressure injuries, surveillance and prevention are primary nursing considerations. Pressure injuries are a common health

problem among individuals who are physically limited or bedridden and include localized injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of pressure or pressure in combination with shear. Complications of pressure injuries include infection, both local and systemic. The nurse's goal is to limit pressure and shearing to prevent pressure injury development. Treatment includes different approaches, including support surfaces to decrease or alleviate pressure, ointments, dressings, and surgical debridement.

Skin cancer is the most prevalent type of cancer, and exposure to the sun is one of the primary risk factors. Ultraviolet damage to the DNA of keratinocytes increases with extended time in the sun and is a major contributing factor to the development of skin cancers. Non-melanoma skin cancers include basal cell and squamous cell carcinomas. The most serious of all skin cancers is malignant melanoma that originates from melanocytes found in the basement membrane of the epidermis. Treatment for skin cancers may be complex, including surgical excision, cryotherapy, radiotherapy, topical chemotherapy, and photodynamic therapy. As with other skin disorders, patients with skin cancer may have to deal with body image disturbances.

Reconstructive surgery is performed by a plastic/reconstructive surgeon following trauma, surgical debridement of a wound, excision of cancerous lesions, or repair of congenital defects (such as a cleft lip or palate) to repair or improve functional deficits. There are two distinct groups of patients who require reconstructive surgery: those who need surgery because of congenital defects or disfiguring birthmarks and those who need surgery because of trauma, excisions of tumors, infections, or chronic wounds.

The skin and its structures serve as a protective barrier against microbial invasion and environmental exposures, and skin disorders cause a compromise in the skin's integrity, thereby facilitating the risk of infection and injury to the patient. Nursing interventions can provide fortification of the mechanical barrier of the skin through education, support, and proactive recommendations. Once skin breakdown occurs, however, nurses must be able to assess, implement, and evaluate the patient before, during, and after treatment. This requires knowledge of skin infections, wound healing, and therapies used in treating patients with skin and soft tissue disorders.

# Chapter 51

## Coordinating Care for Patients With Burns

*Kelly Krout and Carrie Cox*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Discussing the epidemiology of burn injuries
2. Explaining the pathophysiological processes associated with burn injuries
3. Describing classifications of burn injuries
4. Correlating the pathophysiological changes with clinical manifestations seen in patients with superficial, partial-thickness, and full-thickness burns
5. Discussing the appropriate diagnostic examinations for patients with burn injuries
6. Explaining the medical and surgical management of patients with burn injuries
7. Developing comprehensive plans of care for patients with burn injuries
8. Designing a plan of care that includes pharmacological, dietary, and lifestyle-based considerations for patients with burn injuries

### CONCEPTS

- Assessment
- Comfort
- Fluid and Electrolyte Balance
- Infection
- Medication
- Nutrition
- Oxygenation
- Perfusion
- Promoting Health
- Skin Integrity

### ESSENTIAL TERMS

Allograft  
Autograft  
Burn excision  
Burn shock  
Compartment syndrome  
Contracture  
Cultured epithelial autograft (CEA)  
Debridement  
Deep partial-thickness burn  
Donor site  
Eschar  
Escharotomy  
Fasciotomy  
Full-thickness burn  
Hydrotherapy  
Lund and Browder  
Meshed graft  
Myoglobinuria  
Rule of nines  
Sheet graft  
Split-thickness skin graft  
Superficial burn  
Superficial partial-thickness burn  
Systemic inflammatory response syndrome (SIRS)  
Total body surface area (TBSA)  
Xenograft  
Zone of coagulation  
Zone of hyperemia  
Zone of stasis

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Joe Smith is a 40-year-old male weighing approximately 220 lb (100 kg) who presents to the hospital's emergency department with burns to his face, anterior trunk, and bilateral upper extremities. He has singed nasal hairs and carbonaceous sputum but is reporting no difficulty swallowing or breathing. He sustained the burn while throwing gasoline on a brush fire. He has no past medical history and is currently taking no medications. The patient has been placed on 100% oxygen and has two large-bore peripheral IV catheters. The burns are pale and dry, and the patient is not complaining of any pain except around the edges of the wounds...

## INTRODUCTION

Patients with burns are optimally managed at a burn center, where they have the advantage of an interprofessional team of healthcare providers skilled in the specialized treatment of burn injuries. Currently in the United States, there are only 68 burn centers verified by the American Burn Association. Burn center referral criteria established by the American Burn Association are listed in Box 51.1. Because of the limited number of burn centers, the majority of patients receive their initial care at local hospitals prior to transfer to a specialized burn center. For this reason, it is essential for healthcare providers with no specialized education in burn care to have a basic understanding regarding the stabilization and initial management of this patient population.

## INCIDENCE AND EPIDEMIOLOGY

According to the latest data released in October 2018 by the National Fire Protection Agency (NFPA), 1,319,500 fires were reported in the United States in 2017, which resulted in 3,400 civilian deaths and 14,670 civilian injuries. (These statistics are updated annually and are available at [www.nfpa.org/News-and-Research](http://www.nfpa.org/News-and-Research).) As a result of these fires, property damage was estimated at \$23 billion, which is a large increase from previous years and attributed to the wildfires in northern California. The United States has the tenth-highest fire death rate of the 25 industrialized nations. Notably, the southern United States has the highest fire incident rate per thousand people (4.6) and the highest civilian death rate per million population (12.7). The Midwest has the highest civilian injury rate per million population (49.1), whereas the western United States has the highest property loss per capita rate (\$46.9).

## Box 51.1 American Burn Association's Burn Center Referral Criteria

A burn center may treat adults, children, or both.

- Partial-thickness burns equal to or greater than 10% of the total body surface area
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints
- Full-thickness burns in any age group
- Electrical injury, including lightning injury
- Chemical injury
- Inhalation injury
- Burn injury in patients with pre-existing medical conditions that may complicate management, prolong recovery, or affect mortality
- Any patients with burns and concomitant trauma (e.g., fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient's condition may be stabilized initially in a trauma center before transfer to a burn center. Provider judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
- Burned children in hospitals without qualified personnel or equipment for the care of children
- Burn injury in patients who require special social, emotional, or rehabilitative intervention

Questions concerning specific patients can be resolved by consultation with the burn center provider.

Outdoor fires (e.g., fields, vacant lots, trash, wildfires) account for approximately 47% of all property fires. Residential and non-residential structure fires combined account for another 38% of fires. However, residential (one- and two-family homes, including manufactured homes, apartments or other multi-family housing) structure fires account for 76% of all structure fires. Finally, vehicle fires account for 15% of the total number of fires. The largest percentage (78%) of deaths occurs on residential properties, with the majority of these being in one- and two-family homes (67%). Vehicles account for the second-largest percentage of fire deaths at 13%.

The two most commonly reported etiologies for burn injury are fire/flame and scald injuries. Admissions to burn centers show admission cause as 43% fire/flame, 34% scald, 9% contact, 4% electrical, 3% chemical, and 7% other. Scald injuries are most prevalent in children under the age of 5, whereas fire/flame dominates all other age groups. The leading cause of both residential and non-residential structure fires is cooking (80.2%), with fires caused by heating being the second-leading cause (9.6%). The two leading causes that result in fatalities and/or injuries for residential fires are cooking- and smoking-related incidents. Some

examples include grease burns, scald injuries, flame burns, and falling asleep while smoking.

The majority of fire-related fatalities and injuries occur in people between the ages of 20 to 69 years. This age group accounts for more than half of the fire injuries reported in the United States. According to data collected by the NFPA, men are 1.6 times more likely to die in fires than females, and data collected by the American Burn Association demonstrate that men account for nearly 68% of all patients admitted to burn centers. Although the exact reasons for this are unknown, possibilities include the greater likelihood of men participating in risk-taking behavior and the more high-risk occupations of men. Men also suffer more injuries trying to extinguish fires and rescuing people. Approximately 30% of all fire deaths in females occurs in women 70 years old and older, and this may be due to the fact that women have a longer life expectancy than men and are often performing the majority of the cooking. By contrast, male fire deaths are higher in the age range of 40 to 59. Notably, older adult females have twice the number of fire injuries when compared with older males.

People with limited physical and mental abilities, especially older adults, are at a much higher risk of fire death. Older adults (ages 65 and over) have a risk of dying in a fire that is 2.5 times higher than that of the population as a whole. This risk increases to 3.4 times for those ages 85 and over. As the baby boomers enter retirement age, a corresponding increase in fire deaths and injuries among older adults is likely. In the past, children under the age of 5 were also considered to be at high risk of death due to fire. However, for children ages 4 or younger, the risk of fire death was 30% less than that of the general population. The risk of death for this age group was greater than for older children because as children mature and their cognitive and social abilities develop, the risk of fire death drops sharply. For children ages 5 to 9, the fire death risk was 60% less than that of the general population. For those aged 10 to 14, the risk of fire death was 70% less, dropping even further to 80% less for 15- to 19-year-olds.

Other factors that influence the risk of fire death or injury are related to socioeconomic status. The lower-socioeconomic population groups have the highest risk of fire injury or death, whereas the wealthiest have the lowest. Closely tied to income is education level, with those living below the poverty line for extended periods of time experiencing higher fire death rates. African Americans and American Indians/Alaska Natives also have higher fire death rates per capita than the national average, with African Americans accounting for 20% of the total fire deaths while only making up 13% of the U.S. population.

To reduce the incidence of burn injuries, many burn centers are involved in community prevention activities. These activities focus on the higher-risk population groups, including children and older adults. See Box 51.2 for burn injury prevention strategies. In addition, *Healthy People 2020* calls for a reduction in the incidence of residential fire deaths (Box 51.3).

## PATHOPHYSIOLOGY

### Classifications

Burns are generally classified in terms of etiology, depth of tissue damage, **total body surface area (TBSA)** involved, and severity.

### Burn Etiology

A burn injury results when the tissues of the body are damaged by a heat source. The heat source may be thermal, electrical, chemical, or the result of radiation.

### Thermal

Thermal burns can be the result of a flash, scald, or contact with hot objects or flames, and common causes include house fires, car fires, cooking accidents, or injuries as a result of careless smoking. Associated accelerant use (e.g., gasoline, kerosene, or propane) may increase the severity of the burn and associated inhalation injury because this adds a chemical insult in addition to the thermal injury. Contact burns are also thermal in nature and are often associated with cooking or heating incidents. Scald injuries are most prevalent among the young and may be associated with accidents or even abuse. The two factors that determine the depth of a thermal injury are the temperature to which the skin is heated and the duration of contact with the heat.

### Electrical

Electricity has many devastating effects on the body and may result in a wide spectrum of injuries, ranging from mild to lethal. Electrical injuries account for approximately 4% to 5% of admissions to burn centers in developed countries and up to 27% of admissions to burn centers in developing countries. Of these, 61% are a result of work-related accidents such as gas and electric workers injured while working on breaker boxes or overhead power lines. These burns related to work on power lines are the fourth-leading cause of traumatic work-related deaths. Electrical injuries are associated with an overall increase in the length of hospital stay, morbidities, and number of required surgeries. This is due to the fact that electrical injuries often are linked to other types of ensuing trauma due to subsequent falls and the potential cardiac injury. In addition, as electricity passes through the body, it has the potential to cause damage to multiple organs, which then must also be addressed and treated in conjunction with any burns that have occurred. Electrical burn injuries can be associated with extensive burns that may even require amputation. Patients may present with cardiac and/or neurological problems as well as associated trauma and/or flame burns.

Electrical injury may occur by direct contact with the source, by an arc between two objects, or as a result of a flame injury caused by ignition of the surroundings. The effects of electricity on the body depend on certain factors, including the type and strength of the current, the duration of contact, the pathway of flow through the body, and local

## Box 51.2 Burn Prevention Strategies

### Burn Prevention Inside the Home

- Install and maintain working smoke alarms on each level of the home and inside each sleeping area. Each month, check that they are working, and change the batteries every 6 months unless the alarm is hardwired into the home or has a 10-year lithium battery.
- Install and maintain working carbon monoxide detectors on each level of your home.
- Develop and practice a home fire escape plan. Make sure everyone in the home knows the meeting place and knows never to return into a burning home for any reason.
- Keep all windows and doorways free of clutter in case of the need to escape quickly.
- Keep a flashlight and telephone near the bedside.
- Keep a working fire extinguisher on each level of the home and know how to use it properly.
- Never set the water heater above 120°F (48.9°C).
- Teach children how to stop, drop, and roll.
- Keep matches and lighters out of the reach of children.
- Never leave a child unattended in a bathtub or near a fire/fireplace.
- Never smoke in bed or while drowsy.
- Never smoke while receiving oxygen therapy.
- Never leave burning candles unattended, and try not to burn candles on low surfaces for risk of being knocked or bumped.
- Always exercise caution while cooking, and do not leave anything unattended on the stove.
- Avoid wearing long sleeves or flowing clothing while cooking.
- Never let a child play near the stove/oven while cooking. Always turn pot handles inward and use the rear burners when possible.
- Never use the kitchen oven as a means to heat the home.
- Avoid running electrical cords under carpets.
- Avoid using space heaters in the bedroom or while asleep.
- While a space heater is in use, there should be a minimum of 3 feet of clearance around the heater in all directions.
- Avoid falling asleep while using a heating pad.
- Be sure to use proper protection and ventilation while working with chemicals in the home, including cleaning products. Read all product labels carefully before use.
- Never store flammable liquids inside the home or near a source of heat.

### Burn Prevention Outside the Home

- Always store flammable liquids outside the home in clearly labeled, airtight containers in well-ventilated areas (such as a garage or shed).
- Never refill a hot engine (i.e., lawnmower or weed whacker). Wait until thoroughly cooled before refilling with gasoline.
- Never use flammable liquids to start a campfire or grill.
- Never throw flammable liquids onto an already burning fire.
- Use caution with campfires, and do not leave children unattended around the fire.
- Fireworks should be used only by adults and with extreme caution.
- Be careful of overhead and underground electrical wires while working outside.
- If downed electrical wires are found, do not touch! Call the local electric company to report immediately.
- Caution children never to play near or on electrical boxes or climb trees with electrical wires passing through the branches.
- Always use sunscreen with an SPF of at least 30 when outdoors, and be sure to reapply often. Consider a wide-brimmed hat and sunglasses.

SPF, Sun protection factor.

## Box 51.3 Healthy People 2020

As of 2007, the incidence of residential fire deaths was down to 0.95 deaths per 100,000. The *Healthy People 2020* goal set by the surgeon general focuses on a 10% improvement in incidence for 2020.

- Goal (IVP-28): Reduce the incidence of residential fire deaths to 0.86 death per 100,000 people.

tissue resistance. The epidermis is the body's best insulation, but once breached, the body acts as a volume conductor. Bone is more resistant to the flow of electricity, and the electricity tends to flow along the top of the bone, often damaging the overlying muscles, nerves, and vessels. Consequently, deep muscle injury may be present even when skin and superficial muscle may appear uninjured.

When a person comes into contact with alternating current, the body often becomes part of the circuit. In

alternating current, the movement of an electric charge sporadically changes direction, creating a tetany effect, or involuntary state of muscle contraction that interferes with the person's ability to easily break free from the source. This muscle contraction enables the electric current to flow continuously back and forth between the person and the source, which may either throw the person or draw the person into continual contact with the source. As a result, the current may pass through the body for a greater period of time, exacerbating the severity of the associated injury. Direct current is a one-directional, constant flow of electricity. In the United States, direct current injuries occur from lightning strikes, contact with car or boat batteries, and contact with railway train lines. Electrical current also disrupts the electrical activity of the body and may result in immediate cardiac and/or pulmonary arrest on scene.

The common household electric circuit carries a charge of 120 volts. High-voltage injuries occur when a person comes into contact with 1,000 volts or greater. These types of injuries are often work related and are more common in men. Patients who sustain high-voltage injuries often present with very deep burns and sequela from associated trauma. Flash injuries and/or flame burns may also occur as a result of possible ignition of clothing. The hands and mouth are the most frequently injured sites for low-voltage electrical injuries in children as they may have oral contact with electrical cords or sockets. Surgical management and extensive rehabilitation may be required for the best functional outcomes.

### Chemical

Chemical burns account for approximately 3% of all burn center admissions and occur in both the industrial and household settings. The three subclasses of chemical burns include acids, alkalines, and organic compounds. Some

examples of chemical burns include those caused by cement, gasoline, lime, hydrofluoric acid, and bleach. The extent of a chemical injury is dependent on many factors, including the agent, the mechanism of action, the concentration and volume of the agent, and the duration of contact with the agent.

### Radiation

Radiation burns are the least common type of burn injury, and the severity of complications is dependent on the type, dose, and length of exposure. These injuries are often associated with the industrial use of ionizing radiation, nuclear accidents, and therapeutic radiation treatment. Sunburn is also considered a radiation burn because it is caused by ultraviolet radiation and is the most common type of radiation burn seen in healthcare settings. Localized radiation injuries often appear similar in nature to thermal burns because they are characterized by erythema, edema, blisters, and pain. Prolonged full-body exposure to ionizing radiation often causes nausea, vomiting, diarrhea, fatigue, headache, and fever.

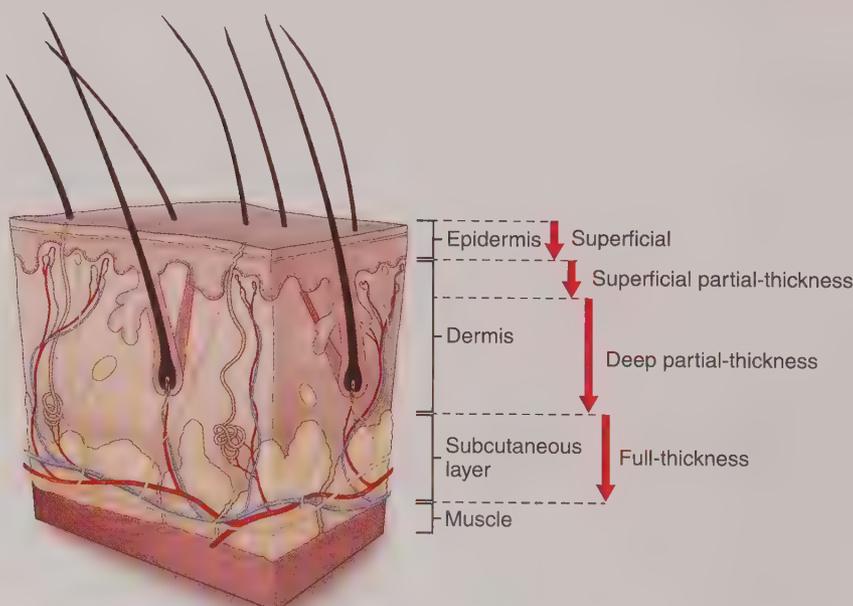

### Connection Check 51.1

The nurse recognizes which etiology as consistent with a thermal burn?

- A. Direct current
- B. Scalding
- C. Exposure to organic compounds
- D. Ionizing radiation

### Burn Depth

Burns are classified according to the depth of tissue damage: superficial, partial-thickness, or full-thickness injuries. Figure 51.1 presents an overview of burn depth in relation

**FIGURE 51.1** Burn depth in relation to skin anatomy.

to skin anatomy. Determination of the exact depth of the burn is often impossible on initial inspection, even for the most experienced burn-care provider. This is because burn wounds frequently evolve or “declare themselves” within the first 24 to 72 hours, and it is essential to frequently reassess the burn injury to ensure appropriate resuscitation and treatment. The traditional classification terms of first-, second-, and third-degree are not used in the burn community because they do not give an accurate or descriptive representation as to the true extent of injury. These terms are replaced with the burn-depth classification system, including superficial, superficial partial thickness, deep partial thickness, and full thickness. See Table 51.1 for a summary of burn-depth classifications.

### Superficial

**Superficial burns** affect only the epidermal layer of the skin and are characterized by mild erythema and hypersensitivity, which typically resolve in 24 to 72 hours. Sunburn is the most common type of superficial burn injury (Fig. 51.2). These types of burns heal quickly, typically do not require medical intervention or admission to a burn center, and do not usually result in scarring.

### Superficial Partial Thickness

A **superficial partial-thickness burn** involves the epidermis and the superficial or minimal layers of the dermis (Fig. 51.3). Because of the exposed nerve endings located within the dermal layer of the skin, these burns are often very painful. The patient is extremely sensitive to touch and even to air currents when the wound dressing is removed

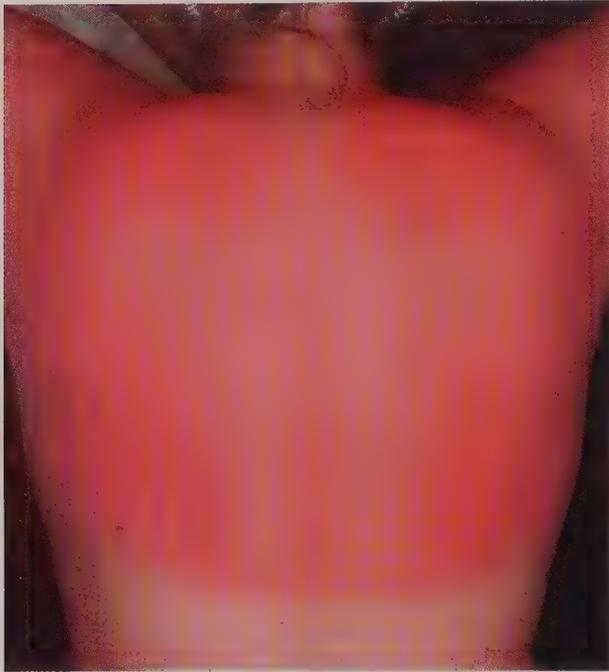

and the burn is exposed. Superficial partial-thickness burns often have wet, weeping blisters and are pink in color. The capillary refill time on areas of open blisters remains normal. Despite the destruction of the entire epidermis, superficial partial-thickness burns usually heal in 1 to 2 weeks with minimal to no scarring. Depending on the location and extent of the superficial partial-thickness burn, medical management and admission to a burn center may be warranted for wound care and pain management. Treatment of superficial and minor partial-thickness burns is highlighted in Box 51.4.

### Deep Partial Thickness

A **deep partial-thickness burn** involves the epidermis and extends into the deeper portions or bottom layers of the dermis (Fig. 51.4). The patient often reports varying areas of pain and decreased sensation. Deep partial-thickness burns appear waxy and do not have the characteristic weeping blisters that are seen in superficial partial-thickness injuries. This is due to the fact that the entire epidermis and the majority of the dermis have been damaged. The burn may appear light pink or cherry red in color, and capillary refill is decreased or absent. The challenge with a deep partial-thickness burn is determining the true extent of the injury and whether it will heal without requiring surgical intervention. It is essential to engage in close observation of the burn wound to monitor for potential progression from a deep partial-thickness to a full-thickness burn injury. The majority of these types of burns take more than 2 weeks to heal, during which time the risk of infection is paramount because patients with burn injuries are immune-compromised

**Table 51.1 Burn-Depth Assessment**

Burn Depth	Tissue Involvement	Wound Characteristics	Pain Assessment	Healing
<b>Superficial</b>	Minimal damage to the epidermis	Dry, no blisters; pink or red; blanches easily	Hypersensitive	3–7 days with no scarring
<b>Superficial partial thickness</b>	Entire epidermis and minimal damage to the dermis	Blisters that may be closed or open and weeping; pink or red; mild edema; blanches easily	Hypersensitive	7–14 days with no scarring
<b>Deep partial thickness</b>	Entire epidermis and deeper layers of the dermis	Blisters that may be closed or open; waxy appearance; cherry red, mottled, or pale in the center; edema; sluggish or no blanching	Hypersensitive around the wound edges but may be sensitive to pressure only in the center	Healing may take 3–6 weeks and may leave some scarring, or the wound may have to be surgically excised and grafted.
<b>Full thickness</b>	Destruction of entire epidermis and dermis have; may involve subcutaneous fat, muscle, and/or bone	Dry, leathery; pale, white, brown, tan, black, charred; no blanching; may be contracted if muscle involvement	No pain in the center of the wound but may be sensitive to pressure	Will not heal without surgical excision and grafting

**FIGURE 51.2** Superficial burn.

**FIGURE 51.3** Superficial partial-thickness burn. A, Pre-debridement of blisters. B, Post-debridement of blisters.

## Box 51.4 Care of the Superficial and Minor Partial-Thickness Burn

Although other mechanisms may cause a superficial burn injury, it is quite common to see this type of burn from the sun. In a true superficial burn, no blisters are noted. If blisters appear, the burn is then considered partial thickness. Minor partial-thickness injuries are commonly seen from scalding liquids. Care of the superficial and minor partial-thickness burn wound is outlined here.

### Superficial

- Do *not* apply ice or submerge in ice water.
- May apply a cool compress or run under cool water.
- A dressing should not be required because there are no open blisters.
- Lotion should be applied liberally once or twice per day.
- Choose lotion that is aloe based and/or fragrance-free.
- Ibuprofen, acetaminophen, or aspirin may be taken as necessary for pain and discomfort.
- Drink plenty of fluids to rehydrate.
- Rest.

### Partial Thickness

- If one to three quarter-sized or smaller blisters appear, try not to open (pop) the blisters. This allows for a moist healing environment, decreased risk of infection, and less discomfort for the patient.
- If the blister or blisters are broken, wash the area with a mild antiseptic soap and warm water.
- Apply a thin layer of bacitracin ointment and cover with a nonadherent bandage.
- The wound should be thoroughly cleansed and the dressing changed at least once per day.
- The patient may continue with his or her usual activities of daily living; however, dependent extremities should be elevated to prevent edema and encourage venous return.
- The patient should be aware of any clinical manifestations of infection, such as fever, increased pain, redness or swelling, purulent drainage, or red streaks radiating from the wound. If noted, the patient should see his or her primary care provider right away.
- It is encouraged that the patient follow up with his or her primary care provider.

without the skin as a barrier to infection. Unfortunately, burns are not an exact science, and the burn surgeon decides whether to operate or to try to let the burn heal on its own.

### Full Thickness

A **full-thickness burn** involves destruction of the epidermis, the dermis, and portions of the subcutaneous tissue (Fig. 51.5). All epidermal and dermal structures are destroyed, including hair follicles, sweat glands, and nerve endings. Full-thickness burns do not heal spontaneously. As a result

**FIGURE 51.4** Deep partial-thickness burn (blisters debrided).

**FIGURE 51.5** Full-thickness burn.

of the extensive damage to the nerve endings, full-thickness burns are often insensate. This absence of pain is often misleading for patients, and many do not comprehend the severity of their injury. Full-thickness burns generally have no blister formation. Although full-thickness burns may take on a variety of colors, they are always very dry and feel like leather to the touch. This full-thickness burn tissue is often referred to as **eschar**. The charred appearance associated with full-thickness injuries is not common. Because all epithelial elements and structures are destroyed, full-thickness burns do not heal spontaneously and require skin grafting. Burns that extend beyond the subcutaneous layer into muscle and/or bone are also considered full thickness, as shown in Figure 51.6.

### Connection Check 51.2

The nurse correlates which clinical manifestation with superficial partial-thickness burns?

- Eschar
- Dry, leathery appearance
- Blisters
- Waxy appearance

**FIGURE 51.6** Full-thickness burn with muscle and bone involvement.

### Total Body Surface Area Percentage

Expressed as a percentage, total body surface area (TBSA) determination is essential to guiding adequate fluid resuscitation and treatment. Both over- and underestimation of the size of the burn can have significant effects on outcome. Underestimation can result in inadequate resuscitation, which may cause shock and organ failure. Overestimation can put the patient at risk for complications such as pulmonary edema due to the excess fluid given during resuscitation. Adult Patients are resuscitated at injuries of 20% or greater TBSA. The three most common methods for determining TBSA are the rule of palm, the rule of nines, and the Lund and Browder classification.

#### Rule of Palm

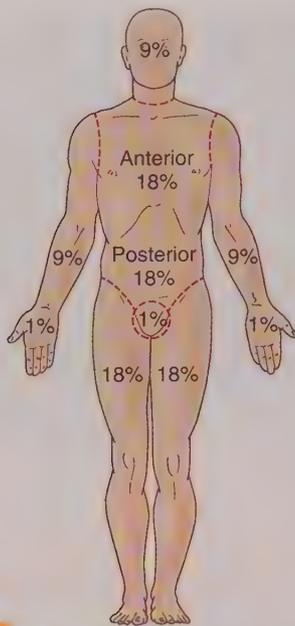

The size of the patient's hand, including the fingers, accounts for approximately 1% TBSA. This quick method of determining burn size is particularly useful in pre-hospital settings for very small and/or very large burns, scattered burns, and in mass-casualty situations where time is of the essence.

#### Rule of Nines

The "rule of nines" is the most commonly used method in pre-hospital settings for making a determination of the percentage of TBSA burned. With this method, the adult body surface areas are broken down into 9% or multiples thereof. This division is modified in infants and children because of the large surface area of the child's head and the smaller surface area of the lower extremities. One concern with the rule of nines is that it assumes all physically mature persons, regardless of weight and body shape, have the same distribution of body surface area percentages. The rule of nines diagram is displayed in Figure 51.7.

#### Lund and Browder Classification

In the hospital setting and in the majority of burn centers, the most widely accepted and accurate method of determining the percentage of TBSA burned is the Lund and

**FIGURE 51.7** Rule of nines for determination of total body surface area (TBSA) burn size. This is expressed as a percentage.

Browder classification. Measurements, which take into account surface area related to age, are assigned to each body part. The Lund and Browder classification chart has come into question because it does not account for the altered body mass distribution in obese patients, and future revisions are currently being considered by burn experts. Only partial- and full-thickness burns are recorded on the Lund and Browder chart because superficial burns are not taken into account during resuscitation. The Lund and Browder chart is not completed until a full and thorough **debridement** (removal of damaged tissue) of the burn wound has been completed because this TBSA percentage provides the basis for determining the amount of fluid resuscitation. A visual representation of the Lund and Browder diagram is displayed in Figure 51.8.

### Severity

There are several other factors that play an important role in determining the severity of a burn and directly impact overall patient outcome. These factors include the presence of an inhalation injury, patient age, past medical history, and presence of concomitant injury, as well as the anatomical location of the burn injury. Of these factors, the two that are of greatest significance in the determination of survival and that warrant further discussion include age and past medical history. Even very small burns can prove fatal to older adults because of the inability to tolerate the aggressive fluid resuscitation and surgical management required. As the baby boomer generation enters into retirement, patient age and past medical history will continue to play a key role in patient decisions and outcomes (see Geriatric/Gerontological Considerations).

## Geriatric/Gerontological Considerations

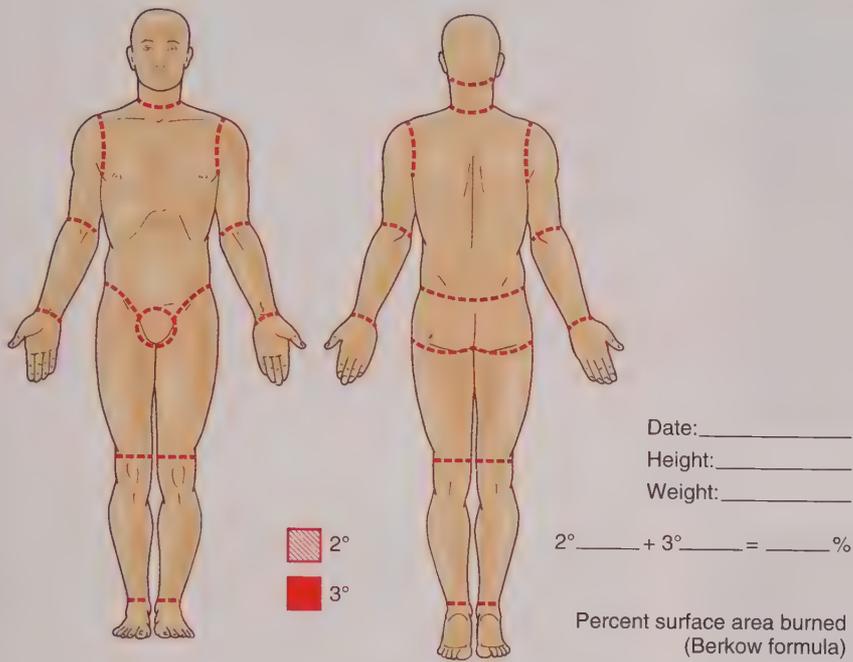

### Burn Care in Older Adults

Managing the care of older adults with burn injuries can present many challenges for the burn team. Common age-related changes in this population put them at a much higher risk of burn injury. These changes include reduced mobility, decreased vision, decreased sense of smell, reduced coordination and strength, and decreased sensation. These normal changes can place older adults at a much higher risk of a severe burn injury because they may have difficulty escaping the fire or removing the source of heat.

Once a burn injury has been sustained, the older adult patient may be much more difficult to manage because of pre-existing medical conditions, decreased immune function, poor nutritional status, decreased pulmonary and/or cardiac function, and poor social support. The skin of the older adult patient is also much thinner and less elastic, which can affect the depth of the injury and the ability of the burn wound to heal. In fact, eschar separation in a full-thickness burn wound is normally delayed in the older adult patient, and many patients are simply not candidates for the operating room because of pre-existing medical conditions. For this reason, older adult patients often have prolonged and complicated hospitalizations and recoveries. Early wound excision and grafting are recommended if they can be tolerated by the patient. The goal is prompt closure of wounds and prevention of infection by decreasing the hospital stay as much as possible.

### Anatomical Changes

The functional outcome of the patient is directly related to the depth of the burn injury, with full-thickness burns resulting in the most significant anatomical skin changes. Skin that has been grafted after a full-thickness burn injury can become severely scarred, and normal movement and appearance are usually significantly impaired. The localized tissue response to the burn can be illustrated by the concentric zones of burn injury, as displayed in Figure 51.9, with each zone representing the localized tissue response. The **zone of coagulation** is the area that had the most contact with the heat source and is the location of the most severe damage. The tissue undergoes protein coagulation, eschar is often present, and the patient often reports no pain within this area because all nerve cells are destroyed. The **zone of stasis** immediately surrounds the zone of coagulation and is characterized by damaged cells and impaired circulation. It is this area of the burn that is most at risk for conversion if the patient does not receive adequate resuscitation. Improper resuscitation or under-resuscitation may

Area	0-1 Year	1-4 Years	5-9 Years	10-14 Years	15 Years	Adult	2°	3°

cause the burn to become deeper because of limited blood flow, causing the zone of stasis to convert into the zone of coagulation, as shown in Figure 51.10. The outermost area is termed the **zone of hyperemia** and is generally an area of increased blood flow in an effort to bring key nutrients for tissue recovery. This area usually sustains minimal injury and recovers spontaneously within 1 to 2 weeks. The full extent of damage may not be evident for 24 to 72 hours post-injury because it may take that long for burns to reveal the true depth of injury.

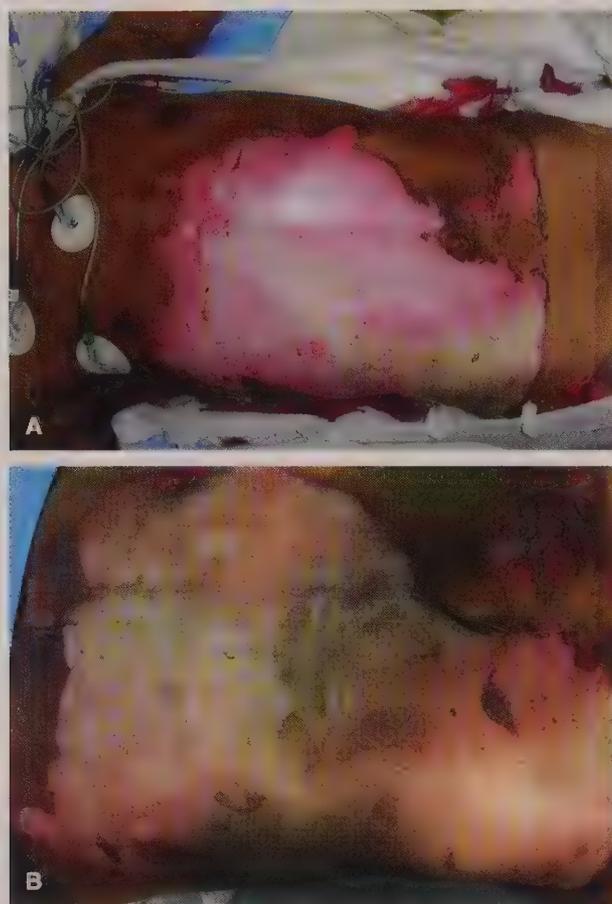

### Connection Check 51.3

The nurse correlates which zone of burn injury as the most susceptible to sustained injury because of insufficient fluid resuscitation?

- Zone of stasis
- Zone of conversion
- Zone of hyperemia
- Zone of coagulation

**FIGURE 51.9** Concentric zones of a burn injury. The zone of coagulation is the area that had the most contact with the heat source and is the location of the most severe damage. The zone of stasis immediately surrounds the zone of coagulation and is characterized by damaged cells and impaired circulation. The zone of hyperemia is the outermost area and is an area of increased blood flow in an effort to bring key nutrients for tissue recovery.

**FIGURE 51.10** Burn wound conversion. A, Chest and abdomen post-burn day 1. B, Chest and abdomen post-burn day 2.

### Functional Changes

The location of a burn injury plays an important part in determining the level of care required and in the functional changes that may result. According to the American Burn Association, referral criteria to a burn center involve injuries to specific areas of the body, including the face, hands, feet, genitalia, and perineum and burns over major joints. Burns

in these locations involve functional areas of the body and may require specialized and highly skilled interventions in order to restore optimal function. Without proper management by the interprofessional burn-care team, long-term morbidity may result from impaired function and altered appearance. Survivors of large burns often require multiple and sometimes lifelong plastic and reconstructive surgical procedures in order to maintain proper function and range of motion.

### Connection Check 51.4

The nurse recognizes that burns to which body areas meet the criteria for referral to a burn center because of the increased risk of functional changes? (*Select all that apply.*)

- A. Chest
- B. Perineum
- C. Elbows
- D. Face
- E. Hands

### SYSTEMIC EFFECTS OF MAJOR BURN INJURIES

Burns that are less than 20% TBSA produce a localized tissue response. Burns that are greater than 20% TBSA are considered major burn injuries and produce both localized and systemic responses. All body systems are affected by the release of cytokines and other mediators into the systemic circulation.

### Respiratory

Inhalation injuries, defined as the toxic effects of heat and the chemical products of combustion on the lungs and in the airways, are present in 10% to 20% of patients admitted to burn centers and significantly increase morbidity and mortality. In order to minimize complications and decrease

the overall mortality rate, rapid diagnosis and management of inhalation injuries are critical (Box 51.5). Recognizing an inhalation injury is particularly important because it has been recognized as the third most important factor, after extent/depth of burn and patient age, in determining mortality. Inhalation injuries should always be considered when the patient was injured or trapped within an enclosed space, such as in a house or car, or there are burn injuries of the face, neck, or chest.

There are three main types of airway inhalation injuries: inhalation injury above the glottis, inhalation injury below the glottis, and carbon monoxide poisoning. Inhalation burns are most commonly limited to the upper airway above the glottis (nasopharynx, oropharynx, and larynx) and are usually thermal or chemical in nature. Because of the protective response of the respiratory tract, the majority of heat absorption and tissue damage occurs above the glottis and vocal cords. These above-the-glottis burns are associated with injury to the nose, throat, and mouth, and because swelling can occur within minutes to hours of injury, emergent intubation may be required to maintain the airway. Inhalation injury below the glottis is almost always chemical in nature and is rarely caused by heated air alone. This type of severe inhalation injury is most common in patients with prolonged exposure to smoke, such as those rendered unconscious by fire. Wheezing and tracheobronchitis may be seen in the first minutes to several hours post-injury.

Most fatalities that occur at the scene of a fire are due to carbon monoxide poisoning. Because carbon monoxide binds to the hemoglobin molecule with an affinity 200 times greater than that of oxygen, tissue hypoxia results when carbon monoxide levels are above normal. In cases of suspected carbon monoxide poisoning, oxygen measurement by pulse oximeter is useless because the determination between the oxygen and carbon monoxide molecules saturating the hemoglobin is not possible. Normal carboxyhemoglobin levels are less than 2% but may be as high as 5% to 10% in heavy smokers. Although carbon monoxide may cause a cherry red discoloration of the skin in patients with carbon monoxide levels at 40% or higher, this manifestation

is seen only in approximately 50% of cases. More common clinical manifestations observed in patients with carbon monoxide poisoning include headache, confusion, nausea, dizziness, vomiting, and dyspnea. These clinical manifestations are usually seen when carbon monoxide levels reach approximately 30%. Table 51.2 provides a listing of clinical manifestations in relation to the percentage of carbon monoxide levels.

Patients with an inhalation injury may present with facial burns, singed nasal and facial hairs, carbon in their sputum, redness of the oral pharynx, inability to swallow, and tachypnea. The respiratory epithelium may be damaged as a result of inhaled gases and particulate matter. Mucus production and impaired ciliary function may result, which ultimately may lead to cell death and sloughing of the respiratory tract. Anxiety and agitation may ensue if the patient begins to experience respiratory distress. Clinical manifestations of respiratory distress may include stridor, progressive hoarseness, rales, rhonchi, and/or retractions of the lower rib cage. Endotracheal intubation should be considered if the patient presents with any of these clinical manifestations.

### Cardiovascular

Initially, the greatest threat to a patient with a major burn injury is **burn shock**, which is a combination of distributive and hypovolemic shock. This type of shock results secondary to a massive fluid shift. Electrolytes, water, plasma, and proteins leak out of the intravascular space and into the interstitial space because of the increase in capillary permeability, which results from the body's initial inflammatory protective mechanism. The large fluid loss within the intravascular space increases the viscosity of the blood, which results in sluggish blood flow, decreased oxygen delivery, and overall decreased cardiac output. Because of the increased viscosity of the blood, the patient initially presents with an elevated hematocrit.

Generally, fluid leakage occurs during the first 8 to 36 hours after the injury, with maximum shifting peaking at approximately 24 hours post-burn. If fluid resuscitation

### Box 51.5 Physical and Clinical Manifestations of an Inhalation Injury

- Facial burns
- Singed nasal and facial hairs
- Carbonaceous sputum (soot), hypersecretion
- Naso- or oropharynx erythema
- Excessive agitation/anxiety (hypoxia)
- Tachypnea, intercostal retractions, flaring nostrils
- Inability to swallow
- Hoarseness, grunting, brassy voice
- Rales, rhonchi, diminished breath sounds

**Table 51.2 Clinical Manifestations of Carbon Monoxide Poisoning**

Carbon Monoxide (%)	Clinical Manifestations
5–10	Mild headache and confusion
11–20	Severe headache, flushing, vision changes
21–30	Disorientation, nausea
31–40	Irritability, dizziness, vomiting
41–50	Tachypnea, tachycardia
Greater than 50	Coma, seizures, death

is not adequate, the burn patient begins to demonstrate clinical manifestations of shock, including hypotension, tachycardia, reduced urinary output, and altered mental status. Figure 51.11 provides an overview of the pathophysiological changes occurring during burn shock. If the state of shock continues to progress without proper fluid resuscitation and management, the patient will begin to decompensate, resulting in multisystem organ failure and potentially death.

In the post-burn shock phase, which begins approximately 24 to 48 hours after injury, the capillaries begin to regain integrity. Burn shock slowly begins to resolve, and the fluid gradually returns to the intravascular space. Urinary output continues to increase secondary to patient diuresis, and blood pressure and cardiac output begin to normalize.

### Fluid and Electrolytes

The two electrolytes of most concern during the burn shock phase are potassium and sodium. Initially, hyperkalemia may result because of the release of potassium from damaged cells into the vascular space. As fluid shifts continue, potassium and sodium begin to leak out of the intravascular spaces, and hypokalemia and hyponatremia may result.

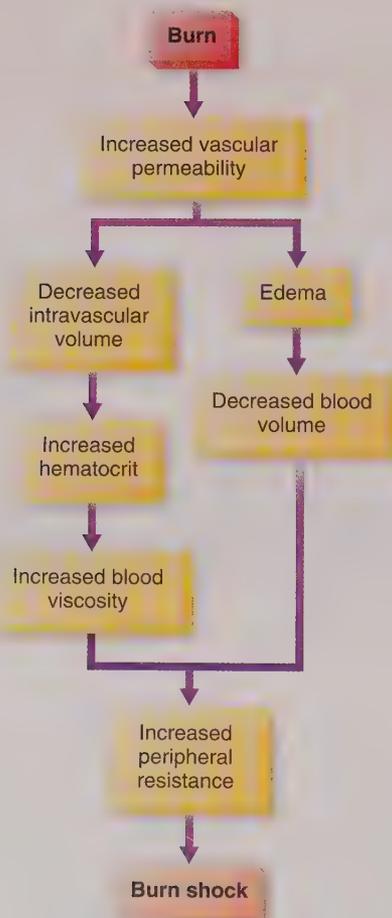

FIGURE 51.11 Pathophysiology of burn shock.

Although potassium and sodium are of utmost importance, all electrolytes are closely monitored, and replacement therapy is initiated as warranted. It is extremely important to account for evaporative fluid loss that may occur through the burn wound, as this amount may be as great as 5 L per day and continues until all wounds are closed.

### Renal

Because of the initial decrease in circulating blood volume, renal function may also be impaired secondary to decreased renal perfusion. Destruction of red blood cells results in free hemoglobin being released into the body following a major burn injury. If the patient has sustained muscle damage as a result of the burn injury, myoglobin may also be present in the bloodstream. When fluid resuscitation and resulting blood flow are inadequate, myoglobin and hemoglobin have the potential to occlude renal tubules, causing acute tubular necrosis. This is most commonly seen with electrical injuries.

### Gastrointestinal

The patient with a burn injury often has complications of the gastrointestinal system secondary to a decrease in both nutrient absorption and gastrointestinal motility. Paralytic ileus is not seen as frequently in the burn population because of the increased use of prokinetic agents and early initiation of enteral nutritional support. A nasogastric tube is placed in patients with large burns for both long-term feeding access and to relieve initial gastric distention, nausea, and vomiting. Patients with burns who have suffered a significant injury and require massive fluid resuscitation are at risk for developing abdominal compartment syndrome secondary to massive resuscitation volumes.

### Metabolic

A burn injury causes an array of physiological alterations within the body, placing the patient in a constant hypermetabolic state for up to 1 to 3 years post-injury. Burn injuries often double the normal resting energy expenditure and greatly increase the patient's caloric needs. Because the nutritional needs are constantly fluctuating for the patient with burn injuries, determining caloric needs is a dynamic and ongoing process. Factors affecting the metabolic rate in patients with burns include age, gender, infection, concomitant trauma, pain, surgery, sleep, and ambient temperature. Without additional nutritional support in patients with large burn injuries, particularly those with a burn greater than 20% TBSA, wound healing is impaired. Even patients who can feed themselves often require supplementary caloric support and/or enteral feeding because of their hypermetabolic state. Nutrition is so important that many burn centers continue to enterally feed patients up to and throughout their entire operative procedures (see Evidence-Based Practice: Impact of Enteral Feeding in Morbidity and Outcomes in Patients With Burns).

## Evidence-Based Practice

### Impact of Enteral Feeding in Morbidity and Outcomes in Patients With Burns

Due to the hypermetabolic state that develops in patients with severe burn injuries, there is increased focus on meeting the nutritional needs in this patient population. This study examined current evidence regarding whether early enteral nutrition impacts patient outcomes in patients with major burn injuries. Data sources included Medline, Embase, and the China National Knowledge Infrastructure throughout May 2018 and only included randomized controlled trials that reported patient outcomes. In total, 958 articles were reviewed, with seven randomized controlled trials enrolling 527 participating included in the final analysis. For purposes of this study, enteral nutrition was described as a standard formula starting within 24 hours of the burn injury or admission to the intensive care unit. The findings of the study supported previously reported improvements in clinical outcomes in those patients who received early enteral nutrition. Specific findings included preservation of gut integrity, fewer gastrointestinal hemorrhages, less infectious complications, and reductions in both organ failures and sepsis. Reduced lengths of hospital stays were also associated with early enteral nutrition in this patient population.

Pu, H., Doig, G. S., Heighes, P. T., & Allington, M. J. (2018). Early enteral nutrition reduces mortality and improves other key outcome in patients with major burn injury: A meta-analysis of randomized controlled studies. *Critical Care Medicine*, 46(12), 2036–2042.

Massive amounts of body heat may be lost through open wounds as a result of impaired thermoregulatory function. Once the patient loses skin, it is impossible for the body to successfully regulate temperature. Because of this, it is essential to maintain a high ambient temperature within the patient's room and within the operating room. This is particularly essential when the wounds are exposed. Many burn centers have specialized heating equipment to assist in patient warming (Fig. 51.12). This equipment may include heat shields located in the ceiling above the patient's bed that may be lowered, as well as additional space heaters that are often placed in the room. Many of the newer or newly remodeled burn centers now have radiant heat under the flooring and behind the walls in each patient room.

### Immunological

Patients with burn injuries are at high risk for infection and sepsis because of loss of the protective function of the skin, altered immunological defenses, and the presence of open

**FIGURE 51.12** Specialized heating equipment in the burn intensive care unit.

burn wounds. The loss of skin integrity is compounded by the release of abnormal inflammatory factors, which alter the patient's underlying metabolic profile. As a result of these alterations, patients with extensive burns develop systemic inflammatory response syndrome (SIRS). The term SIRS relates to the exaggerated inflammatory response that occurs in the body after injury and may precede the development of sepsis. All patients with extensive burns exhibit some form of SIRS regardless of whether or not sepsis ensues. Burn professionals demonstrate expertise in recognizing other factors that may indicate sepsis, such as a change in mental status, increased fluid requirements, decreased urine output, and a decline in respiratory function. (See Chapter 14 for more discussion of shock and sepsis.)

### Sepsis

The skin is the body's largest protection barrier, and once it is breached, the patient is continuously at risk for infection. If the patient survives the first 24 hours after the initial burn injury, sepsis is usually the leading cause of death (see Evidence-Based Practice: Infection and Sepsis in Patients With Burns). Current medical definitions regarding sepsis are not applicable in the burn population because many patients with burns may demonstrate all of the criteria of sepsis without actually having an infection and/or being septic.

## Evidence-Based Practice

### Infection and Sepsis in Patients With Burns

A panel of experts in burn care came together in 2007 to develop a consensus for definitions concerning infection and sepsis among burn patients. This definition is still relevant today. The panel defined sepsis in patients with burns as "a change in the burn patient that triggers the concern for infection."

The triggers include at least three of the following clinical manifestations:

- A. Temperature greater than 102.2°F (39°C)
- B. Progressive tachycardia and tachypnea
- C. Thrombocytopenia, low platelet count (does not apply until 3 days after resuscitation)
- D. Hyperglycemia
- E. Insulin resistance
- F. Enteral tube feed intolerance characterized by large amounts of residual tube feeding

In addition to these indicators, documented incidence of an infection or clinical response to antimicrobials is also required to make a definitive diagnosis of sepsis in the patient with burns.

Pu, H., Doig, G. S., Heighes, P. T., & Allington, M. J. (2018). Early enteral nutrition reduces mortality and improves other key outcomes in patients with major burn injury: A meta-analysis of randomized controlled studies. *Critical Care Medicine*, 46(12), 2036–2042.

Greenhalgh, D., Saffle, J., Holmes, J., Gamelli, R., Palmieri, T., Horton, J., ... Latenser, B. (2007). American Burn Association consensus conference to define sepsis and infection in burns. *Journal of Burn Care and Research*, 28(6), 776–790.

Infection control is a high priority when dealing with the patient who has suffered a burn injury. Approximately 28% to 65% of these patients die as a result of sepsis. The majority of burn centers employ multiple infection control strategies and techniques, including contact precautions for all patient interactions; disposable equipment, including blood pressure cuffs, stethoscopes, electrocardiogram (ECG) leads; and antibiotic-coated urinary and central line catheters. Although the prevention of infection in the patient with burns may be impossible, every method should be employed to reduce the overall risk.

## SPECIAL CONSIDERATIONS IN THE PATIENT WITH BURNS

### Inhalation Injuries

An inhalation injury can exist in the presence or absence of a cutaneous burn (Fig. 51.13). Regardless of the TBSA percentage burned, an inhalation injury increases the overall mortality rate because the patient often develops pneumonia or hypoxemia and requires lengthy ventilatory support. Although inhalation injuries can significantly increase morbidity and mortality, there are few standards for diagnosis, treatment, and the measurement of outcomes. Chest x-rays performed on admission are often normal in patients with an inhalation injury, and as a result, a fiberoptic bronchoscopy examination is recommended for definite diagnosis because this study can reveal damage to the respiratory tract and lungs that is not evident on chest x-ray. It is

**FIGURE 51.13** Inhalation injury characterized by edema around the nose and mouth with soot present in the nares. Endotracheal and nasogastric tubes in place.

important that patients are observed closely for approximately 24 hours post-burn injury because of the insidious onset of inhalation injuries.

Patients with burns rarely exhibit immediate signs of respiratory distress; therefore, it is essential to monitor for less obvious indicators of an inhalation injury, including a change in voice (such as hoarseness), anxiety, and/or confusion. It is also important to note whether the burn injury occurred outside or inside because confinement in a burning environment increases the risk of sustaining an inhalation injury. At any time that airway patency is questionable, early intubation is recommended. Delay may result in severe airway obstruction, at which time intubation may become extremely challenging and may require an emergent tracheostomy. As a result of upper airway edema, an endotracheal tube that becomes dislodged may be almost impossible to replace. It is essential to secure the patient's endotracheal tube with umbilical twill or commercially prepared endotracheal tube holders and not adhesive tape because tape does not stick to the burned face and does not allow for swelling. An emergency tracheostomy tray is maintained at these patients' bedsides in the event of unplanned extubation.

### Connection Check 51.5

The nurse correlates which clinical manifestations with the possibility of an inhalation injury? (Select all that apply.)

- A. Facial burns
- B. Singed nasal hairs
- C. Soot in the sputum
- D. Hoarseness
- E. Eschar

Because of the risk of carbon monoxide poisoning associated with inhalation injuries, treatment requires immediate application of 100% oxygen by mask, which is maintained

until carboxyhemoglobin levels are below 10%. The half-life of carbon monoxide in the blood is approximately 30 minutes to 1 hour on 100% oxygen as opposed to 4 hours on room air. Because the majority of patients with burns are placed on 100% oxygen at the scene, it is important to note that measurement of carbon monoxide levels may be a poor indicator of injury because the majority of the carbon monoxide may have been dissipated by the time the patient arrives at the hospital.

## Electrical Injuries

The American Burn Association describes electrical injuries as “the grand masquerader” because the extent of tissue damage is not always apparent on the surface of the skin. Burn healthcare professionals are making efforts to move away from the terms *entrance* and *exit points* because the two may be difficult to distinguish. Instead, the term *contact points* is used when describing electrical injuries (Fig. 51.14). The patient’s entire body is assessed for contact points, with close attention paid to the scalp because contact points may be hidden by the hair.

In addition to burn wound management, there are additional priorities to consider when caring for patients with electrical injuries. In 15% of patients experiencing electrical injuries, there is also associated physical trauma secondary to the patient falling or being thrown. Patients with electrical burns should be placed in a cervical collar until cervical spine films are cleared for possible injury. Other priorities when managing patients with electrical injuries include cardiac monitoring, fluid resuscitation, neurological assessment, renal management, and maintenance of peripheral circulation.

Continuous cardiac monitoring is recommended for at least 24 to 48 hours for patients presenting with a documented cardiac arrest or dysrhythmia and/or extremes in burn size and age. It is important to obtain a baseline ECG to track any cardiac abnormalities that may arise. Neurological assessments are completed on a regular basis to monitor for any changes in level of consciousness. Fluid

**FIGURE 51.14** Contact point associated with electrical injury.

resuscitation is calculated based on the TBSA of the burns. However, it is important to remember that this calculation is just a starting point for fluid resuscitation because there may be extensive damage to internal structures underneath the skin’s surface that are not obvious with external assessment. Urine output is closely monitored for signs of **myoglobinuria**, which indicates muscle damage and manifests as red or tea-colored urine. If myoglobin is suspected, a urinalysis is performed. Myoglobin can occlude renal tubules and cause acute tubular necrosis; thus, it is important to maintain a urine output of 1 mL/kg/hr for patients with electrical injuries.

## Chemical Injuries

Early recognition and immediate initiation of continuous irrigation to the affected area is crucial when dealing with chemical burns (Fig. 51.15). The three most common classes of chemicals that cause burn injuries are acids, alkalis, and organic compounds. It is important to note that alkali burns tend to penetrate deeper, causing liquefaction necrosis of the underlying tissue requiring a lengthy irrigation period. Organic compounds, such as gasoline, are also of importance because of their ability to systemically absorb into the body, causing renal and hepatic damage. Tar and asphalt burns are also common injuries but are thermal and not chemical in nature and require immediate cooling rather than removal. Refer to Table 51.3 for additional information on each chemical classification.

**FIGURE 51.15** Chemical injury to the back.

**Table 51.3 Mechanisms of Action of Chemical Burn Injuries**

Acids	Alkalis	Organic Compounds
Protein donor that releases hydrogen ions and can reduce pH to values as low as 0; results in coagulation of proteins and possible full-thickness injury	Protein acceptor that strips hydrogen ions from protonated amine and carboxylic groups. This increases pH values above neutrality and may cause liquefaction necrosis. This allows for deeper tissue penetration and often results in full-thickness injury.	Act by dissolving the lipid membrane of cells and disrupting the protein structure of the cell, which may result in full-thickness injury. This also allows for systemic absorption, which may lead to hepatic and renal damage.
Examples: bathroom cleaners, drain cleaners, rust removers, glass etching, home swimming pools	Examples: oven cleaners, drain cleaners, wet cement, fertilizers, heavy industrial cleaners	Examples: phenols, creosote, and petroleum products (gasoline)

The use of personal protective equipment by all healthcare team members is crucial when managing suspected chemical injuries to ensure that no one else is injured or affected by the chemical. Initial treatment of chemical burns involves the removal of saturated clothing, brushing off the skin if the agent is in powder form, and continuous irrigation with copious amounts of water. The use of a neutralizing agent is usually not recommended because of the exothermic (heat-producing) reaction that occurs. Irrigation continues until the patient reports a decrease in pain, the patient's temperature can no longer tolerate further irrigation, or the patient is transferred to a burn center. Chemical injuries to the eyes are flushed continuously until an ophthalmologist can complete a full examination.

**Safety Alert** Protect yourself! It is imperative that healthcare workers ensure that the scene is safe and protect themselves using the appropriate personal protective equipment when a chemical injury is suspected.

### Escharotomies and Fasciotomies

Any circumferential burn to an extremity is at risk for developing **compartment syndrome**. As fluid seeps from the intravascular spaces into the interstitium, pressure within the tissues continues to rise and confines swelling inside muscle compartments, resulting in compartment syndrome. Involved extremities are elevated, and pulses in both burned and unburned extremities are assessed and compared on an hourly basis. Clinical manifestations of compartment syndrome include progressive diminishing of the pulse, numbness, tingling, and complaint of pain with flexion and/or extension. This pain is often not proportional to the extent of the injury and is unrelenting despite appropriate administration of pain medication. Compartment syndrome is a medical emergency and requires immediate surgical intervention in order to salvage the limb.

In full-thickness burns, eschar acts as a tourniquet, and as fluid resuscitation continues, vascular compromise may result. Pulses are monitored on an hourly basis in all affected extremities. In some patients, if it is difficult to palpate pulses, a Doppler may be required to assess peripheral circulation. Other assessments include skin color, temperature, sensation, and capillary refill. It is imperative that the nurse monitor for progressive diminution of pulses and report these data to the healthcare provider rather than waiting until pulses are completely absent. An **escharotomy** (surgical incision through eschar) is performed to relieve the pressure (Fig. 51.16) and should extend only through the eschar and into the immediate subcutaneous fat. This procedure may be performed at the bedside using a scalpel or an electrocautery device. In circumferential burns to the chest, pulmonary function may be restricted because of the inability of the chest wall to expand with ventilation. The chest wall escharotomy (Fig. 51.17) is considered a medical emergency and in rare instances may be performed by scene first responders after consultation with a burn center. See Figure 51.18 for common escharotomy sites.

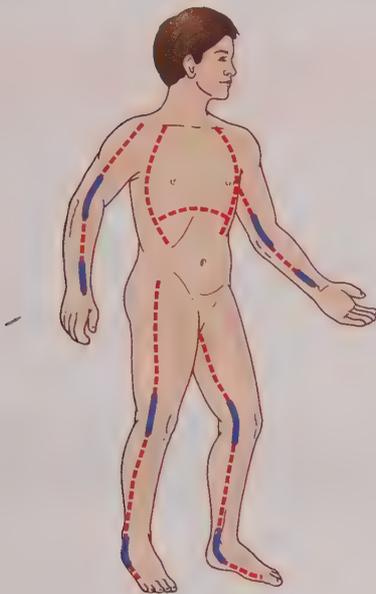

A **fasciotomy** is performed when the burn extends into the muscle and is more commonly seen in patients who have sustained an electrical injury and have developed

**FIGURE 51.16** Upper extremity escharotomy.

**FIGURE 51.17** Chest wall escharotomy.

**FIGURE 51.18** Preferred escharotomy sites. Patient should be placed in anatomical position (palmar surface up), and mid-medial and mid-lateral incisions are made for each extremity, extending the length and depth of the eschar only. The chest wall should have an H-type pattern, with all efforts to avoid the axilla because it contains many lymph nodes, vessels, and nerves. The connecting horizontal line should be placed roughly at the patient's diaphragm.

**compartment syndrome.** A fasciotomy is an incision that extends through the subcutaneous fat and muscle fascia, allowing for expansion of the muscle compartment. Fasciotomies are done by the provider under sterile conditions in the operating room.

## MANAGEMENT OF BURN INJURIES

Although other areas of medicine are traditionally delineated into separate medical and nursing tasks and priorities, burn care is an exception. Burn treatment is based on an interprofessional team approach including physicians, registered nurses, advanced practice registered nurses, physician assistants, wound-care technicians, intensivists, clergy, environmental

services, physical therapists, occupational therapists, clinical nutritionists, social workers, case management, psychologists, psychiatrists, respiratory therapists, research coordinators, community outreach educators, child life specialists, and outpatient management services. The primary goal of this extensive team is to return the whole patient to his or her highest level of function, including the physical, psychological, social, and vocational aspects of his or her life. Members of the interprofessional burn team work closely together to ensure an optimal outcome during the emergent phase by focusing on the following priorities. Burn management has traditionally been organized into three phases: the emergent (resuscitative) phase, the intermediate phase, and the rehabilitative phase. Care among the phases is not static, and the nursing and medical priorities in each phase may overlap. Although the rehabilitative phase is listed last, planning for rehabilitation and functional outcome starts immediately upon admission.

### Emergent Phase

#### Medical Management

Although the emergent phase does not officially begin until the patient reaches the hospital, it is vital that basic burn care be initiated at the scene. The initial priorities for emergency personnel on scene include stopping the burn process, airway management, fluid resuscitation, and prevention of hypothermia. Although the receiving registered nurse is given a comprehensive patient report, it is essential that two key pieces of information are provided in the handoff: the circumstances surrounding the injury and the total amount of fluid the patient received during transport. Primary and secondary survey recommendations in the emergent phase are outlined in Box 51.6.

During the emergent phase, the primary goal is to resolve immediate life-threatening issues resulting from the burn injury. These priorities include baseline diagnostic evaluation, airway management, fluid resuscitation, pain management, prevention of hypothermia, and initiation of wound care.

#### Diagnostic Studies

To determine the patient's baseline condition and identify pre-existing illnesses, basic laboratory studies and radiographical examinations are necessary for all patients with burn injuries. Specific diagnostic studies include complete blood count (CBC), serum glucose, creatinine, blood urea nitrogen (BUN), prothrombin time/activated partial thromboplastin time (PT/aPTT), international normalized ratio (INR), complete metabolic panel (CMP), arterial blood gases (ABGs), ECG, chest x-ray, and a toxicology screen. A serum carboxyhemoglobin level is obtained on all patients with suspected inhalation injuries, and bronchoscopy is indicated for a definitive diagnosis. For electrical injuries, it is important to obtain a baseline ECG and troponin and creatine kinase-MB (CK-MB) levels. Patients with concomitant trauma require additional diagnostic and

## Box 51.6 Primary and Secondary Survey of the Burn Patient in the Emergent Phase

### Primary Survey Assessment Includes:

#### Airway and C-spine stabilization

- Maintain a patent airway (may require intubation).
- Consider cervical spine immobilization if warranted.

#### Breathing

- Provide high-flow 100% oxygen by mask.

#### Circulation

- Elevate extremities (*no* pillow under head).
- Remove tight jewelry or clothing.
- Neurovascular checks with circumferential burns and electrical burns to extremities

#### Disability

- Neurological examination

#### Expose and examine

- Extent and depth of burn wounds and possible associated trauma

#### Fluid resuscitation

- Insert a minimum of two large-bore peripheral IV lines and start Lactated Ringer's.

### Secondary Survey Assessment Includes:

- Circumstances of the injury
  - Cause of burn injury?
  - Exact time of burn injury?
  - Enclosed space?
  - Associated trauma (electrical)?
  - Length of time before rescue?
  - Chemicals involved?
  - Use of accelerant?
- Medical history, current medications, allergies, and vaccinations
- Last food and fluid intake documentation
- Complete "head-to-toe" physical examination
- Determine the extent and depth of burn injury (calculate TBSA percentage)
- Cover the wounds with a clean, dry sheet
- Maintain core body temperature
- Pain medication, IV narcotics preferred
- Tetanus status (considered current if received within the previous 5 years)
- Initial laboratory values/tests: CBC, CMP, PT/aPTT, urinalysis, surveillance cultures
  - ABG and carboxyhemoglobin level for suspected inhalation injury
  - 12-Lead ECG and CK-MB/troponin for electrical injury
- Fluid resuscitation calculation and IV fluid rate adjustment

It is important to note that burn wound care does not begin until the patient is stabilized. The immediate concern is for airway, breathing, and circulation, followed by fluid resuscitation and prevention of hypothermia.

radiographical examinations. Common laboratory findings and electrolyte changes are displayed in Table 51.4.

### Airway Maintenance

The assessment of the patient's airway takes top priority. A nonrebreather mask is placed on all patients with burn injuries, and 100% oxygen is administered. Patients at risk for intubation include those with facial burns, changes in voice (such as hoarseness), carbon noted in the sputum, and with injury associated with a fire in an enclosed space. If intubation is warranted, the most experienced person performs the procedure, and special care is taken to secure the endotracheal tube, especially if facial burns are present. It is essential to secure the patient's endotracheal tube with umbilical twill or commercially prepared endotracheal tube holders and not adhesive tape because tape does not stick to the burned face and does not allow for swelling.

### Fluid Resuscitation

Fluid resuscitation is crucial to the survival of the patient who has suffered a burn of 20% TBSA or greater. The overall objective is to maintain tissue perfusion and organ function while at the same time avoiding potential complications of inadequate or excessive fluid resuscitation. It is important to note that insufficient fluid resuscitation can lead to organ failure and death, and excessive amounts of fluid can also cause morbidity and mortality. Intravenous resuscitation is initiated in adults at 20% TBSA, and if

**Table 51.4 Fluid and Electrolyte Changes in the Emergent Phase**

Clinical Findings	Explanation
<b>Generalized dehydration</b>	Plasma leaks through damaged capillaries (third spacing) and into interstitial spaces.
<b>Reduction in blood volume</b>	Secondary to third spacing, blood pressure falls, and cardiac output is diminished.
<b>Decreased urinary output</b>	Secondary to fluid loss and decreased renal blood flow
<b>Hyperkalemia</b>	Massive cellular trauma causes the release of potassium into extracellular fluid.
<b>Hyponatremia</b>	Large amounts of sodium are lost to third spacing, wound drainage, and shifting into cells as potassium is released.
<b>Metabolic acidosis</b>	Loss of bicarbonate ions accompanies the loss of sodium.
<b>Elevated hematocrit</b>	Plasma is lost to extravascular spaces, leaving the remaining blood very viscous.

ABG, arterial blood gas; CBC, complete blood count; CMP, complete metabolic panel; CK-MB, creatine kinase-MB; ECG, electrocardiogram; PT/aPTT, prothrombin time/activated partial thromboplastin time; TBSA, total body surface area.

possible, it is recommended to consult with a burn center prior to the initiation of resuscitation. The fluid of choice for resuscitation is lactated Ringer's. Intravenous access is essential and should be obtained as soon as possible. Ideally, two large-bore, preferably No. 20 gauge or larger, peripheral IV catheters are placed through unburned skin. However, if no such areas exist, the IV lines can be inserted through burned tissue but must be well secured. If obtaining a peripheral IV catheter is extremely difficult, an intraosseous line is also acceptable. Major burn injuries often require the placement of a central venous catheter because of the large volumes of fluid that need to be administered during the emergent phase.

There are numerous resuscitation calculations and/or formulas available for burn resuscitation; however, most burn centers throughout the United States follow Advanced Burn Life Support (ABLS) guidelines. These guidelines are based on the patient's age, weight in kilograms (kg), %TBSA burned, and whether electrical injury was involved. The guidelines require 2 to 4 mL of lactated Ringer's per kilogram of body weight multiplied by %TBSA burned. Half of the total volume is given in the first 8 hours post-burn, and the remaining half is given over the next 16 hours. It is important to note that the resuscitation begins from the time the burn injury occurred. For example, if emergency services personnel (EMS) were unable to obtain an IV line on the scene and the patient arrives at the emergency department 2 hours post-injury, fluid volume should be adjusted, and the initial 8-hour volume now must be infused over 6 hours. For adults and children age 15 or greater, fluid resuscitation should be initiated at 2 mL per kilogram; for children age 14 or younger, including infants, resuscitation should be initiated at 3 mL per kilogram; and for electrical injuries in *all* ages, resuscitation should be initiated at 4 mL per kilogram. An example calculation of the fluid-resuscitation formula is provided in Box 51.7. Some providers choose to introduce the use of colloids prior to the 24-hour

resuscitation mark or after the 24-hour mark. This decision is often based on patient response to resuscitation and laboratory values. Examples of colloids given include albumin or plasma.

During fluid resuscitation, an indwelling urinary drainage catheter is placed in the bladder to closely monitor urine output because this is the most reliable indicator of adequate fluid resuscitation. Urine output should be maintained at 0.5 mL/kg/hr. If myoglobin is present in the urine, output should be maintained at 1 mL/kg/hr until clearing of the urine occurs to prevent the development of acute renal failure. Diuretics are not indicated during the emergent phase, and if urine output drops, the rate of fluid administration is increased. Other parameters that are monitored (as listed in Table 51.5) during fluid resuscitation include heart rate, blood pressure, central venous pressure, serum chemistries, hemoglobin, and hematocrit.

The calculated fluid volume is the starting point in the fluctuating fluid-resuscitation process. Patients with inhalation injuries, electrical injuries, associated trauma, and/or alcohol and drug dependencies may require higher volumes of fluids related to pre-existing medical conditions or poor health. If there is a delay in starting fluid resuscitation, patients usually require higher volumes of fluid. It is also important to note that some patient populations, such as older adults, children, and those with pre-existing cardiac disease, may be very sensitive to fluid and should be closely monitored for signs of fluid volume overload. Inadequate fluid resuscitation, which results in inadequate blood flow, may also result in conversion of the burn wound within the first 24 to 72 hours, as shown in Figure 51.10.

### Box 51.7 Fluid-Resuscitation Example

Patient weight: 70 kg  
TBSA burned: 50% flame burn

The patient is a young healthy adult with no pertinent past medical history.

#### Resuscitation Calculation:

$4 \times \text{mL} \times 70 \times 50 = 7,000 \text{ mL}$  of lactated Ringer's in the first 24 hours

First 8 hours: 3,500 mL, rate = 438 mL/hr

Calculate from time of injury.

Next 16 hours: 3,500 mL, rate = 218 mL/hr

TBSA, Total body surface area.

**Table 51.5 Indications of Adequate Fluid Resuscitation**

<b>Urine output</b>	0.5 mL/kg/hr 1 mL/kg/hr if myoglobin present
<b>Systolic blood pressure</b>	Greater than 100 mm Hg
<b>Heart rate</b>	Less than 120 bpm
<b>Central venous pressure (CVP)</b>	5–10 mm Hg
<b>Pulmonary</b>	Lungs sound clear, blood pH within normal range (7.35–7.45)
<b>Gastrointestinal</b>	Abdomen soft, non-tender; no nausea, vomiting, or ileus; bladder pressure less than 10 mm Hg
<b>Level of consciousness</b>	Clear; alert; and oriented to person, place, and time (keep in mind any narcotics that may have been administered for pain)

**Connection Check 51.6**

Using the resuscitation guidelines, the nurse determines that a patient requires a total of 12 L of fluid in the first 24 hours post-injury. How much of the total volume needs to be given within the first 8 hours?

- A. 4,000 mL lactated Ringer's
- B. 6,000 mL lactated Ringer's
- C. 8,000 mL lactated Ringer's
- D. 10,000 mL lactated Ringer's

**Connection Check 51.7**

When hemodynamic status is monitored in a patient with a burn injury, what amount of urine output indicates adequate fluid resuscitation?

- A. 0.5 mL/kg/hr
- B. 1 mL/kg/hr
- C. 2 mL/kg/hr
- D. 3 mL/kg/hr

**Prevention of Hypothermia**

Hypothermia is commonly seen in patients with burns because the skin, their primary insulation, is no longer intact. It is imperative to keep the patient covered at all times and to closely monitor his or her temperature, especially in the emergency department, where patients are typically exposed for assessments. The ambient room temperature is usually increased to decrease heat loss in patients with significant burn injuries.

**Wound Care**

Typically, the burn wound is not the first priority during the emergent resuscitative phase because more life-threatening issues often take precedence. Although the burn wound is covered with clean, dry blankets to prevent hypothermia, the initiation of wound care may be delayed for several hours until the patient is stabilized because there are more life-threatening concerns for the patient at this point.

**Pain Management**

A burn is one of the most painful injuries an individual can sustain. Intravenous narcotics, such as morphine sulfate (morphine), are used for the initial management of pain. The intramuscular route of administration is avoided because there may be impaired medication absorption due to an edema formation and decreased peripheral perfusion. Pain medication is administered intravenously in doses no larger than those needed to manage pain. The nurse monitors closely for signs of respiratory depression when giving large doses of pain medication. Although morphine sulfate (morphine) is commonly used, other types of narcotics may also be used, including fentanyl (Sublimaze) and hydromorphone (Dilaudid).

**Connection Check 51.8**

The nurse recognizes which diagnostic test as most sensitive in a patient with a suspected electrical burn injury?

- A. Arterial blood gas
- B. CK-MB levels
- C. Echocardiogram
- D. Serum carboxyhemoglobin

**Connection Check 51.9**

Which intervention is the priority for the patient during the emergent phase of burn management?

- A. Application of silver sulfadiazine cream
- B. Use of clean, dry sheets and warm blankets
- C. Initiation of wet normal saline dressings
- D. Maintaining the injured area open to air

**Medications**

In addition to pain management, patients with burn injuries are given a variety of other pharmacological therapies. Medications are given to treat common concerns or potential complications facing the burn patient, including anticoagulation therapy, nutritional support, gastrointestinal motility, anxiety, and depression. See Table 51.6 for a listing of medications commonly used in patients with burn injuries.

**Nursing Management****Assessment and Analysis**

During the emergent phase, the priority assessments focus on immediate life-threatening injuries, including airway management, particularly with suspected inhalation injury; fluid volume status; temperature control; and pain management. Clinical manifestations during this phase may include:

- Facial burns
- Naso- or oropharynx erythema
- Hoarseness, grunting
- Carbonaceous (soot) sputum
- Dyspnea
- Wheezing
- Tachypnea
- Intercoastal retractions and flaring nostrils
- Elevated carboxyhemoglobin levels
- Tachycardia
- Hypotension
- Confusion, agitation, changes in level of consciousness
- Decreased urine output
- Hypothermia
- Headache
- Complaints of pain

**Nursing Diagnoses**

- **Ineffective airway clearance** related to airway edema secondary to injury from heat and/or chemicals

**Table 51.6 Medications in Burn Care**

<b>Medication Type and Name</b>	<b>Medication Purpose</b>
<b>Analgnesia</b>	Pain management
Morphine sulfate (morphine)	
Hydromorphone (Dilaudid)	
Fentanyl (Sublimaze)	
Ketamine (Ketalar)	
Oxycodone (OxyContin, Tylox)	
Methadone (Dolophine)	
Nonsteroidal anti-inflammatory medications (ibuprofen or naproxen sodium)	
<b>Sedation</b>	Induce sedation and decrease anxiety
Haloperidol (Haldol)	Antipsychotic and sedative effects
Lorazepam (Ativan)	Helps reduce anxiety
Diazepam (Valium)	Helps reduce anxiety and treat alcohol withdrawal
Midazolam (Versed)	Short-acting amnesic effects
Propofol (Diprivan)	Short-acting hypnotic agent
Dexmedetomidine hydrochloride (Precedex)	Initial sedation in mechanically ventilated patients
<b>Anticoagulation Therapy</b>	Both promote venous return and decrease risk for thromboembolism
Enoxaparin (Lovenox)	
Heparin	
<b>Nutritional Support</b>	Provide essential nutrients
Multivitamins	Promote wound healing
Zinc sulfate (zinc) and ferrous sulfate (iron)	Promote hemoglobin formation and cell integrity
Oxandrolone (Oxandrin)	Preservation of lean body mass and promotion of weight gain
<b>Gastrointestinal Support</b>	Promote gastrointestinal function
Ranitidine (Zantac)	Decreases stomach acid and risk of ulceration
Esomeprazole (Nexium)	Decreases stomach acid and risk of ulceration
Pantoprazole (Protonix)	Decreases stomach acid and risk of ulceration
Aluminum/Magnesium antacid (Mylanta, Maalox)	Neutralizes stomach acid
Nystatin (Mycostatin)	Prevents overgrowth of yeast in oral mucosa
Metoclopramide (Reglan)	Promotes stomach emptying and decreases nausea
Polyethylene glycol 3350 (MiraLAX) Docusate sodium (Senokot)	Laxative agents for use in constipation

- **Impaired gas exchange** related to carbon monoxide poisoning, smoke inhalation, and upper or lower airway obstruction
- **Risk for fluid volume deficit** related to hypovolemia due to third spacing of fluids and inadequate fluid resuscitation
- **Altered tissue perfusion** related to decreased cardiac output
- **Risk for hypothermia** due to altered skin integrity
- **Risk for infection** due to loss of skin's protection and the burn injury

- **Acute pain** secondary to the burn injury
- **Anxiety** related to fear surrounding the burn injury

## Nursing Interventions

### ■ Assessments

- **Breath sounds, respiratory rate, and indicators of inhalation injury**  
*Edema and irritation of the airway may develop secondary to damage caused by heat and chemical irritants as evidenced by hypoxemia, rhonchi, stridor, change in voice (hoarseness), and/or dyspnea. Inhalation injuries may impair respiratory function, leading to decreased ventilation and changes in rate and effort, resulting in lower oxygenation.*
- **Oxygen saturation, ABGs, and carboxyhemoglobin levels**  
*The oxygen molecules may be saturated by carbon monoxide instead of oxygen, which is evident only through measurement of carboxyhemoglobin levels. Carbon monoxide binds to the hemoglobin molecule with an affinity 200 times greater than that of oxygen; tissue hypoxia results when carbon monoxide levels are above normal. Results of ABGs also provide information related to the acid-base status of the patient.*
- **Face and neck for burns, singed nasal and/or facial hair, and singed eyebrows/eyelashes**  
*Edema and irritation of the airway may develop secondary to damage caused by heat and chemical irritants as evidenced by hypoxemia, rhonchi, stridor, change in voice (hoarseness), and/or dyspnea.*
- **Upper airway**  
*Damage and irritation caused by the heat and chemical irritants in smoke may cause the airway to appear red and edematous. The mouth and/or airway may also appear black because of soot.*
- **Changes in voice, hoarseness, and swallowing difficulty**  
*Damage for the heat and chemical irritants in smoke may cause edema and irritation, resulting in changes in the voice, hoarseness, and/or difficulty swallowing.*
- **Vital signs**  
*Blood pressure may be low and pulse elevated secondary to potential hypovolemia due to significant fluid losses and shifts. The pulse may also be elevated secondary to increased work of breathing with inhalation injuries, pain, and fear/anxiety. Because of impaired skin integrity, temperature may be decreased. Patient shivering further accelerates the patient's metabolic rate and may exacerbate tachycardia.*
- **Urine output**  
*Indicators of inadequate resuscitation and development of hypovolemia may be evidenced by urine output less than 0.5 mL/kg/hr.*
- **Pain**  
*Pain will be noted in areas of partial-thickness burns because nerve endings are exposed.*
- **Anxiety**  
*Patient anxiety levels may be high because of the appearance of the burn wound and exposure to trauma.*

- **Burn wound size and depth**  
*Although wound treatment is not a priority in this phase, estimations of %TBSA burned and wound depth are required to determine fluid resuscitation.*

### ■ Actions

- **Place patient on 100% humidified oxygen or assist with intubation if necessary.**  
*Immediate intervention is necessary for respiratory distress and to provide humidified oxygen and assist in the clearing of carbon monoxide. The half-life of carbon monoxide while on 100% oxygen is 30 minutes to 1 hour compared with 4 hours breathing room air.*
- **Trend ABG values and carboxyhemoglobin levels.**  
*Increasing PaCO<sub>2</sub> and decreasing PaO<sub>2</sub> and oxygen saturation may indicate the need for intubation. As carboxyhemoglobin levels lower, weaning of oxygen support (FiO<sub>2</sub>) to a minimal level to sustain oxygenation is indicated.*
- **Elevate the head of the bed to allow for better oxygenation.**  
*Raising the head of the bed decreases the work of breathing by lowering the diaphragm.*
- **Maintain emergency airway (intubation and tracheostomy) trays at the bedside.**  
*Inflammation and edema secondary to airway injury may make endotracheal intubation difficult or impossible. In patients with an endotracheal tube in place, a tracheostomy tray should be maintained at the bedside in the event of an unplanned extubation.*
- **Assist with intubation as necessary.**  
*Delaying intubation may result in edema and possible airway obstruction.*
- **Ensure securement of the endotracheal tube if the patient is intubated.**  
*If the tube is dislodged, it may be impossible to reinsert due to the edema. In addition, the securement device will require adjustment (e.g., twill) as the edema continues to worsen/decrease.*
- **Monitor mechanically ventilated patients closely for signs of respiratory compromise.**  
*Close monitoring of mechanically ventilated patients allows for early detection of respiratory distress.*
- **Place two large-bore IV catheters and begin fluid resuscitation with lactated Ringer's.**  
*Adequate fluids are necessary to prevent hypovolemic shock from developing as a result of massive fluid loss and fluid shifts. Lactated Ringer's is an isotonic fluid that supports intravascular volume.*
- **Roughly estimate the %TBSA burned and patient weight in kilograms.**  
*A quick estimation of the %TBSA burned and patient weight guides the determination of fluid to be administered in the first 24 hours on the basis of the resuscitation formula.*
- **Cover wounds with a clean, dry sheet.**  
*Minimizes evaporative heat loss and decreases the risk of hypothermia.*

- Institute warming measures in the form of blankets or other external heat sources.  
*Minimizes evaporative heat loss and prevents the development of hypothermia*
- **Teaching**
  - Immediately report difficulty breathing and/or swallowing.  
*Respiratory distress may develop quickly or may be delayed in patients with an inhalation injury.*
  - Instruct patient to cough and deep breathe every hour.  
*Assists in clearing airway and mobilizing secretions*
  - Signs of inhalation injury  
*Because the signs of inhalation injury may be insidious, it is important that the patient and family be able to recognize early signs of compromised airway and breathing difficulties.*
  - Explain all procedures to the patient and family in clear and simple terms.  
*Understanding helps alleviate fear and anxiety in the patient, which may result in tachycardia and hypertension.*
  - Importance of maintaining a warm environment  
*Decreases risk of heat loss and development of hypothermia*
  - Risk factors that increase chances of infection  
*Because of loss of skin integrity, the patient is at increased risk of infection, so family members must follow instructions regarding gloves, gowns, and hand washing.*

## Evaluating Care Outcomes

At the end of the emergent phase, the anticipated outcomes include the absence of respiratory distress, appropriate fluid resuscitation manifested by stable vital signs and adequate urine output, temperature regulation, and effective pain management. In the event of inhalation injuries, stabilization of the airway and sufficient oxygenation are positive outcomes during this emergent phase. The nurse anticipates adequate urine output with an expected outcome of 0.5 mL/kg/hr, with the recognition that any decrease in urine output below the recommended level must be immediately reported to the provider. Because patients with burns lose the ability to effectively manage their temperature, the nurse anticipates normothermia with appropriate interventions. Adequate pain management and lessened anxiety are also expected outcomes of management during the emergent phase.

## Intermediate Phase

### Medical Management

The burn patient enters into the intermediate phase after resuscitation and stabilization have been achieved. This phase usually begins 48 to 72 hours after the initial burn injury. Within the intermediate phase, the management priorities shift to wound healing and closure, pain management, ensuring optimal nutrition, and continued prevention of infection. Although the focus moves away from the life-threatening priorities of the emergent phase, continued assessment and management of respiratory and

circulatory status are essential during the intermediate phase.

## Wound Care

### Hydrotherapy

Wound-healing practices vary greatly among facilities and burn centers. **Hydrotherapy** is the favored cleansing method within most burn centers because it allows for thorough wound cleansing and uses water during dressing changes to assist in the removal of residual topical agents and necrotic tissue. In the past, hydrotherapy involved total immersion into a tank or tub of water. More recently, burn centers have begun using portable shower trolleys covered with disposable plastic liners to help prevent the spread of infection and cross-contamination. For patients who cannot tolerate extensive hydrotherapy, burn wound care may be done at the bedside.

### Clean Technique and Infection Control

It is important to note that burn wound care is a clean, not a sterile, procedure. Sterile technique involves employing techniques to reduce exposure to microorganisms, such as using a sterile field and sterile instruments and gloves. Clean technique involves using techniques to reduce the overall number of microorganisms, such as preparing a clean field and using clean gloves and instruments. Burn wound care is extensive, physically exhausting, and time-consuming, with some dressing changes lasting up to 2 to 4 hours. Often, these dressing changes occur in patient rooms where the temperature is usually set as high as 90°F (32.2°C) to prevent the risk of hypothermia.

During every dressing change, it is essential that both the nurse and physician assess the burn wound for progression of healing and evidence of infection. The dressing change is also the ideal time for the physical and occupational therapists to assess the wound, as well as to observe the patient's function and range of motion.

### Topical Medicines and Wound Dressings

There are numerous variations of topical medications and wound dressings that are used on burn wounds. The choice of the agent and dressing depends on wound depth, location of the injury, presence of infection, and provider preference. The most commonly used topical medications and dressings for wound management are outlined in Table 51.7, and a common application is displayed in Figure 51.19. Special care is taken when wrapping fingers and toes because they must be dressed individually to prevent *webbing* (the growing together of the skin between the fingers and toes) and maintain full range of motion (Fig. 51.20).

### Mechanical and Enzymatic Debridement

The preferred method of wound cleansing involves the use of a mild soap or chlorhexidine and water along with gentle debridement of the burn wound (Fig. 51.21). The three kinds of debridement are mechanical, enzymatic, and surgical. While cleansing, removal of the loose tissue is important to allow for proper visualization of the burn wound and is

**Table 51.7 Topical Medications and Wound Dressings**

<b>Antimicrobial Agent</b>	<b>Effective Against</b>	<b>Wound Indication</b>	<b>Application</b>	<b>Benefits</b>	<b>Disadvantages</b>	<b>Nursing Considerations</b>
<b>Silver sulfadiazine</b> (Silvadene)	Broad-spectrum and <i>Candida</i> coverage	Partial- and full-thickness burn wounds	1/4-in.-thick application with roll gauze to cover; dressing changes every 12 hours	Cooling effect when applied; easy, painless application	May cause transient leukopenia; may also cause a wound film on partial-thickness burns, making it hard to assess healing	Avoid in patients with a documented sulfa allergy. Avoid application to face.
<b>Bacitracin</b>	No gram-negative or fungal coverage	Partial-thickness burn wounds and grafts	Thin layer applied with a nonadherent gauze and an outer roll gauze; dressing changes every 24 hours	Easy, painless application; only once-per-day dressing change	Not as effective on full-thickness burn wounds because of minimal penetration of eschar	Best choice for use on a face, but left open to air. Use bacitracin ophthalmic ointment near and around eyes.
<b>Mafenide acetate 10% cream or 5% solution</b> (Sulfamylon Cream or Slurry)	Broad-spectrum, effective against <i>Pseudomonas</i> but has little anti-fungal coverage	Cream used on full-thickness burns to ears only; solution used on partial-thickness burn wounds and grafts	Cream is applied 1/16 in. thick and left open to air. Solution is applied to nonadherent gauze and roll gauze. Cream is changed every 12 hours; solution dressings are changed every 24 hours and may be wet down at 12 hours.	Cream penetrates eschar. Solution is only a once-per-day dressing change.	Solution is a wet-type dressing and may not be used on initial large burn wounds because it may cause hypothermia.	Some patients may complain of stinging upon application to partial-thickness burn wounds. Frequent sensitivities noted.
<b>Silver sheeting products</b> (Acticoat, Silverlon, Mepilex)	Broad-spectrum, effective against MRSA and fungus	Partial-thickness burn wounds, Stevens-Johnson syndrome (SJS), and patients with toxic	Some products are a wet application with sterile water and roll gauze. Dressing changes every	Dressing needs to be changed only every 4–7 days.	Expensive. Burn wounds often need to be observed daily. Solution is a wet-type dressing and may not be used on initial large burn	This is best used in the patient with SJS/TEN as the dressing change process is extremely painful and wounds do not need to be

Table 51.7 Topical Medications and Wound Dressings—cont'd

Antimicrobial Agent	Effective Against	Wound Indication	Application	Benefits	Disadvantages	Nursing Considerations
		epidermal necrolysis (TEN), donor sites	3–7 days; wet down with sterile water every 12 hours. Some products are applied dry and not wet down.		wounds because it may cause hypothermia.	observed daily. May also be of good use in the outpatient setting. Some patients may complain of stinging upon application. Do not use with normal saline because it will deactivate silver.
<b>Enzymatic cream</b> (collagenase)	No antimicrobial effects and thus is often mixed with other ointments and/or creams	Full-thickness burn wounds (specifically digests collagen in necrotic tissue without harming intact tissue)	Thin layer applied with a nonadherent gauze and an outer roll gauze; dressing changes every 24 hours	Easy, painless application; only once-per-day dressing change; may help penetrate and soften eschar for debridement		Considered for use in patients with full-thickness burn wounds who are not candidates for the operating room because of age or medical condition; also considered for use in very small areas of full-thickness burns in an attempt to heal without surgery.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

**FIGURE 51.19** Silver sulfadiazine and roll gauze.

**FIGURE 51.20** Dressing applied to hand. Note that each finger is wrapped loosely and individually.

**FIGURE 51.21** Wound cleansing with normal saline and chlorohexidine solution and roll gauze.

accomplished through the use of tweezers and scissors and is often aided by the removal of gauze dressings and hydrotherapy. An example of a partial-thickness wound pre- and post-debridement is shown in Figure 51.22. Enzymatic debridement involves the application of a proteolytic ointment that hastens eschar separation and wound healing. Enzymatic debridement is often reserved for patients with

**FIGURE 51.22** Wound debridement of a partial-thickness burn. A, Pre-debridement. B, Post-debridement.

deep partial-thickness wounds where signs of healing are evident. This type of debridement is also considered in patients with full-thickness burns who may not be candidates for surgery. If mechanical and enzymatic debridement are not effective, surgical debridement is necessary.

### **Surgical Debridement and Wound Closure**

Early excision and grafting of burns decrease the length of hospital stay and greatly increases the survival rates of these patients. **Burn excision** is considered as soon as the patient is hemodynamically stable and able to tolerate the procedure. It is not uncommon for the patient with a large full-thickness burn to be taken to the operating room for excision and grafting within 24 to 48 hours of admission. Types of skin substitutes and grafts are described in Table 51.8.

The ideal replacement for lost skin is **autograft** because it is the patient's own skin and will not be rejected by the body. The epidermis and a partial layer of the dermis (**split-thickness skin grafts**) are harvested from an unburned area, known as the **donor site**. The most common donor site is the thigh because of the ability to obtain a continuous donor sheet of skin. However, in patients with large burns, any site on the body may be utilized, including the scalp and scrotum if necessary. Once healed, donor sites may be re-harvested numerous times. These split-thickness skin grafts are then applied to the excised wound in the form of a sheet or **meshed graft**. **Sheet grafts** are often utilized on exposed areas of the body, such as the face and hands, because they give a more seamless and cosmetic appearance due to the fact that the grafts are not meshed. Skin grafts are meshed (have holes placed in them that allow for expansion) when unburned skin is in short supply in order to provide maximal wound coverage and closure. A mesh expansion ratio of 1:2 upward to 1:4 is commonly utilized. Examples of meshed and sheet autografts are presented in Figure 51.23. In some instances, the burn surgeon may choose to apply a small full-thickness skin graft to allow for the best function in certain anatomical areas, such as the eyelids.

In extensive burns where there is not enough unburned tissue to harvest, **allograft** (cadaver skin) is often utilized. With the placement of allograft as a temporary covering, there is decreased evaporative loss of heat and better pain control for the patient, and it provides a barrier against bacterial growth. Allograft, as seen in Figure 51.24, is only a temporary covering and is eventually rejected by the body and is replaced by the patient's own skin. When allograft is not available, **xenograft** (pig skin) may also be considered. In some developing countries where allograft and xenograft are not readily available, things such as fish skin are being sterilized and used for temporary burn wound coverage.

Another alternative to consider with massive burns is the use of **cultured epithelial autograft (CEA)**. This technique is considered only in the most severely burned patients where there is no other alternative because the patient remains very vulnerable to infection, and the CEA skin is extremely fragile. Cultured epithelial autograft involves a biopsy taken from an area of unburned skin and then sent

**Table 51.8** Types of Skin Substitutes and Grafts

Graft	Source	Coverage	Benefits	Drawbacks
<b>Autograft</b>	Patient's own unburned skin May be meshed to cover larger areas or placed as a sheet on faces and hands for a smoother, more cosmetic appearance	Permanent	This is the ideal coverage for all patients' burns and has the highest chance of wound closure.	May be delicate if meshed widely before application. Staple removal may be tedious.
<b>Cultured epithelial autograft (CEA)</b>	Patient's own skin sample is sent to a laboratory, where the epidermis is grown in larger patches.	Permanent	Is a good choice in patients with large burns of 70% or more TBSA burn who do not have enough unburned skin to use as donor for autografting	Is extremely expensive, very fragile, and susceptible to infection once applied. Dermal layer will never regenerate.
<b>Integra (artificial skin)</b>	Two-layer man-made silicone membrane used to replace dermis and is covered with autograft	Permanent	May provide a functional dermis and better chance of wound closure	High risk for infection of the Integra and subsequent graft loss
<b>Allograft</b>	Cadaver skin	Temporary	Used as a temporary covering once eschar is removed to help close and protect wound	Will eventually reject and have to be replaced by permanent grafting
<b>Xenograft</b>	Pig (most common) or bovine (cow) skin	Temporary	Used as a temporary covering once eschar is removed to help close and protect wound	Will eventually reject and have to be replaced by permanent grafting

TBSA, Total body surface area.

**FIGURE 51.23** Autograft. A, Meshed autograft to the forearm. B, Sheet autograft to the hand/fingers.

to a laboratory where, over a 2-week period, epithelial cells are grown in the laboratory and attached to petroleum-impregnated gauze. Excision of the burn wound is not delayed while waiting for the CEA, and ideally, the wound is excised, and an allograft is placed as a temporary covering. Cultured epithelial autograft is extremely delicate because it involves the growth of only the epidermal layer. After the

placement of the CEA, the patient is often placed in traction, which allows elevation of extremities and pressure relief. These patients then require extensive one-on-one nursing care that focuses on time-consuming wound healing and infection control. It is for this reason that CEA is utilized only in burn centers. Examples of CEA are shown in Figure 51.25.

**FIGURE 51.24** Allograft.

**FIGURE 51.25** Cultured epithelial autograft (CEA). A, CEA to abdomen. B, CEA to lower extremities that are placed in traction.

## CASE STUDY: EPISODE 2

It has been determined that Joe Smith's wounds are full thickness. Current wound management includes silver sulfadiazine cream twice a day. The surgeon has determined that the patient requires surgery. Medical and nursing priorities continue to focus on pain management and infection prevention...

## Pain Management

Burn pain continues to be managed aggressively throughout the emergent phase and well into the intermediate and even rehabilitative phases. The multifaceted pain experienced by the burn patient includes background, procedural, and breakthrough pain. *Background pain* is the underlying pain from the primary injury that is continuous and ongoing. *Breakthrough pain* is pain related to specific episodes associated with activities of daily living (ADLs), such as walking. *Procedural pain* is associated with therapeutic activities such as wound care and physical therapy. Inadequate and inconsistent management of pain is well documented in the burn literature, and pain is whatever the burn patient says it is. Although the pain is aggressively managed and patient comfort is a priority, the patient needs to actively participate in the plan of care and particularly in the rehabilitation process. Because of the large doses of pain medication that are administered, the patient is optimally treated at a burn center, where his or her pain can be effectively managed by the interprofessional team.

The pain management plan of care is individualized and includes both pharmacological and nonpharmacological methods of pain management. Recommended IV narcotics, usually used during dressing changes, include morphine sulfate (morphine), fentanyl (Sublimaze), ketamine, and/or hydromorphone (Dilaudid). Intravenous narcotics are continued while the pain is severe and unrelenting; however, all efforts are made to transition to oral pain medications as soon as tolerated. It is important to differentiate between pain and anxiety because they are treated differently. In addition to pain management, patients are often given anxiolytics for anxiety related to wound-care procedures, appearance changes, and fear. However, these medications are indicated only once the pain is under control. In addition, pain medication is given on a scheduled basis instead of on an as-needed (prn) basis because this helps to better manage the pain over time and hopefully prevents it from becoming intolerable.

**Safety Alert** When giving large doses of IV pain medication, especially during dressing changes, ensure that proper ventilatory support and emergency equipment are immediately available.

## Nutritional Support

Nutrition plays a significant role in the outcomes of the patient with major burn injuries. Large burn injuries place the patient in a prolonged hypermetabolic and catabolic state, resulting in an increased caloric need to assist in wound healing. Early enteral nutrition is associated with a reduction in ileus and stress ulcers because it reduces the inflammatory mediators released by the body. Once a person has sustained a burn of approximately 20% or greater, it is difficult to consume the amount of calories and

protein needed for wound healing, and nutritional supplementation is often required because of the fact that his or her metabolic rate is greatly increased as a result of the burn injury. Nutritional supplementation is most often achieved through the placement of a nasogastric tube, where feedings can be given continuously or intermittently in the form of a bolus. In large burn injuries, longer nutritional support is required, and the placement of a duodenal feeding tube is often recommended to help prevent aspiration and allow for feeding up to and during procedures. Supplemental vitamins and minerals are also often administered to promote wound healing. Total parenteral nutrition is not often utilized among patients with burns because of its complication rates, including an increased risk for infection and hyperglycemia.

### Prevention of Infection

Prevention of infection after burn injury is challenging. The most common cause of death after the emergent phase is infection resulting in sepsis and multisystem organ failure because these patients have lost the largest protective barrier, the skin. Infection control practices vary widely among burn units, and prevention and outbreak control represent major challenges. Prophylactic antibiotics are not recommended because of the potential of breeding antibiotic-resistant pathogens, and instead, treatment is based on positive culture results. Cross-contamination among patients with burn injuries is common, and as a result, isolation guidelines are widespread practices among burn centers. Proper hand-washing technique continues to be one of the most effective methods of preventing the spread of infection. Some burn centers require the use of contact precautions when entering all patient rooms. Regardless of the type of infection control method employed, it is essential that all members of the healthcare team, as well as family and visitors, are knowledgeable about and adhere to all standards.

### Connection Check 51.10

The nurse anticipates supplementary feeding via a nasogastric tube in a patient for which reasons? (Select all that apply.)

- A. Hypermetabolic state.
- B. Multiple open wounds.
- C. Increased heat loss.
- D. Increased caloric needs.
- E. Burn greater than 20% TBSA.

### Nursing Management

#### Assessment and Analysis

As the patient progresses into the intermediate phase after successful resuscitation, the priorities expand to wound management and infection control. The patient continues to require close observation of respiratory status and hemodynamic stability. The nurse monitors for the following

additional clinical manifestations during the intermediate phase:

- Wound color and consistency
- Wound drainage
- Eschar
- Responses to therapeutic interventions
- Graft sites
- Pain
- Weight
- Serum total protein and albumin
- Infection

### Nursing Diagnoses

- **Risk for infection** related to impaired immune response and loss of skin integrity
- **Altered nutrition less than body requirements** related to hypermetabolism and burn injury
- **Acute pain** related to exposure of nerve endings in wound bed and wound-care procedures
- **Anxiety** related to painful wound-care procedures
- **Self-care deficit** related to impaired mobility due to the burn injury
- **Powerlessness** related to hospitalization and inability to care for self

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*An elevated heart rate may be secondary to sustained hypovolemia, as well as pain and anxiety. Respiratory rate and blood pressure may also be elevated secondary to pain and anxiety. Temperature may be elevated with an infection. The patient also needs to be assessed for hypothermia, particularly with large burns that can lead to increased loss of heat through the open wounds.*
- Daily weight  
*Increased metabolic rate may result in weight loss.*
- Daily caloric intake  
*Increased metabolic rate results in an increased caloric need to assist in wound healing.*
- Total protein and albumin levels  
*Assessment of nutritional status includes monitoring total protein and albumin levels. Normal serum total protein is 6 to 8 g/dL, and serum albumin is 3.4 to 5.1 g/dL. Adequate albumin also supports oncotic pressure that promotes fluid remaining in the intravascular space.*
- White blood cell counts  
*Loss of the protective mechanisms due to burn injuries increases the risk of infection, and an elevated white blood count may indicate a wound infection.*
- Wounds for signs of healing and clinical manifestations of infection  
*If the burn wound is not showing any evidence of healing, surgery may be indicated, or a change in the wound-care regimen may be warranted. With the loss of the skin as a protective barrier, the patient remains at constant risk for infection resulting from the invasion of microorganisms.*

- Pain and anxiety  
*Pain associated with daily dressing changes places the patient at risk for tachycardia and hypertension.*
- Participation in plan of care and ADLs  
*It is important for the patient to be actively involved in the plan of care and to understand the rationales for all interventions.*

### ■ Actions

- Time medication administration so that the patient receives the full benefit during wound-care procedures.  
*Procedural pain is often the most intense pain associated with a burn injury, and medication must be timed to allow for maximum absorption, as well as to time the most painful procedures during the peak effectiveness times of medications.*
- Give pain medication on a scheduled basis instead of on an as-needed (prn) basis.  
*Assists in effectively managing pain and allows a steady state to develop within the body; also ideally provides the patient with more consistent pain relief*
- Explore the effectiveness of nonpharmacological pain relief techniques, such as music therapy and guided imagery.  
*Nonpharmacological techniques have been shown to assist in the reduction of procedural burn pain and anxiety.*
- Calorie counts and encouragement of oral intake  
*Maintenance of caloric needs is essential in determining whether adequate nutrition is provided for wound healing.*
- Wound care  
*Daily wound care and assessment are essential for wound healing and the prevention of infection.*
- Assist with ADLs and compliance with rehabilitation exercises.  
*Even though the patient's injury location may present a challenge, encouragement of self-performance of ADLs and rehabilitation exercises is essential for rehabilitation therapy.*

### ■ Teaching

- Instruct patient to request additional pain medication when needed and not to delay until the pain is intense.  
*If pain becomes intolerable, it can be difficult to assist the patient in achieving a tolerable pain level.*
- Provide information to patient and family about the natural progression of burn wounds, grafts, and/or donor sites.  
*Providing information can help to reduce misconceptions and anxiety related to surgery and recovery.*
- Provision of a rehabilitation plan and discussion of the importance of doing ADLs and rehabilitation therapy  
*Providing a rehabilitation plan and encouragement of self-performance of ADLs helps prevent complications associated with decreased mobility and provides a sense of self-control.*
- Education on the importance of nutrition and provision of a diet plan  
*Maintenance of caloric needs is essential for wound healing, performance of daily activities, and the rehabilitation regimen.*

## Evaluating Care Outcomes

During the intermediate phase, there are several additional priorities for the nurse to focus on, including outcomes related to adequate nutrition, pain management, wound healing, and infection control. Stable body weight and normal albumin and total protein levels are indicative of improving nutritional status. Effective pain management is supported by stable vital signs, as well as the patient reporting adequate comfort. Additionally, the patient is comfortable enough to participate in ADLs and understands the importance of asking for pain medications prior to pain becoming intolerable. The effectiveness of wound management is determined by evidence of the healing of burn injuries as well as no signs of infection. Stable vital signs, including normal heart rate and blood pressure, are consistent with adequate fluid volume status and pain management. Normal temperature and normal white blood cell counts support a lack of infection.

## Rehabilitative Phase

### Medical Management

The last phase in the burn process is the rehabilitation phase. This stage begins from the time the patient is admitted to the burn center and may last for several years, even extending well beyond discharge. All members of the interprofessional team are essential during this phase; however, rehabilitative and psychological support are of primary importance.

Not only is a burn injury physically painful, but dealing with the long-term emotional consequences is also often difficult. The patient with a burn injury may endure many psychological and emotional challenges throughout his or her lengthy course of treatment and recovery. The patient may experience posttraumatic stress disorder (PTSD), body image disorder, anxiety, and/or depression. To ensure that these issues are effectively managed, the interprofessional team at a burn center must include mental health professionals. Psychologists, psychiatrists, and advanced practice mental health nurse practitioners and clinical specialists are often involved, and many patients may require both emotional and pharmacological interventions for mental health issues. Although the patient may suffer emotional consequences as a result of the burn injury, the family members and loved ones are also often affected by this traumatic experience. Psychological and emotional support and/or counseling are geared toward the patient as well as the family. Nurses often have the most contact with the patient and his or her family and play a key role in the provision of support. Many burn centers have specialty support groups for survivors of burn injuries and their families.

Although survival rates for patients with major burn injuries are increasing, it is essential to return the patient to his or her highest level of function and mobility. Physical and occupational therapists are important members of the interprofessional team and begin working with the burn patient immediately upon admission. Modalities including range of motion, positioning, splinting, ambulation, and

ADLs are implemented as soon as the patient is physiologically stable. Once the patient is discharged, physical and occupational services continue in the home, at a rehabilitation facility, or in an outpatient setting. In some cases, these patients require rehabilitation therapy for several hours a day up to 5 days a week for many months after their injury.

### Complications

One of the most devastating sequelae associated with burn injuries is the development of **contractures**. There are several contributing factors to the development of contractures, including the extent, depth, and location of the burn. Contractures are characterized as permanent tightening of the skin that may involve underlying muscles and tendons and result in limited mobility. The patient's personal motivation and compliance with therapy regimens play important roles in the development of contractures. Contractures are especially devastating in the pediatric population because burned or grafted skin is unable to expand as the child grows. Splinting is the most common method used to help prevent the formation of contractures (Fig. 51.26). Splints are placed by rehabilitation therapists to maintain range of motion and function of the involved joints. It is especially important to employ the use of splints when a burn injury crosses over a major joint, such as the elbow or knee.

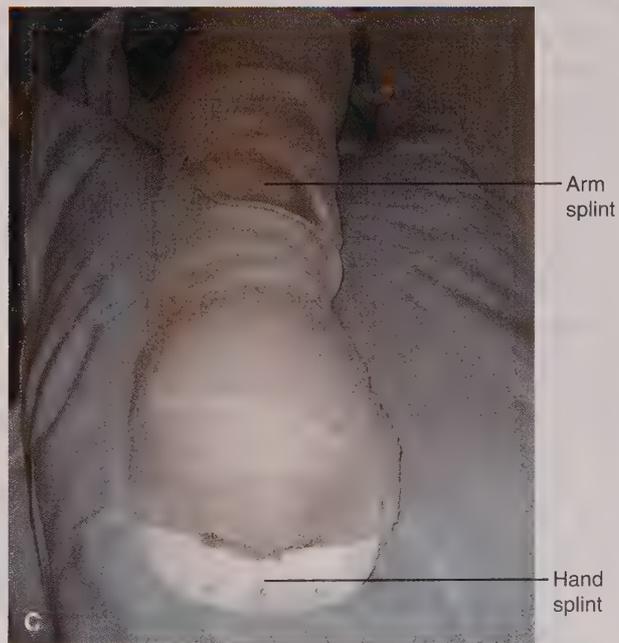

**Scarring** is another major concern when dealing with a burn injury. Any area that has been grafted will have some element and degree of scarring. As burn wounds mature over the course of months to years, hypertrophic scarring can result. Burns to the face and hands that have caused scarring are particularly traumatic to the patient and may result in appearance changes and disfigurement. As patients progress to discharge, they are measured and fitted for specialty pressure garments (Fig. 51.27). The purpose of these garments is to apply continuous and uniform pressure over the area of burn to prevent hypertrophic scarring. These garments are to be worn 23 hours a day for up to a year or more after injury in some patients. Specialty face masks may also be utilized to help prevent scarring.

### Nursing Management

#### Assessment and Analysis

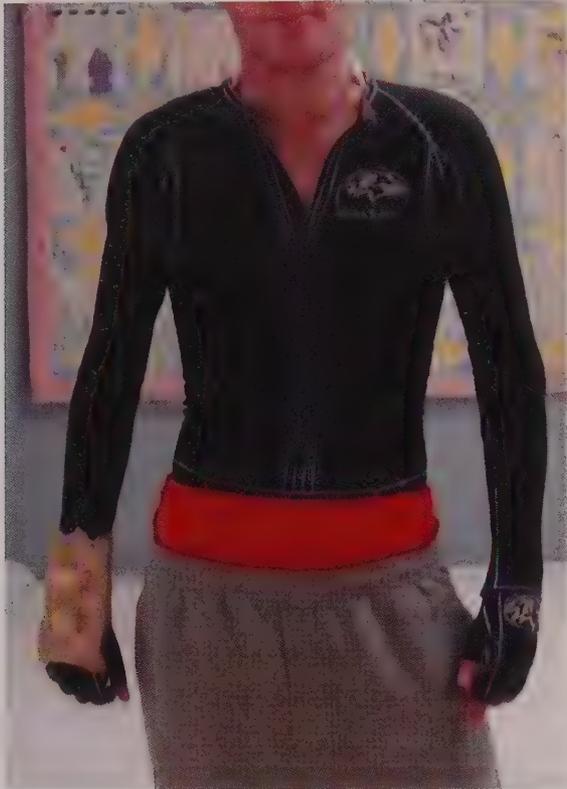

The rehabilitative phase is the longest and may last several years depending on the TBSA affected, the severity of the burns, and the complexity of the treatments. Just as in the two previous phases, the patient must be monitored for infection, nutritional status, and pain during this phase. Additionally, the priorities expand to promoting greater mobility, flexibility, comfort, and psychosocial health. During this phase, the nurse observes for the following clinical manifestations:

- Pain/discomfort
- Contractures
- Scarring
- Disfigurement

**FIGURE 51.26** Splints. A, Hand splints. B, Foot splint. C, Hand and arm splints with burn dressings.

- Limited mobility
- Altered/depressed mood
- Flat affect
- Fear
- Anxiety

**FIGURE 51.27** Full-body pressure garment.

### Nursing Diagnoses

- **Activity intolerance** related to pain when exercising because of the burn injury
- **Impaired physical mobility** related to pain on movement and potential scar and contracture development
- **Disturbed body image** related to altered physical appearance
- **Moral distress** related to anticipation of discharge to home and/or a rehabilitation center

### Nursing Interventions

#### ■ Assessments

- Pain level  
*If the patient is in pain, participation in physical activities may be impaired, further complicating recovery.*
- Range of motion  
*In the patient with extensive scarring and/or contracture development, the mobility of joints may be limited, requiring specific strengthening and flexibility exercises.*
- Compliance with treatment and the rehabilitation regimen  
*Helps to prevent tightening of the skin and the development of contractures and scarring*
- Assess readiness for integration into society.  
*Many patients have anxiety about pending discharge and perceive difficulties with returning to society.*

#### ■ Actions

- Splinting and encouragement of rehabilitation exercises and ADLs  
*Essential to help prevent development of contractures and maintain joint function*
- Include psychology in patient treatment decisions.  
*Burn patients may deal with multiple associated sequelae, including PTSD, nightmares, and body image disorder.*
- Provide community resources for support upon discharge, including psychological support.  
*Community resources for burn survivors may be difficult to find but can provide essential social and psychological support.*

#### ■ Teaching

- Teach patient and family the importance of and how to apply pressure garments and/or face masks.  
*Prevent hypertrophic scarring*
- Teach patient and family about burn prevention, sun protection, and prevention of hyperthermia.  
*Patients with burns may be lacking sweat glands, and new skin and/or grafted skin is sensitive to sunlight.*

### Evaluating Care Outcomes

The focus during the rehabilitative phase is to return the patient to the highest functioning level, and expected outcomes include pain management, prevention of complications, improvements in mood, and increasing independence with activities of daily living. The nurse plays an integral role in assisting and encouraging the patient during physical and occupational therapy treatment regimens. It is important for the patient and family to verbalize and demonstrate an understanding of therapy routines because noncompliance can quickly lead to contractures and loss of function. The nurse also works closely with the patient and the psychologist to effectively manage and deal with the possible psychological sequelae, which may include body image disorder, nightmares, and PTSD.

### OTHER CONDITIONS TREATED IN A BURN CENTER

Burn center referrals are not always limited to treating typical burn injuries, and patients with various disease processes that involve the integumentary system, underlying soft tissue, and/or muscle are treated and managed at burn centers. Some of the conditions and disease processes treated at burn centers include Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), erythema multiforme, purpura fulminans, staphylococcal scalded skin syndrome, bullous pemphigoid, necrotizing fasciitis, calchiphylaxis, scleroderma, and frostbite.

### Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

Although both Stevens–Johnson syndrome and toxic epidermal necrolysis (TEN) have been related to multiple etiologies, the most common causes are an adverse medication

reaction, viral infection, or reaction to the staphylococcal toxin. In both disorders, the epidermis separates from the dermal layer and sloughs. Stevens–Johnson syndrome (SJS) may involve less than 30% TBSA, whereas TEN may involve greater than 30% TBSA. In both conditions, slough to the oral mucosa, conjunctiva, vaginal canal, gastrointestinal tract, and urethral lining may also occur. The mortality rate associated with TEN ranges from 25% to 80% and is usually due to septicemia, which leads to multiple organ failure. The lesions associated with SJS and TEN are extremely painful and hypersensitive. Immediate concerns focus on protection of the airway because of the oral lesions and inability to control oral sloughing and bleeding. Endotracheal intubation may be required. A definitive diagnosis is confirmed through biopsy. Because of the complexity of this type of condition, in which treatment often includes electrolyte replacement, nutritional support, expert wound care, strong infection control practices, and extensive rehabilitation, these patients are often best managed at a burn center.

4. The nurse anticipates that the donor site(s) for Mr. Smith will be from which area?
  - A. Upper extremities
  - B. Thigh
  - C. Scalp
  - D. Chest
5. What are nursing priorities for Mr. Smith during the rehabilitative phase? (*Select all that apply.*)
  - A. Prevention of contractures
  - B. Sustaining oxygenation
  - C. Compliance with physical and occupation therapy regimens
  - D. Psychological readiness for integration into society
  - E. Fluid resuscitation

## Making Connections

### CASE STUDY: WRAP-UP

Joe's surgery is successful, and he is prepared for discharge to home. During discharge teaching, the nurses discuss the importance of proper nutrition to promote wound healing, as well as monitoring for signs of infection. The nurse ensures that Joe has appropriate referrals for psychological and rehabilitative therapy.

#### Case Study Questions

1. On the basis of the initial burn wound description, what depth of injury has this patient sustained?
  - A. Superficial
  - B. Superficial partial thickness
  - C. Deep partial thickness
  - D. Full thickness
2. Using the rule of nines, what is the approximate size of Mr. Smith's burn injury?
  - A. 80% TBSA
  - B. 65% TBSA
  - C. 40% TBSA
  - D. 24% TBSA
3. On further assessment, Mr. Smith's estimated TBSA is determined to be 45%, and his weight is 220 lb. Using the resuscitation formula, the nurse calculates what volume to be administered during the first 24 hours?
  - A. 9,000 mL lactated Ringer's
  - B. 14,000 mL lactated Ringer's
  - C. 18,000 mL lactated Ringer's
  - D. 21,000 mL lactated Ringer's

## CHAPTER SUMMARY

Because of the limited number of burn centers within the United States, it is essential that all healthcare providers possess the basic burn-care knowledge required in the initial management of patients with burns. As a result of the resource-intensive nature of caring for patients with burns, they are best managed in burn centers, where they can be cared for by an interprofessional specialty team of providers. It is important that healthcare providers are familiar with American Burn Association transfer criteria.

Burns are generally classified in terms of etiology, depth of tissue damage, total body surface area (TBSA) involved, and severity. Special considerations must be given to patients who sustain inhalation, electrical, and/or chemical injuries because specialized treatment may be warranted. Burn injuries may be superficial, partial thickness, or full thickness in depth. The TBSA of the burn can be determined using various methods, including the rule of palm and the rule of nines. Burns that are 20% TBSA or greater are considered major burn injuries and produce both localized and systemic responses within the body. All body systems are affected by a major burn injury. Rapid and adequate fluid resuscitation is essential to prevent the development of hypovolemic shock.

The management of a burn injury can be broken down into three phases: the emergent, intermediate, and rehabilitative phases. In the emergent phase, the focus is on airway management, fluid resuscitation, and prevention of hypothermia. The intermediate phase focuses on wound healing, pain management, ensuring optimal nutrition, and continued prevention of infection. The rehabilitative phase begins the day the patient is admitted to the burn center and often lasts for many years, even extending well beyond discharge.

Burn injuries can be physically and emotionally devastating for both the patient and the family. Caring for this unique population of patients even presents physical and emotional challenges to members of the burn healthcare team. Many recent studies are investigating the effects of burnout and

emotional exhaustion among healthcare providers, especially those working with the burn population. Special emphasis also needs to be placed on education regarding the location of community resources to assist patients in both the prevention and management of burn injuries.

## Promoting Health in Patients With Musculoskeletal Disorders

### Chapter 52

## Assessment of Musculoskeletal Function

*Kelley Miller Wilson*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the musculoskeletal system
2. Discussing the function of the musculoskeletal system
3. Describing the procedure for completing a history and physical assessment of musculoskeletal function
4. Correlating relevant diagnostic examinations to musculoskeletal function
5. Explaining nursing considerations for diagnostic studies relevant to musculoskeletal function
6. Discussing changes in the musculoskeletal function associated with aging

#### CONCEPTS

- Assessment
- Cellular Regulation
- Comfort
- Mobility
- Promoting Health

#### ESSENTIAL TERMS

Amphiarthrosis	Hyaline cartilage
Articular cartilage	Ligaments
Automaticity	Nonsynovial joint
Bursa	Osteoblasts
Cartilage	Osteoclasts
Collagen	Osteoporosis
Diaphysis	Paresthesia
Diarthrosis	Periosteum
Dowager's hump	Sarcopenia
Endosteum	Sesamoid bones
Epiphyseal line	Synarthrosis
Epiphyseal plate	Synovial fluid
Epiphysis	Synovial joint
Fascia	Tendon
Fasciculi	Trabeculae
Goniometer	Viscoelastic
Hematopoietic	

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Twenty-four-year-old Abby Ridgeway recently graduated from a prestigious Midwestern college where she was a 4-year scholar athlete on the school's championship women's soccer team. Since graduation, Abby has been playing on a weekly intermural coeducational soccer team with a talented and competitive group of young adults. Last Tuesday evening during one of the games, Abby, in uncontested pursuit of the ball, extended her left leg to keep the ball in play. Almost as soon as she extended her leg, she felt a "pop" followed by instant unyielding pain, the kind that every soccer player dreads. After being assisted to a standing position, Abby was unable to bear any weight on the injured left leg. Assisted by teammates, Abby was taken to the closest emergency department (ED) for medical evaluation...

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

### Bones

The musculoskeletal system, the second largest system of the body, is an amazing group of structures performing in perfect precision, allowing for movement, protection of vital organs, production of blood cells in the marrow, support

for standing erect, and finally, a reservoir for essential minerals in the bones. The skeleton forms the framework of the human body and consists of 206 bones. These bones support the integumentary system of the body and allow for upright posture and weight bearing. Even though bones are made up of minerals, resulting in a hard structure, they contain both living and nonliving tissues. The portion of the bone that contains living tissue includes the blood vessels, nerves, **collagen** (predominant protein in the connective tissue), and living cells. The living cells contain **osteoblasts** (cells that help form bone) and **osteoclasts** (cells that help demineralize and destroy old bone).

Bones are generally classified in two ways, by structure (composition) or by shape. **Classification by bone shape includes long bones, short bones, flat bones, irregular bones, and sesamoid bones.** Long bones (Fig. 52.1), often weight-bearing bones, are cylindrical in shape with rounded ends. Examples of long bones found in the human body include the femur located in the upper leg, the tibia and fibula located in the lower leg, the humerus located in the upper arm, and the radius and ulna located in the lower portion of the arm. Long bones also serve as levers for muscles. Short bones found in the body are defined as being as wide as they are long (Fig. 52.2). The primary function of short bones is to provide stability with little movement. Examples of these bones are the carpals and tarsals located in the wrist and foot. Flat bones are another type of bone found abundantly in the human body (Fig. 52.3). Flat bones are strong flat plates of bone with the purpose of protecting vital organs. Examples of flat bones include the sternum (breast bone), the cranium (skull), and the ribs. In adults, the highest numbers of red blood cells are formed in these flat bones. The irregular bones (Fig. 52.4) are bones that do not fall into any specific category because of their nonuniform shape. Examples

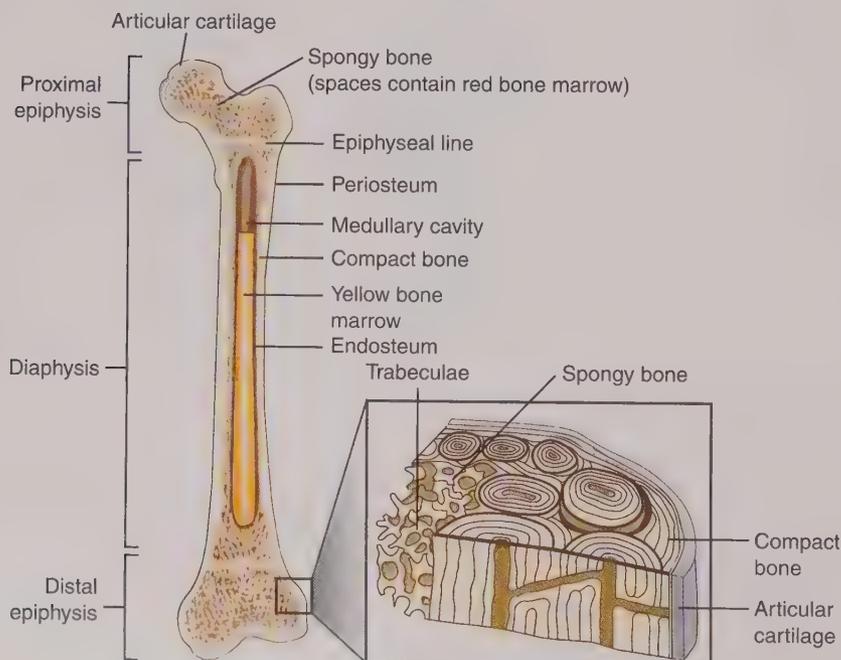

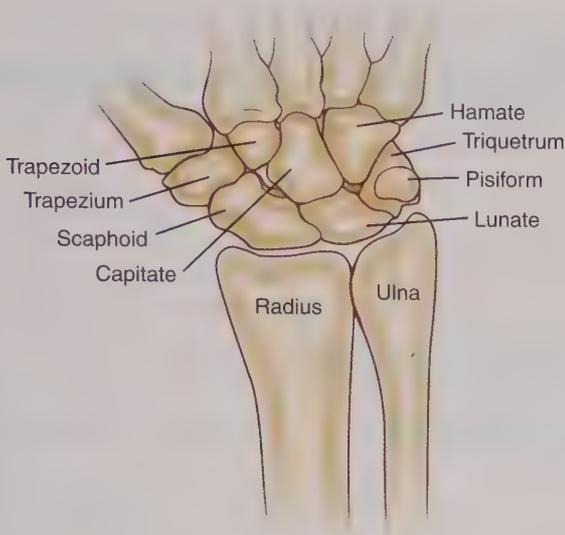

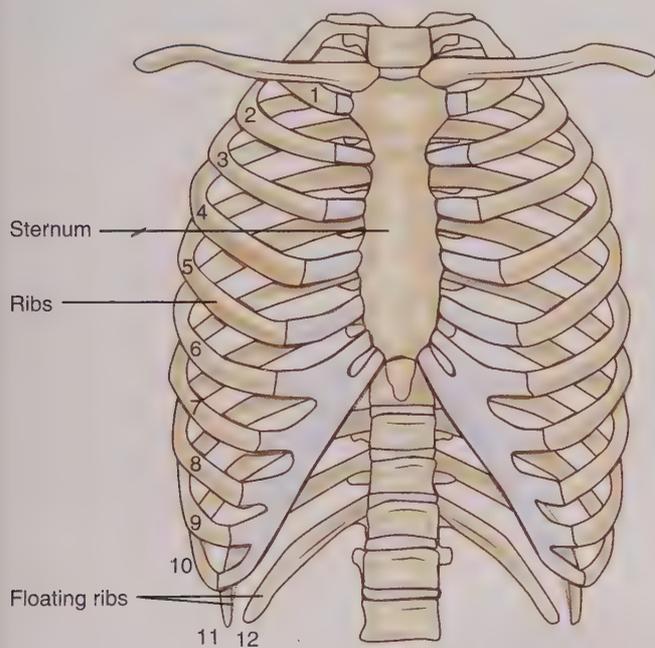

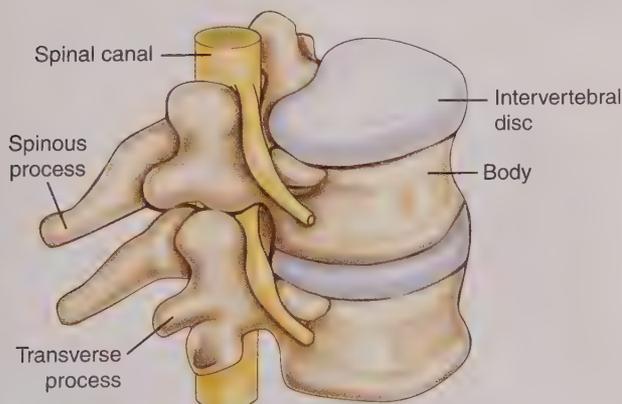

FIGURE 52.1 Long bone.

**FIGURE 52.2** Short bones. Examples are carpal bones in the wrist.

**FIGURE 52.3** Flat bones. Examples are the protective bones of the chest and sternum.

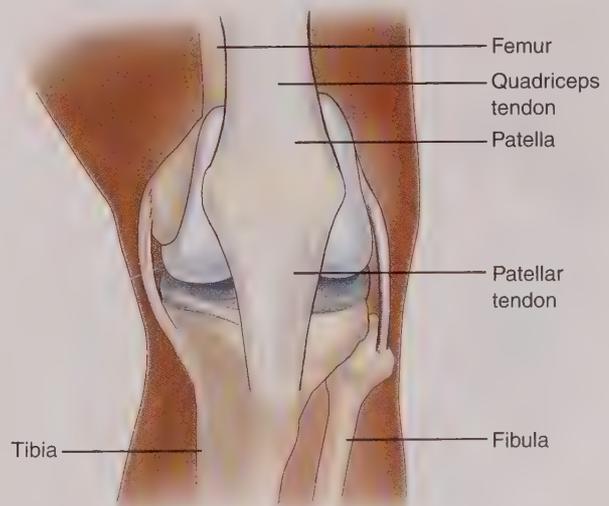

**FIGURE 52.4** Irregular bones. Example is the vertebral body.

of irregular bones are the vertebrae and the mandible (lower jaw). Finally, **sesamoid bones** are short and irregular bones embedded in a tendon. The most commonly cited example of a sesamoid bone is the patella (kneecap), which sits within the patellar or quadriceps tendon (Fig. 52.5).

Bones of different shapes contain different portions of osseous tissue known as *compact* and *spongy* bone. Compact bone is dense and looks smooth. Microscopically, compact bone contains the canals and passageways that serve as conduits for nerves, blood vessels, and lymphatic vessels. Spongy bone, on the other hand, is composed of small latticelike pieces and therefore has more open space. The lattice pieces, called **trabeculae**, form an open network that is filled with bone marrow, which functions to produce essential blood cells of the body. Two types of marrow are present in the bones of healthy individuals, red and yellow marrow. Red marrow consists mainly of **hematopoietic** tissue, whereas yellow marrow is made up mainly of fat cells. Hematopoietic tissue contains specialized cells that give rise to the formation of blood cells. Red blood cells, platelets, and white blood cells are all produced in the red marrow. Yellow marrow stores fat that the body may use in cases of extreme starvation. Yellow marrow also may transform into red marrow in cases of severe blood loss or anemia.

Long bones, which are similar in structure to many of the bones in the human body, typically have the following structures (see Fig. 52.1):

- **Diaphysis:** This is the shaft, which is made up of the long portion of the bone. It is constructed of a thick compact bone that surrounds the medullary cavity in adults. The medullary cavity contains fat known as the yellow marrow.
- **Epiphysis:** This is known as the end portion of the bone. A thin layer of compact bone forms the exterior portion of the bone, and the interior of this portion of the bone contains spongy bone.

**FIGURE 52.5** Sesamoid bone. Example is the patella or “knee cap.”

- **Epiphyseal plate:** In the bones of younger patients, **cartilage** is present at the junction of the diaphysis and the epiphysis, which allows growth to occur and the bones to lengthen.
- **Epiphyseal line:** This is a remnant of the epiphyseal plate; the cartilage that is present is converted to bone after puberty so that no further bone growth is possible.
- **Periosteum:** This is the tough outer surface of the bone (diaphysis). It consists of connective tissue, primarily of bone-forming cells known as osteoblasts. This portion of the bone also provides an insertion or anchoring point for tendons and ligaments.
- **Endosteum:** This is the internal bone surface that is covered with a delicate connective tissue membrane.
- **Articular cartilage:** This is where the long bones articulate at the epiphyseal surfaces. The bony surfaces are covered with a specialized cartilage called **hyaline cartilage**, which cushions the bones' ends and absorbs stress during joint movement.

Bones consist of both inorganic and organic substances. The organic components consist of cells and the bone matrix. The inorganic substances consist of mineral salts, most notably calcium phosphate. Calcium salts are present in the form of very tiny crystals, which help to create the hard quality of the bone.

### Hormonal Influences

Several hormones have been identified as factors that influence bone growth and loss. The specific hormones and their roles in creating this influence include:

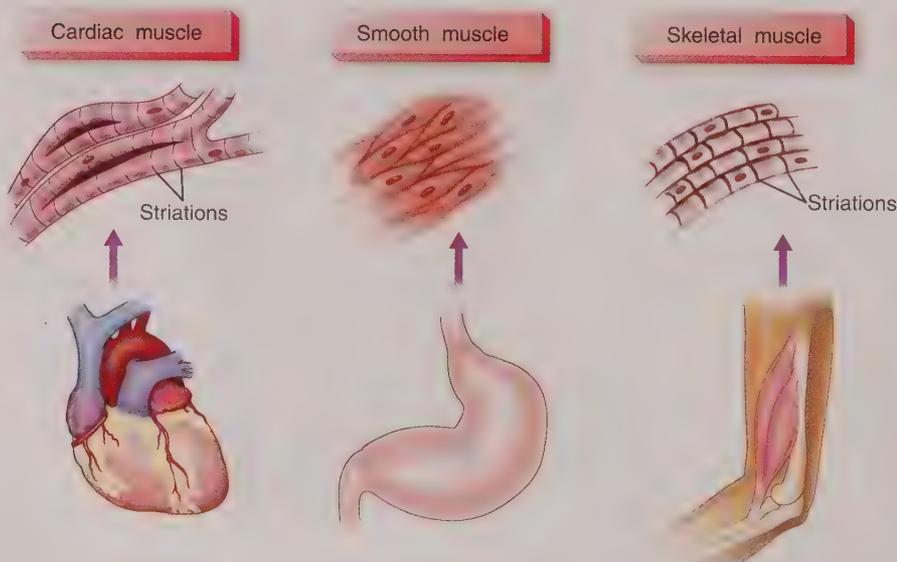

- **Estrogen:** Induces a chemical in osteoclasts that causes them to self-destruct and slow the rate of bone destruction. Menopause with the associated loss of estrogen makes women more prone to bone loss. Asian and

Caucasian women are especially vulnerable to this process.

- **Calcitonin and thyroid-stimulating hormone (TSH):** These two hormones inhibit the activity of osteoclasts. Recent research has found that TSH, a hormone produced in the anterior pituitary gland, can promote bone growth independent of its usual thyroid functions. This suggests that TSH or other medications that mimic its effect on bone may be a key factor for possible treatments of **osteoporosis** or other bone loss conditions.
- **Parathyroid hormone:** Promotes the activity and number of osteoblasts
- **Growth hormone:** Initiates the growth of bone until adult size is achieved

### Muscles

Muscles are structures that contract and help produce movement. Muscles account for approximately 40% to 50% of the body's weight. There are three types of muscles present in the human body: skeletal muscle, smooth muscle, and cardiac muscle (Fig. 52.6). Skeletal muscles are striated muscles marked by dark and light bands. They consist of bundles of muscle fibers called **fasciculi** and are attached to a bone by a fibrous cord known as a tendon. The main function of skeletal muscles is conscious or voluntary control of movement of the body or its parts. These movements include flexion (bending a limb at a joint), extension (straightening a limb at a joint), abduction (moving a limb away from the midline of the body), adduction (moving a limb toward the midline of the body), pronation (turning the forearm down so that the palm is down), supination (turning the forearm so that the palm is up), circumduction (moving the arm in a circle around the shoulder), inversion (moving the sole of the foot inward at the ankle), eversion (moving

**FIGURE 52.6** Muscle tissues; cardiac striated muscle, striated skeletal muscle, and smooth muscle.

the sole of the foot outward at the ankle); rotation (moving the head around a central axis), protraction (moving a body part forward and parallel), retraction (moving a body part backward and parallel to the ground), elevation (raising a body part), and depression (lowering a body part) (Fig. 52.7).

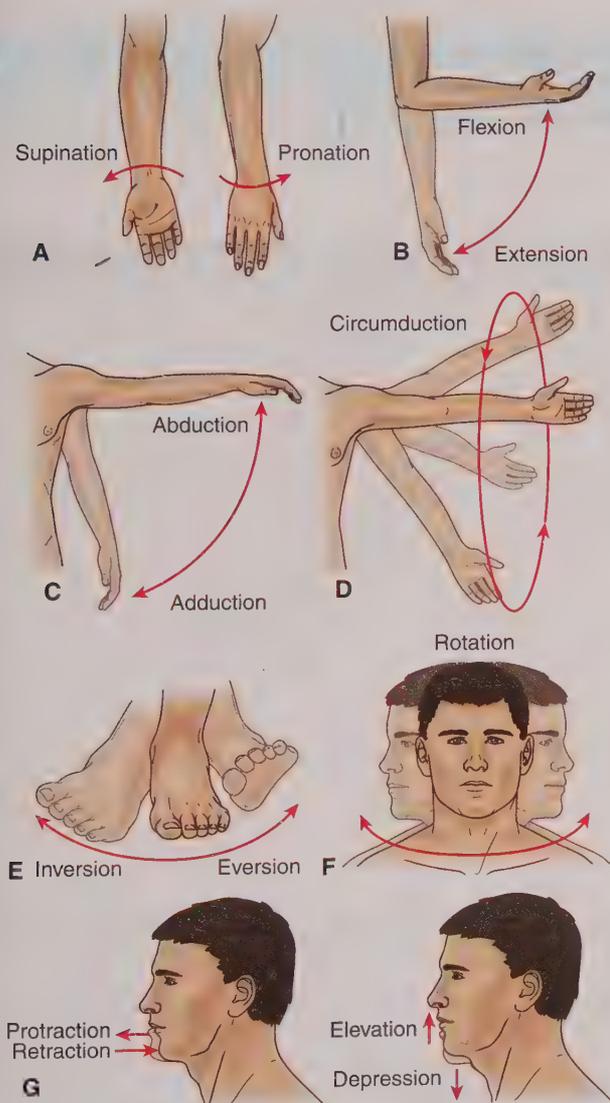

Smooth muscle, or nonstriated muscle, is involuntary. Smooth muscles are under control of the autonomic nervous system, which controls contractions of organs and blood vessels automatically. This specific muscle tissue is found in the walls of hollow organs such as the stomach, esophagus, blood vessels, and bronchi. Stimulation is by involuntary neurogenic impulses. Examples of this action include moving food along the esophagus or constricting/dilating blood vessels.

Cardiac muscle is a highly specialized striated muscle that can contract without neural stimulation because of

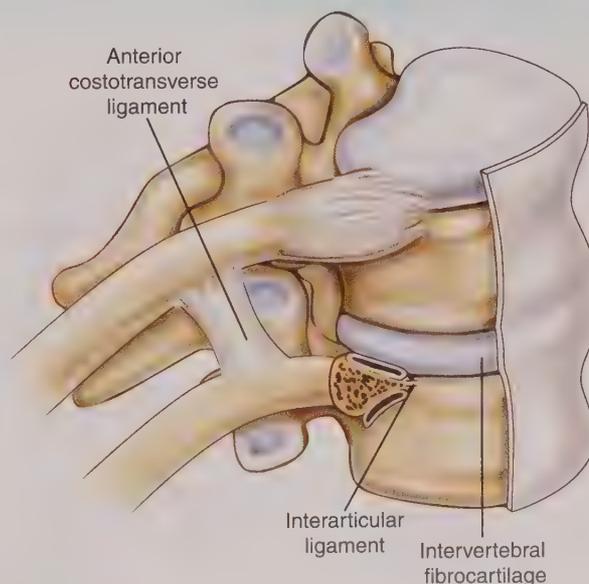

the property of **automaticity**. Automaticity allows cardiac tissue to set a contraction rhythm through the presence of pacemaker cells. Cardiac muscle can also be stimulated to increase or decrease the contraction rate through input from the autonomic nervous system. Cardiac muscle tissue is highly resistant to fatigue, allowing it to beat continuously throughout a lifetime because of the presence of a large number of mitochondria, myoglobin (oxygen-carrying protein found within the muscle), and an excellent blood supply. These properties allow for continuous aerobic metabolism. The properties of cardiac muscle cells are discussed in detail in Chapter 28.

### Joints

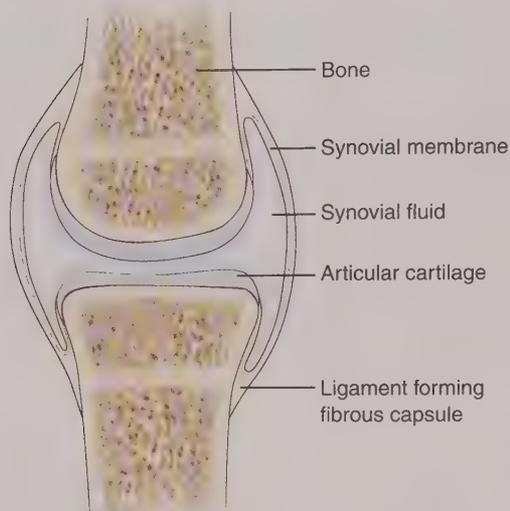

Joints are defined as a place of union between two or more bones. They permit mobility, provide mechanical support, and are an essential part of the musculoskeletal system. Joints are often referred to as either nonsynovial (Fig. 52.8) or synovial (Fig. 52.9). **Nonsynovial joints** are joined by fibrous tissue or cartilage and are immovable. **Synovial joints** are freely moveable because of the lubricating liquid called **synovial fluid** that fills the joint space. Synovial joints are enclosed in a joint cavity where the two bones meet. It is the presence of synovial fluid that prevents friction and allows for freedom of movement. The synovial joints are also covered with a layer of cartilage that lines the entire inner surface of the joint space. **Cartilage** is an avascular structure that receives its necessary nutrients from the synovial fluid while it is circulated during joint movement. The cartilage also provides additional cushion to the joint to allow for unencumbered and comfortable movement. Another structure that helps reduce friction with movement is a **bursa**. Not a part of synovial joints but frequently found close to them, a bursa is a fluid-filled sac lined with synovial tissue. It acts as a cushion between tendons, skin, or ligaments

**FIGURE 52.7** Skeletal muscle movements. A, Supination and pronation; B, Flexion and extension; C, Abduction and adduction; D, Circumduction; E, Inversion and eversion; F, Head rotation; G, Protraction, retraction, elevation, and depression.

**FIGURE 52.8** Nonsynovial joint. Example is vertebral body.

**FIGURE 52.9** Synovial joint. Examples include elbow, wrist, and knee.

and bones to facilitate the friction-free movement between soft and hard (bone) structures (Fig. 52.10).

Joints may also be classified functionally. There are three specific classifications to consider when referring to skeletal joints. These functional descriptions include:

- **Synarthrosis:** These joints permit little or no mobility (e.g., skull sutures).
- **Amphiarthrosis:** These joints permit slight mobility (e.g., vertebrae).
- **Diarthrosis:** These joints permit a variety of movements (e.g., the shoulder).

### Ligaments, Tendons, and Fascia

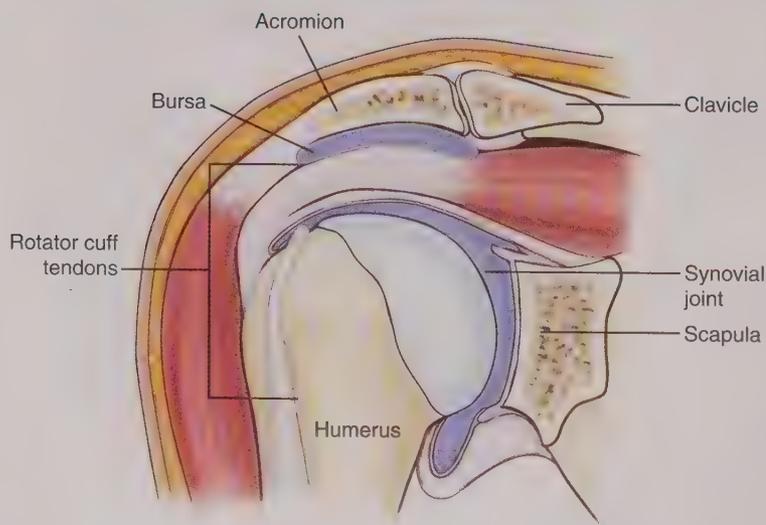

**Ligaments** are fibrous connective tissues present at joints to help provide stability to the joint. These fibrous bands composed of tough collagen fibers run directly from one bone

to another to reinforce the joint and help prevent undesired directional movements (Fig. 52.11). To prevent joints from becoming too loose or unstable, ligaments are arranged in crossing patterns. Ligaments are also **viscoelastic**, which means they gradually lengthen when under tension and return to their original shape when the tension is removed. However, ligaments do not generally retain their original shape when stretched past a certain point for a prolonged period of time. This has strong implications for dislocated joints. The longer a bone remains outside a socket, as happens with a dislocation, the greater the potential for permanent damage from this overstretching of the ligaments, which can increase the risk of more frequent dislocations. Broken or torn ligaments result in joint instability; surgical intervention may be necessary to return the joint to proper functioning.

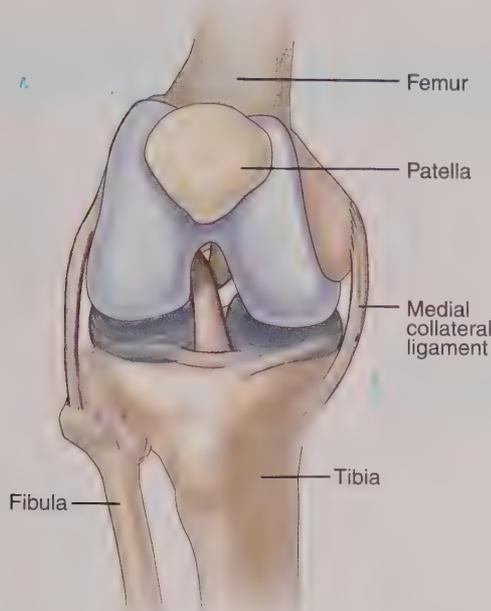

**Tendons** are fibrous connective tissues that connect muscle to bone or structures such as the eye. Where ligaments provide stability, tendons facilitate movement (Fig. 52.12). Injuries to a tendon are usually not sudden but are the result of multiple tiny tears due to the stress of overuse over time. **Fascia** is a layer of interconnected fibers of connective tissue with elastic properties that encloses, stabilizes, and separates muscles and internal organs. Superficial fascia lies directly under the skin. Deep fascia encloses individual muscles, providing strength and allowing for ease of movement.

### CASE STUDY: EPISODE 2

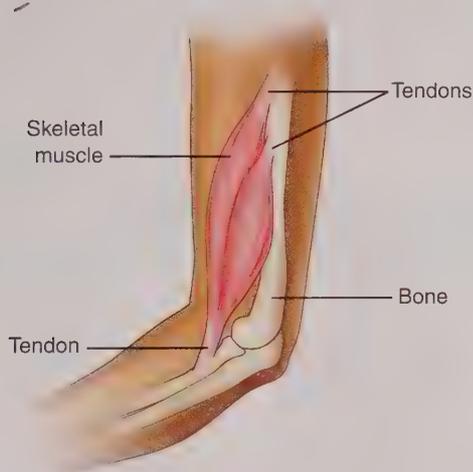

Shortly after arriving at the local ED, Abby is seen by the department's nurse practitioner. The nurse practitioner completes a thorough history and a modified physical examination of Abby's left leg. Pain prevents Abby from completing a full range of motion (ROM) evaluation. After an initial x-ray, the practitioner decides to send Abby to the radiology department for magnetic resonance imaging (MRI) of her left knee...

**FIGURE 52.10** Bursa provides a cushion between tendons, skin, or ligaments and bones.

**FIGURE 52.11** Medial collateral ligament of the knee provides joint stability and protection against undesired directional movement.

**FIGURE 52.12** Tendons connect muscle to bone and facilitate movement.

### Connection Check 52.1

The nurse understands which of the following are considered the key components of the musculoskeletal system?

- Bones, ligaments, smooth muscle, and joints
- Bones, tendons, ligaments, and cardiac muscle
- Bones, muscle, joints, and ligaments
- Bones, skeletal muscle, tendons, and ligaments

## ASSESSMENT

### Past Medical History and History of Present Illness

As with any thorough assessment of a system of the human body, one of the first parts of the examination process is always obtaining the patient's history. Past medical history may have implications for current injury or disease. For example, a shoulder dislocation in the past may predispose a person for future dislocations. Hormonal disturbances may have implications with calcium balance. Also, patients with Down's syndrome are known to experience accelerated aging, which has musculoskeletal implications.

The aim of gathering the history of the present illness or chief complaint is to gain a clear description of the current problem so that proper treatment may be initiated. Some conditions of the musculoskeletal system may be managed by a primary care practitioner, whereas others require the expertise of a specialist and interprofessional team. The interview of patients presenting with musculoskeletal difficulties includes asking the patients to recite:

- Location of pain including quality of pain (sharp, stabbing, dull, throbbing, continuous); time frame associated with pain (when did the pain start); factors that make the pain better/worse
- Presence of swelling? Note time swelling was first noticed and any increase/decrease of swelling.
- Stiffness? Note location, duration, and degree of stiffness present.
- Deformity? Note any change from the uninjured state of the affected area.
- Weakness? Note the presence of weakness and measure the degree of weakness present. Has the weakness increased or resolved since the injury?
- Instability of the affected area? Is there instability present? If so, note the degree of instability present by recording the specific current level of functioning of the injured area.
- Loss of function? Is there an inability of the affected area to function in a manner that it previously did?
- Are there color or temperature changes present with the affected area?
- Is there any altered sensation present such as numbness or tingling?
- Are there any other associated symptoms or past medical history that could impact the injury? Is there any significant family past medical history related to this type of injury?
- How have the symptoms responded (if at all) to any treatment that has been administered?

### Physical Assessment

After a complete and thorough interview has been obtained from the patient or designee of the patient, a complete and thorough focused physical assessment must take place. A

physical examination begins with a general inspection of the posture, gait, joint mobility, and skin. It involves looking for symmetry of movement, involuntary movements, deformity, swelling/edema, discoloration, and hypertrophy/atrophy. Palpation is also an important part of the physical examination to assess muscle tone and strength, range of motion, sensation, skin temperature, and quality of pulses. The examination is usually completed in a sequential order and notes any pain or discomfort present without stimulus and/or evoked during the process.

### Posture

Posture is the position in which minimum stress is placed on each joint in the body. In 1949, the American Academy of Orthopaedic Surgeons defined good posture as a state of muscular and skeletal balance that protects the supporting structures of the body against injury or progressive deformity. Good posture maintains the body's alignment in sitting, standing, and prone and supine positions; poor posture causes compensation on other bones, joints, and muscles, which can result in damage to a structure. To assess the posture of a patient, the patient should stand comfortably erect as appropriate for age. A plumb line (imaginary or actual) should be drawn through the anterior ear, shoulder, hip, patella, and ankle. Curvature of the spine as well as the length, symmetry, and movement of the extremities should be noted (Fig. 52.13).

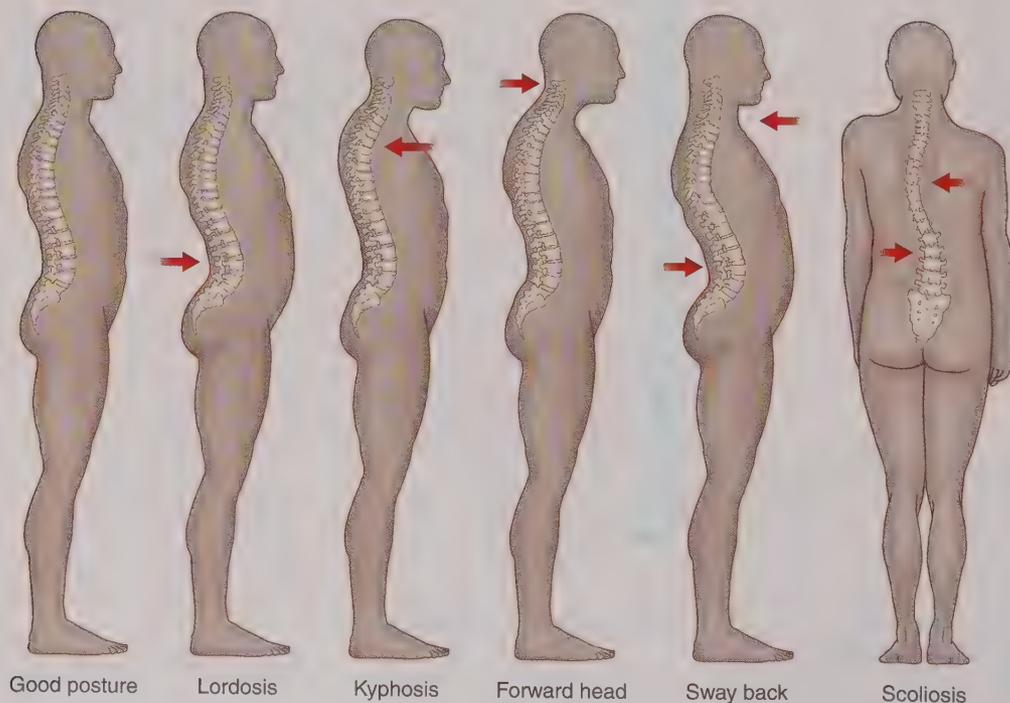

### Gait

Gait is described as the patient's ability to demonstrate an erect stance and swing phase with walking. The stance

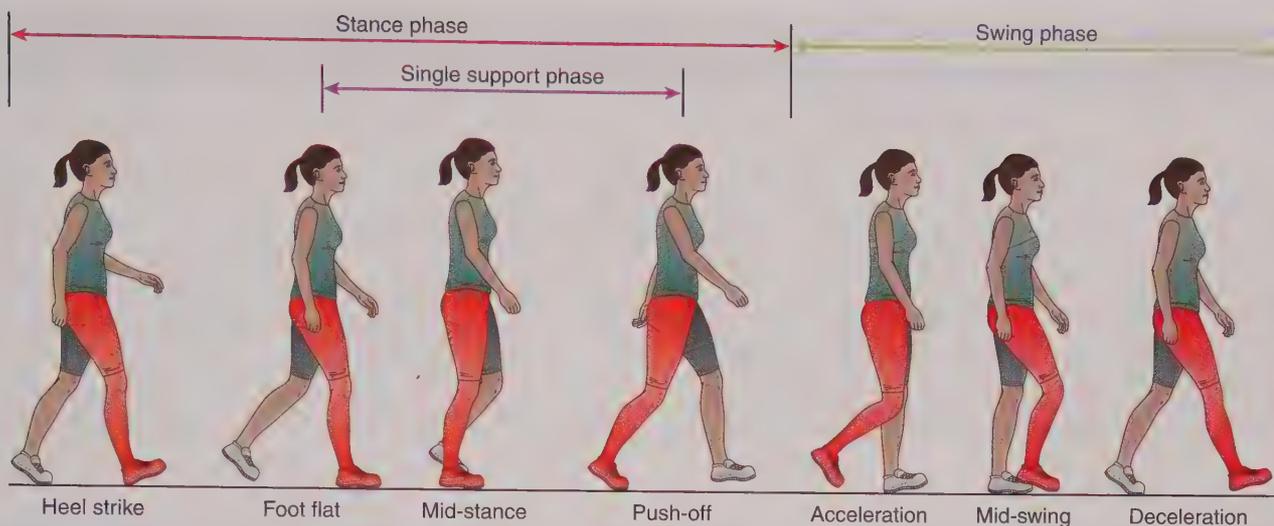

phase, 60% of the cycle, is when the foot is on the ground. The swing phase is defined as the time when the foot is not on the ground. Assessment of gait must be done by directly observing the patient walking. Normal gait is assessed first by noting the base of the walking movement. The base is said to be as wide as the shoulder width of the patient. Foot placement is accurate, and the walk is smooth, even, and well balanced in a patient with a normal gait. A symmetrical arm swing should also be noted during assessment and observation of a patient's gait status (Fig. 52.14).

### Joint Mobility

Joint mobility is an essential part of the assessment process for the musculoskeletal system. Movement for joints is deliberate, accurate, smooth, and coordinated. Assessment of ROM or joint mobility should be completed while stabilizing the body part proximal to the joint being assessed. Familiarity with each type of joint in the body is essential so that abnormalities may be readily identified. Joint motion is not expected to cause pain or discomfort upon movement. A **goniometer** is an instrument that is used to measure the angles that a patient is able to achieve with the movement of each specific joint (Fig. 52.15). To use the goniometer, the provider extends the joint being assessed to a neutral or zero-degree position. The zero-degree point of the goniometer is centered on the joint. With the limb kept at a zero-degree line on the goniometer, the moveable arm is used as a measuring device. When using the goniometer for assessment, flex the joint and measure the angle of greatest flexion.

**FIGURE 52.13** Assessing postures.

**FIGURE 52.14** Assessing for normal walking gait.

**FIGURE 52.15** Goniometer to assess joint mobility.

### Connection Check 52.2

The functions of the musculoskeletal system include which of the following? (Select all that apply.)

- A. Provides stability
- B. Facilitates movement
- C. Hormonal control
- D. Maintains cardiac output
- E. Facilitates digestion

### Sensation

Evaluation of sensation is another key indicator regarding skeletal bone function. Numbness or tingling (**paresthesia**) is an abnormal assessment finding when evaluating the musculoskeletal system. Paresthesia often indicates damage to a sensory nerve by pressure or fracture and often resolves after treatment of the injury has been initiated. Assessing the patient's ability to determine the presence of a stimulus is also important. The pinprick test may be used. With the use of a paper clip or other specific instrument designed specifically for this purpose, a stimulus is applied to assess whether the patient is able to feel the stimulus equally and symmetrically near the suspected area of injury. The inability to feel sensation is an indicator that sensory nerve damage may be present.

### Pulse Assessment

An assessment of pulses in the patient's extremities is a standard part of the physical examination. It is particularly important to assess the pulses when injury or suspected injury is present. Pulses indicate whether blood flow is adequate to an extremity. Pulse assessment is done using two fingers and avoiding the use of the thumb because it has its own pulse, which may be misleading. It is important to assess the pulse rate, rhythm, depth, and symmetry.

### Muscle Tone and Strength

Tone is the normal degree of tension (contraction) in voluntary relaxed muscles. Muscle tone may be found to be increased or decreased. Assessing for increased tone is usually a bit easier to detect. Ask the patient to completely relax all muscles, or "go limp." The practitioner then takes the extremity and moves it through a full ROM. It is expected in a normal examination that the practitioner will note a mild, even resistance to movement. Notations should be made for any extra or involuntary movements of the muscles if they are present.

Muscle strength is tested by having the patient resist force as the practitioner attempts to move the patient's body part against the direction of pull. Muscle strength should be equal bilaterally. Muscle strength is graded on a 0 to 5 scale, with 0 representing no contraction of muscle and 5 representing full ROM against resistance. A grade of "5" is considered to represent normal muscle strength. Oftentimes, it is easier to determine the presence of muscle weakness when there is a normal side present from which to compare. Table 52.1 summarizes the grading scale for muscle strength evaluation in adults.

**Table 52.1 Muscle Strength Grade Table**

Grade	Examination Result	Assessment Result
5	Full range of motion against full resistance	Normal
54	Full range of motion against some resistance	Good
53	Full range of motion against gravity but not resistance	Fair
52	Full passive range of motion but not against gravity or resistance	Poor
51	Slight contraction but no movement	Trace
50	No visible contraction	Zero

### Connection Check 52.3

The assessment of the musculoskeletal system begins with which of the following?

- Comprehensive assessment of medical history
- Comprehensive assessment of pain
- Comprehensive assessment of movement
- Comprehensive assessment of bone integrity

### Connection Check 52.4

Comprehensive assessment of ROM by the practitioner provides what information?

- Detailed information regarding tendon function
- Information regarding muscle strength and tone
- Information regarding the health of the joint space
- Information regarding the condition of the ligaments

**Safety Alert** If you suspect an acute bone injury:  
● Immobilize the extremity

- Control bleeding if present
- Elevate above the level of the heart, if possible
- Apply ice/cold packs to extremity with cloth covering tissue to prevent possible frozen tissue injury
- Refer for emergency medical evaluation

## DIAGNOSTIC STUDIES

### Laboratory Studies

Bones are the major source of calcium in the body. Adequate calcium levels are essential for bone health. Assessing calcium levels through blood tests is an important indicator of bone integrity or density. Low calcium levels are an indicator of increased fracture risk. In addition to calcium, phosphorus and vitamin D levels are all common laboratory values used to assess bone health. Vitamin D works in the

body to promote the gastrointestinal absorption of calcium and phosphorus. In a healthy individual, calcium and phosphorus have an inverse relationship, meaning that while calcium levels rise, phosphorus levels decrease. The hormones calcitonin and parathyroid hormone work together to keep the equilibrium of calcium and phosphorus. These concepts are discussed in detail in Chapter 40. Estrogens also play an important role in stimulating osteoblast activity. The decrease of estrogens with menopause increases fracture risk. Assessing estrogen levels is primarily done through an analysis of urine.

### Imaging Studies

#### X-Ray

Obtaining images of a part of the musculoskeletal system is often needed to find a specific injury or confirm the presence of an abnormality. These images assist the practitioner in assessing the full extent of the injury/abnormality that is present so that effective treatment may be initiated.

#### Preparation of Patient/Nursing Implications

- Removal of clothing or jewelry from the site to be x-rayed because they can potentially obscure the image.
- Proper shielding of the patient is required to limit the degree of radiation exposure. Lead aprons are applied to cover the ovaries or testes. Thyroid glands are also covered in an attempt to prevent potential damage to these sensitive structures.

#### Computed Tomography

A computed tomography (CT) scan combines a series of x-ray views from different angles to produce cross sectional images of bones and soft tissues within the body. The addition of contrast material can be used to identify blockages or other blood vessel abnormalities. Computed tomography scans are done to diagnose muscle and bone disorders including tumors and fractures. Computed tomography-guided biopsy may also be completed for selected patients with known tumors. Abnormal values are defined as any fracture, break in bone surface, or presence of other structure that is not expected to be there, for example, neoplasms.

## Preparation of Patient/ Nursing Implications

- Patient education regarding test to be performed
- If contrast is to be used, see Safety Alert

**Safety Alert** There are several nursing implications important to be aware of for any imaging study:

- Assess pregnancy status. Fetuses are susceptible to injury from x-rays or imaging studies.
- Assess for allergies
- Assure consent has been signed if required for procedure
- Many imaging studies require the administration of IV contrast to improve visualization of structures. Contrast dye is nephrotoxic and can also have a negative impact if administered to a patient receiving metformin. If contrast dye is to be used, the nurse should:
  - Ensure insertion of IV if IV contrast is to be administered
  - Assess for allergies to contrast dye
  - Assess patient's renal status
  - Verify whether the patient is taking metformin. Contrast medium can greatly increase the level of metformin in the blood. In addition to the potential of hypoglycemia, increased levels can also increase the patient's chances of developing lactic acidosis. Metformin should be stopped before the procedure and held for 48 hours after the procedure.
  - Encourage fluids after the examination if contrast dye is used

## Magnetic Resonance Imaging

Magnetic resonance imaging is a radiological imaging test that uses a magnetic field and radio wave energy to create pictures of internal structures of the body. The pictures from an MRI often provide more detail than those from other imaging methods. It is used to diagnose disk disease, tumors, osteomyelitis, and ligamentous tears. The scanner is typically a long tube-like structure. Many patients have difficulty with the claustrophobic feeling they experience from being in a closed space. These patients may require sedation to complete the MRI. Open MRI machines are available in some areas and allow the patient to complete the examination in the open, thereby limiting feelings of claustrophobia.

### Preparation of Patient

- Patient education regarding the loud banging sounds that will be heard during the examination
- No food or drink for 8 hours before the test for patients having an MRI of the abdomen or pelvis
- Ensure that there is a family member or friend to drive the patient home after the test if sedation is administered

## Nursing Implications

- Assessment of the potential for claustrophobia
- Assess the patient for any metal objects such as hairpins, earrings, pacemaker, metal clips (surgically implanted), metal heart replacement valves, and intrauterine device. External metal objects need to be removed because they might interfere with the magnetic imaging. The decision to do the test with internal metal in place is made on an individual basis, but MRI may de-program pacemakers.
- Assess for the presence of any medication patches. A burn at the site may occur if the patch is left in place.

## Arthrogram

An arthrogram is a series of images taken of a joint after contrast medium has been injected. After administration of local anesthetic, a radiologist or orthopedic provider uses fluoroscopy or ultrasound to accurately inject the appropriate quantity of contrast into the joint. This procedure allows for visualization of soft tissue structures of a joint: the tendons, ligaments, muscles, cartilage, and joint capsule. An abnormal result can reveal degenerative changes in the cartilage, a partial or complete tear, an enlarged or ruptured joint capsule, or a joint cyst. Pieces of bone, cartilage, tumor, or tissue may also be seen in the joint space with this examination.

### Preparation of Patient

- Education regarding the procedure
- Remove objects or clothing from the joint area

### Nursing Implications

- Verify whether the patient is taking any anticoagulants including aspirin
- Ensure "time-out" taken by staff before the start of the procedure to confirm the right patient, right procedure, and right anatomical location
- Provide post procedure instructions and information regarding joint pain for 1 to 2 days after the procedure

## Bone Mineral Density Studies

Radiological examinations using CT scans, dual-energy x-ray absorptiometry (DEXA) scans, and ultrasound can assess bone density or the amount of calcium and other minerals in the bone. The most common test is the DEXA scan. Low bone density is an indicator of the presence of osteoporosis and increased fracture risk. The bones most often used for this test are located in the spine, the hip, the hand, the foot, and the forearm. The test is painless for the patient and takes less than 30 minutes in most cases. This test is done to both identify patients with osteoporosis and to monitor treatment progress.

Results for bone scans are reported in T scores and Z scores. A T score is a determination of bone density compared with what is expected in a healthy young (approximately 30-year-old) adult of the same sex. A Z score is a comparison of what is expected for a patient of the same age, sex, weight, and racial origin. Because a low bone

mineral density is more common in older adults, the Z score can be misleading when diagnosing osteoporosis. A low Z score,  $-2$  or lower, may suggest that something other than aging is causing abnormal bone loss and requires close examination by the practitioner. The determination of osteoporosis is typically done through the T score. Table 52.2 illustrates the interpretation of T score results for osteoporosis.

### Preparation of Patient/Nursing Implications

- Patient education regarding test and potential results
- Notify the practitioner of any recent examination completed that required contrast because contrast material can sometimes interfere with accurate test results

### Bone Scan

A bone scan is a diagnostic scan to find damage to bones, disease (such as cancer), infection, or trauma. A radioactive material, a tracer, is injected IV. The tracer travels through the body and after approximately 3 hours is absorbed into the bones. The bone images are then completed. Areas that show little or no amount of tracer appear as dark or “cold” spots. These areas of “cold” spots define areas with a lack of blood supply to the bone and may indicate the presence of cancer. “Hot spots” are areas where the tracer accumulates in the bone. These spots are often attributed to fractures that are healing, bone infection, or diseases of bone metabolism. Hot spots, as cold spots, may also indicate bone cancer and need further evaluation.

### Preparation of Patient

- Patient education regarding the test. If the patient is breastfeeding, the nurse needs to instruct the patient to use formula and discard the breast milk for the next 48 hours until radioactive tracers are removed from the body.
- Ensure insertion of IV
- Verify that the consent for the test has been signed

### Nursing Implications

- Verify that the patient has not had a procedure or taken a medication with bismuth in the last 72 hours because this can interfere with the test
- Increase fluids post-test to help excrete the radioactive tracer from the body

**Table 52.2 Interpretation of Bone Density Study Results**

T Score	Interpretation
$-1$ and greater	Bone density within normal limits
$-1$ to $-2.5$	Indicates a sign of osteopenia, a condition that may lead to osteoporosis
$-2.5$ and below	Indicates presence of osteoporosis

### Electromyography

Electromyography (EMG) is a diagnostic test that assesses the health of motor neurons and muscle. Motor neurons transmit electrical signals to the muscles that make them contract. Using tiny needle electrodes that are strategically placed on the muscles, the EMG machine translates these signals into graphs or numbers that the practitioner interprets. This test takes approximately 30 to 60 minutes and is done to distinguish nerve dysfunction, muscle dysfunction, or problems with nerve-to-muscle signal transmission. It is expected that an EMG recording will show no electrical activity when a muscle is at rest. Abnormal electrical activity seen in muscles at rest may indicate a problem with the nerve supply to the muscle. Abnormal wave lines with muscle contractions may indicate a muscle or nerve problem such as amyotrophic lateral sclerosis, inflammation, or other muscle problems.

### Preparation of Patient

- Education regarding the test:
  - There is a possibility of slight pain on needle insertion.
  - Slight bruising at the site where the electrodes were placed may occur.
  - Shower before the test and do not apply any lotions to allow for better electrode contact.
  - Do not eat or drink foods or fluids that contain caffeine 2 to 3 hours before the test.

### Nursing Implications

- Verify that the patient does not have a pacemaker or bleeding disorder
- Verify medications patient is taking because some may interfere with muscle contraction
- Assess for pain during and after testing

### Arthroscopic Examination

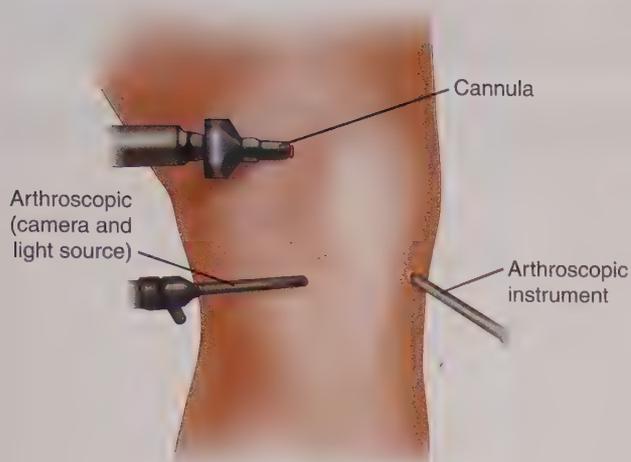

Arthroscopy is a surgical procedure that allows a practitioner to view the inside of a joint through an instrument called an arthroscope (Fig. 52.16). This procedure is used to diagnose, repair, and remove loose or foreign materials in the joint. It may also be used to monitor the progress of a previously diagnosed disease. Abnormal findings during an arthroscopic examination include abnormal color/shape of the ligaments and cartilage, the presence of growths or cysts, evidence of joint dysfunction such as arthritis, and the presence of infection.

### Preparation of Patient

- Education regarding the procedure
- Standard preoperative protocols according to the institution
- Ensure consent has been signed

### Nursing Implications

- Assess patient medications; special concern with anticoagulants and aspirin because these increase the risk of postoperative bleeding
- Assess pregnancy status

**FIGURE 52.16** Arthroscopic surgery allows visualization inside of the joint to diagnose, repair, and/or remove loose or foreign materials.

- Verify last time the patient had food or drink. Patients can be at risk for aspiration if food/drink is ingested less than 12 hours before surgery.
- Ensure that “time-out” is taken by staff before the start of the procedure to confirm the right patient, right procedure, and right anatomical location
- Verify that the patient has not had a test such as an arthrogram in the previous 10 days on the affected joint. Contrast may cause inflammation and cause difficulty with visualization of the joint.
- Discharge instructions to include:
  - Apply ice to site for the first 1 or 2 days; do not apply ice directly to the skin—use a towel between the skin and ice
  - Elevate leg
  - Follow provider advice regarding weight bearing
- Ensure that there is a family member or friend to drive the patient home after discharge

## Arthrocentesis

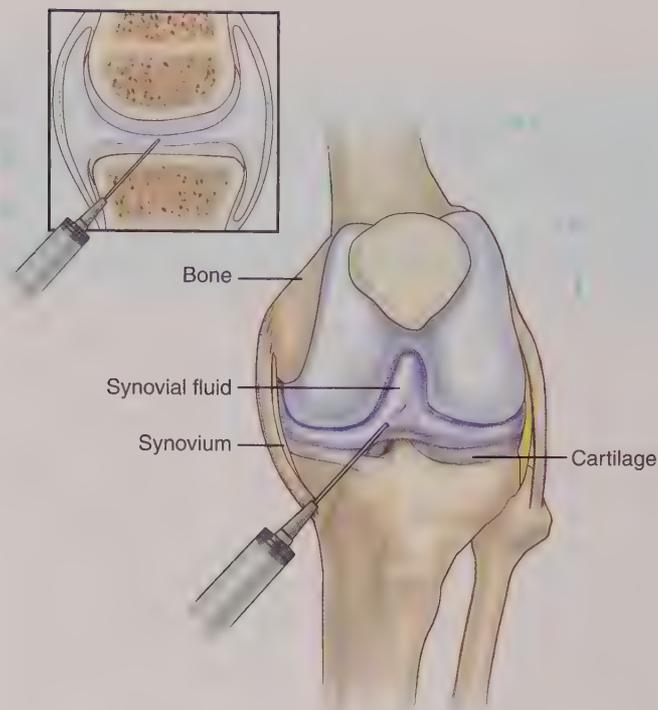

Arthrocentesis is a clinical procedure where fluid is aspirated from a joint (Fig. 52.17). This procedure is done for diagnostic reasons as well as for pain relief. The most common reason for an arthrocentesis is to diagnose gout, arthritis, and synovial infections. This test may be done under guided fluoroscopy or with no imaging guidance at all. Abnormal results for this test include greater than expected amounts of fluid present, abnormal color of joint fluid (i.e., red or cloudy), or purulent fluid.

### Preparation of Patient

- Education regarding the procedure
- Positioning of the patient to assure best access to joint to be examined

### Nursing Implications

- Assess whether patient is taking any medications, especially anticoagulants or aspirin

**FIGURE 52.17** Arthrocentesis; a procedure to aspirate fluid from a joint for diagnostic reasons as well as for pain relief.

- Ensure “time-out” before the start of the procedure to verify right patient, right procedure, and right anatomical location
- Postprocedure instructions from the practitioner to include the application of ice to the wound for the first 24 hours postprocedure; do not apply ice directly to the skin—use a towel between the skin and ice

## Connection Check 52.5

The nurse anticipates which follow-up test after a postmenopausal woman presents with a tibial fracture confirmed by x-ray?

- Bone scan
- Arthrogram
- EMG
- DEXA scan

## AGE-RELATED CHANGES OF THE MUSCULOSKELETAL SYSTEM

Obvious changes with the musculoskeletal system while people age include changes in bone density, posture, and gait. From age 30, bone density begins to diminish. The loss of bone density accelerates in women after menopause because of loss of estrogen. These are not always obvious bone changes that occur in mass or density. Also, while

patients age, changes in the cartilage and connective tissue within the bones begin to take place. The joint cartilage decreases in mass because of a decrease in bone mineral content, making joints thinner and more likely to fracture. Joints become stiffer and less flexible because fluid often decreases in the joint spaces. Minerals may also deposit in and around some joints, which is known as calcification. Degenerative changes are often noted while joint cartilage begins to be lost. Connective tissues within ligaments and tendons lose water content and become more rigid. Older persons with advanced bone loss including osteoporosis may develop a hump in the upper back, called a **Dowager's hump**.

Muscle fibers gradually decrease in size, number, and contractility starting at approximately age 30. **Sarcopenia** is a medical term often used to describe a decline in muscle mass and strength associated with aging. This identified loss of strength places more stress on an individual's joints and predisposes to arthritis and falling, two major concerns of aging. Regular weight-bearing exercise, vitamin D/mineral supplementation, and follow-up with a practitioner on a regular basis are all necessary to maintain a healthy, functional musculoskeletal system.

## Making Connections

### CASE STUDY: WRAP-UP

Abby returns to the ED after her MRI. Results are returned shortly and confirm that Abby has a medial meniscus tear of her left knee. She is promptly fitted for crutches and is given detailed instructions for care at home that include ice, elevation, and immobilization as well as strict follow-up instructions to see an orthopedic surgeon in the next 48 hours.

#### Case Study Questions

- Signs and symptoms of an acute knee injury include which of the following?
  - Pain that is transient
  - Inability to bear weight
  - Loss of popliteal pulse
  - An unsteady gait
- The ED nurse anticipates the orthopedic surgeon will perform which diagnostic procedure for further analysis of Abby's injury?
  - Bone scan
  - X-ray
  - Arthroscopy
  - Arthrocentesis
- Abby's nurse in the ED provides discharge instructions that include which of the following?
  - Exercise the joint as tolerated
  - Follow-up with her primary care doctor after swelling has decreased
  - Ice, elevation, and follow-up with an orthopedic surgeon within 48 hours
  - Application of warm packs and keeping the leg in a dependent position as often as possible
- The nurse should intervene if she notices that Abby has which of the following?
  - Increased pain after immobilization and ice application
  - Worry about her soccer career
  - Her leg elevated above the level of her heart
  - Developed some nausea
- Which statement by Abby indicates that the discharge teaching has been ineffective?
  - "Elevation and application of ice to the knee will help decrease swelling."
  - "Crutches are optional and should be used only if needed."
  - "Follow-up with an orthopedic surgeon within 48 hours is essential."
  - "Take pain medication and immobilize the leg."

**Safety Alert** The following things can be done to help prevent falls in older adults:

- Exercise regularly:** Regular exercise increases joint flexibility, muscle strength, and balance.
- Review medications:** Identification of over-the-counter and prescription medications that may increase dizziness or drowsiness, which predisposes patients to a fall, is essential for safety.
- Yearly eye examinations:** Yearly eye examinations maximize vision and decrease the possibility of falls due to visual impairment.
- Home safety review:** Review the home environment to assess for tripping hazards from rugs and furniture; placement of grab bars in bathrooms around toilets, baths, or showers; and the presence of railings and adequate lighting. Attention to these items can decrease the risk of a fall in the home.

### Connection Check 52.6

What are the most important supplements for bone health for patients of advancing age?

- Calcium and vitamin D
- Omega-3 fish oil and vitamin D supplements
- Phosphorus and calcium
- Phosphorus and omega-3 fish oil supplements

## CHAPTER SUMMARY

The musculoskeletal system, the second largest system of the body, is a group of structures performing in perfect precision allowing for movement, protection of vital organs, production of blood cells in the marrow, support for standing erect, and finally, a reservoir of storage for essential minerals in the bones. The skeleton forms the framework of the human body and consists of 206 bones. These bones support the integumentary system of the body and allow for upright posture and weight bearing.

Muscles are structures that contract and help produce movement. There are three types of muscles present in the human body: skeletal muscle, smooth muscle, and cardiac muscle. The main function of skeletal muscle is movement of the body or its parts under conscious or voluntary control. Smooth muscle is involuntary muscle under the control of the autonomic nervous system which controls contractions of organs and blood vessels automatically. Cardiac muscle is specialized striated muscle that can contract without neural stimulation because of the property of automaticity. Automaticity allows cardiac tissue to set a contraction rhythm through the presence of pacemaker cells.

Joints are defined as a place of union between two or more bones. They permit mobility and provide mechanical

support. Ligaments are present at joints to help provide stability to the joint. These fibrous bands composed of tough collagen fibers run directly from one bone to another to reinforce the joint and help prevent undesired directional movements. Tendons are fibrous connective tissues that connect muscle to bone or structures such as the eye.

As with any thorough assessment of a system of the human body, the first step is obtaining the patient's history. After a complete and thorough interview has been obtained from the patient or designee of the patient, a complete and thorough focused physical assessment must take place. A physical examination includes a general inspection of posture, gait, symmetry, joint mobility, bone assessment, and sensation. Inspection includes noting the presence of symmetry, involuntary movements, deformity, swelling/edema, discoloration, hypertrophy/atrophy, and posture/alignment. Palpation is also an important part of the physical examination to assess muscle tone and strength as well as presence of bone integrity. A final part of the physical assessment is radiographical diagnostic studies such as x-rays, CT scans, or MRI. Specialized musculoskeletal studies include arthroscopic examination, electromyography, bone scan, and bone mineral density studies.

# Chapter 53

## Coordinating Care for Patients With Musculoskeletal Disorders

*Regina Twigg*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of musculoskeletal disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Muscular dystrophies
  - b. Osteoporosis
  - c. Paget's disease
  - d. Osteomyelitis
  - e. Scoliosis
  - f. Total joint replacement
  - g. Bone cancer
3. Describing the diagnostic results used to confirm the diagnoses for musculoskeletal disorders
4. Discussing the medical management of:
  - a. Muscular dystrophies
  - b. Osteoporosis
  - c. Paget's disease
  - d. Osteomyelitis
  - e. Scoliosis
  - f. Total joint replacement
  - g. Bone cancer
5. Developing a comprehensive plan of nursing care for patients with musculoskeletal disorders
6. Designing a plan of care for patients with musculoskeletal disorders that includes pharmacological, dietary, and lifestyle considerations
7. Coordinating the interprofessional plan of care for the patient undergoing joint replacement surgery

### ESSENTIAL TERMS

Arthroplasty  
Bone mineral density (BMD)  
Bone remodeling  
Cobb's angle  
Dual-energy x-ray absorptiometry (DEXA) scan  
Dystrophin  
Muscular dystrophy (MD)  
Osteoblastic  
Osteoblasts  
Osteoclastic  
Osteoclasts  
Osteomyelitis  
Osteopenia  
Osteoporosis  
Osteosarcoma  
Osteotomy  
Paget's disease of the bone (PDB)  
Scoliosis  
Spinal instrumentation  
Spinal stabilization  
Thoracic-lumbar spinal orthotic (TLSO)  
Total joint replacement (TJR)

### CONCEPTS

- Assessment
- Cellular Regulation
- Infection
- Medication
- Mobility
- Nutrition
- Perioperative
- Promoting Health

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Eileen Doherty is a 55-year-old female patient who presents to her healthcare provider with complaints of increasing difficulty in walking and increasing pain in her lower back. She shows early signs of kyphosis in her posture. She is currently on no medications and states she takes a multivitamin and calcium “when she remembers them.” Eileen has annual checkups with her healthcare provider, and despite her relatively good health, she is concerned about the recent pain and resulting limitations on her activity level...

## INTRODUCTION

Musculoskeletal disorders are important to discuss because they impact our ability to move and thus affect our ability to perform activities of daily living. Weakness, pain, or infection affects our movement and/or bone strength, at times limiting our ability to walk. Although not life threatening, foot problems (Table 53.1) or foot pain is a common complaint with many causes. As with other musculoskeletal

disorders, however, they can negatively impact our ability to move freely.

This chapter discusses disorders resulting in muscle weakness, weakened bone, disorders that are the result of infection, and musculoskeletal problems that result in pain.

## MUSCULAR DYSTROPHIES

### Epidemiology

**Muscular dystrophy (MD)** is a disease with many different subtypes that affect certain muscle groups, are age specific in relation to presenting symptomatology, have variations in severity, and are caused by a defect in different genes. They are classified as an inherited group of progressive myopathic (muscle) disorders that are caused by imperfections in normal muscle function. The primary symptoms are progressive muscle weakening and wasting of skeletal or voluntary muscle groups. Muscular dystrophy can appear at any age from infancy until middle age and beyond. The type of MD and its severity are partially determined by age at onset. Some people with MD have rapidly progressive muscle weakness and wasting and die young, in their 20s. Others experience mild, slowly progressing symptoms and have a normal life span.

Overall, the different types of MD affect more than 50,000 Americans. The most severe forms of MD are Duchenne and Becker. Duchenne muscular dystrophy (DMD) is the most well-known form and is the most common in children. It occurs in one of every 7,250 males between the ages of five and 24. The prevalence for females

**Table 53.1** Foot Disorders

Disorder	Description	Symptoms	Management
<b>Hallux valgus (Bunion)</b>	A deformity or lateral deviation in the first metatarsophalangeal joint	Pain at the affected joint	Conservative treatment includes wearing footwear that provides adequate space, foot padding, splinting, foot exercises, and nonsteroidal anti-inflammatories. Surgery is an option if pain or functional disability progress.
<b>Plantar fasciitis</b>	Inflammation of the plantar fascia, the thick band of tissue that connects your heel to your toes	Stabbing heel pain that is typically worse with the first steps in the morning, decreasing in severity while the foot loosens up	Conservative therapies include physical therapy, night splints that stretch the calf and arch of the foot, orthotics, and nonsteroidal anti-inflammatories
<b>Morton's neuroma</b>	A neuroma or thickening of nerve tissue that occurs between the third and fourth toes	Pain, tingling, burning, or numbness, and/or a feeling that something is inside the ball of the foot or something is bunched up in the shoe under the ball of the foot	Conservative treatment includes padding to support the metatarsal arch, icing the affected area, orthotics, nonsteroidal anti-inflammatories, or injections of cortisone or local anesthetics into the affected area
<b>Flatfoot (pes planus)</b>	Loss of metatarsal arch	Pain in the foot primarily in the heel or arch	Treatment includes orthotics to provide arch support, stretching exercises, and a structurally supportive shoe

is three per 100,000. Approximately two-thirds of all cases have a genetic component, and the remaining one-third of the reported cases are found to be caused by new genetic mutations. Becker MD is also primarily prevalent in males and typically occurs in childhood. Myotonic dystrophy is the most common form of MD found in adults. The inherited X chromosome link is the only known associated risk factor (see Genetic Connections: Muscular Dystrophy).

## Genetic Connections

### Muscular Dystrophy

The Duchenne and Becker muscular dystrophies (MDs) are caused by a mutation to the dystrophin gene. Dystrophin is a protein responsible for muscle repair. Persons affected by MD are lacking the dystrophin gene, thereby resulting in the inability to repair muscle. Both Duchenne and Becker MDs are inherited X-linked recessive traits; the gene responsible for these conditions is located on one of the two sex chromosomes, the X chromosome. Because males have only one X chromosome, one altered gene can cause the disorder. Females have two X chromosomes. The gene mutation has to be present on both to cause the disorder. Because of this, MDs are far more common in boys. Females can be carriers but are not typically affected by the disease. The diagnosis of MD usually includes genetic testing. Genetic counseling is recommended for those with a family history of MD.

### Connection Check 53.1

The nurse recognizes which patient is at greatest risk for development of DMD?

- A. Female at birth
- B. Male at birth
- C. Female at adolescence
- D. Male at adolescence

### Pathophysiology

The Duchenne and Becker muscular dystrophies (MDs) are caused by a mutation to the dystrophin gene. **Dystrophin**, a protein responsible for muscle repair, is located on the plasma membrane of muscle fibers and provides reinforcement and stabilization of the glycoprotein complex (a molecule that contains carbohydrate and protein). In the absence or reduction of dystrophin, the glycoprotein complex is digested by proteases, which causes degeneration of the muscle fibers resulting in muscle weakness. The primary commonalities among all the MD disorders are progressive

muscle weakness, muscle wasting, and increased muscle enzyme serum levels. With the wasting and breakdown of muscles, serum enzymes such as creatine kinase (CK), lactate dehydrogenase (LD), alanine aminotransferase (ALT), aspartate aminotransferase (AST), and aldolase are elevated and are used in clinical practice to measure the extent of damage and/or deterioration.

### Clinical Manifestations

There are nine subgroups of the MDs. Each has a distinct clinical presentation; however, all present with progressive muscle weakness and all typically present with chronic pain, most notably in the lower back and legs. See Figure 53.1 for areas of muscle weakness associated with each subgroup of MD.

The nine subgroups of MD are as follows:

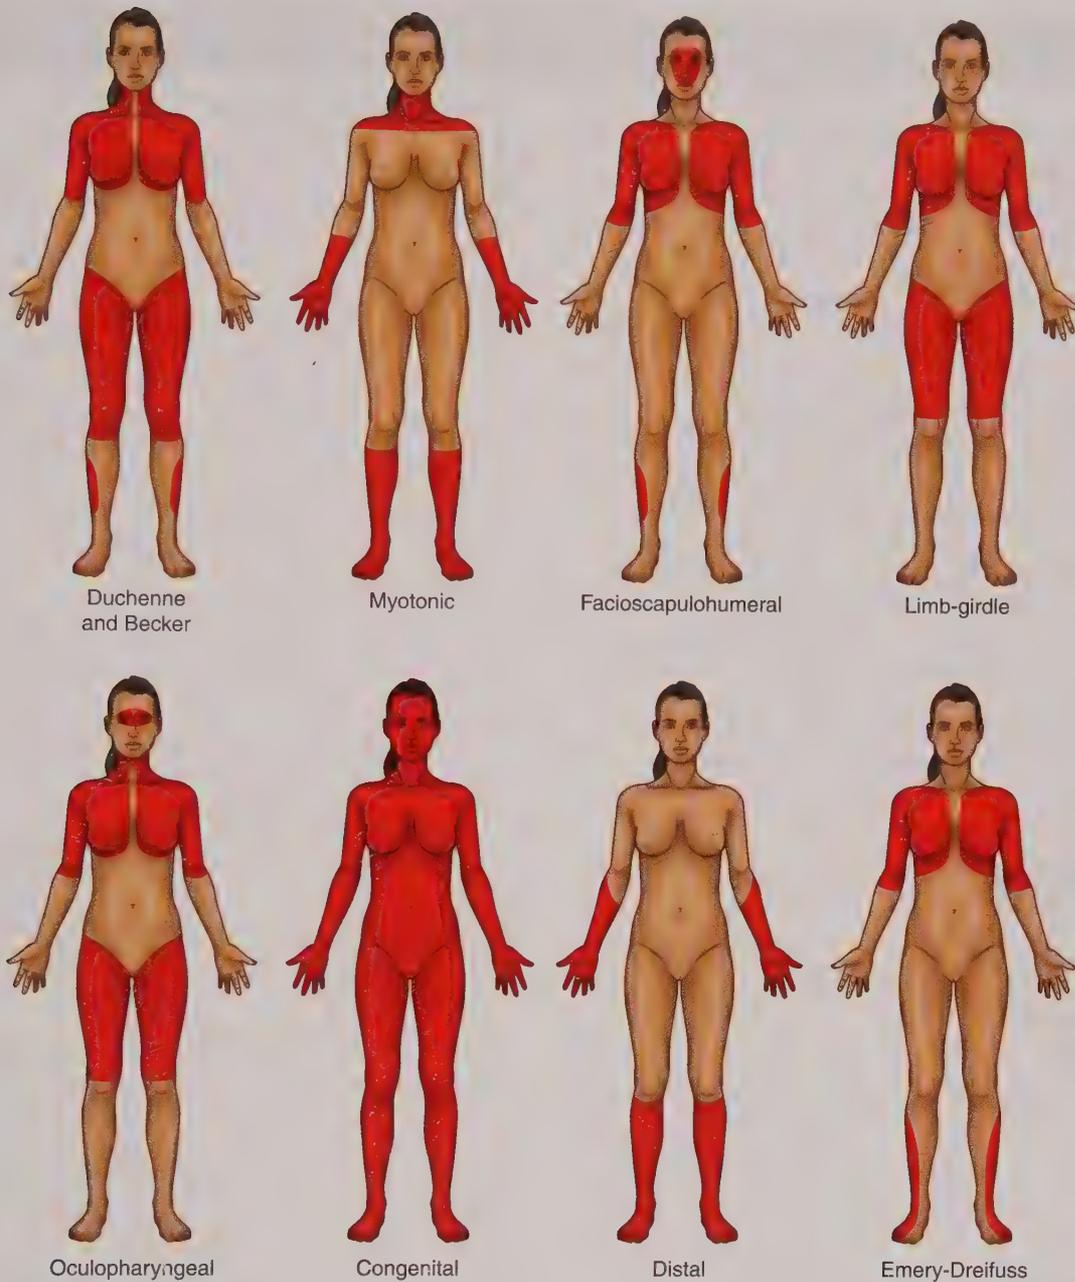

- Duchenne
- Becker
- Myotonic
- Facioscapulohumeral
- Limb-girdle
- Oculopharyngeal
- Congenital
- Distal
- Emery-Dreifuss

With progressive deterioration and weakness to the facial, limb, respiratory, and cardiac muscles, the ultimate result is muscular damage. This is caused primarily by the lack of the key protein (dystrophin) to maintain the integrity of the muscle fibers as well as the ability to repair muscle tissue while it breaks down and/or deteriorates. Muscle bulk is reduced, resulting in fat and excessive scar tissue. Because of progressive muscle wasting and weakness, falls are often associated with MD, which puts patients at risk for fractures. Progressive deterioration of facial muscles is associated with problems with dental hygiene, speech clarity, and articulation. As a result of immobility, gastrointestinal (GI) dysfunction is often associated with MD. The most life-threatening result of this progressive deterioration is the cardiopulmonary compromise that occurs as a result of the development of cardiomyopathy. Cardiomyopathy, a form of heart disease that presents with weakened heart muscle and decreased pumping ability, results in arrhythmias, shortness of breath, and extreme fatigue. Refer to Table 53.2 for a summary of the subtypes of MD.

### Connection Check 53.2

The nurse recognizes that which of the following pathophysiological manifestations are associated with MD? (Select all that apply.)

- A. Decreased tissue oxygenation
- B. Decreased blood flow to muscles
- C. Degeneration of muscle fibers
- D. Decrease in enzyme activity
- E. Increased muscle bulk

**FIGURE 53.1** Main areas of muscle weakness in different subtypes of muscular dystrophy.

## Management

### Medical Management

#### Diagnosis

Diagnosis of MD usually begins with a preliminary review of serum muscle enzymes such as CK, which is usually an early sign of the disease and requires frequent and close monitoring. Other serum enzymes such as LD, ALT, AST, and aldolase are elevated and are frequently evaluated in clinical practice to monitor for muscle wasting and/or deterioration. Recent literature supports monitoring serum creatinine levels as a differential diagnosis between Duchenne and Becker MD, as well as a prognostic indicator of severity of disease progression. Other diagnostic studies such as chest x-ray, electrocardiogram, computed tomography (CT), and

electromyography are frequently warranted to determine the extent of muscle wasting or the presence of cardiopulmonary compromise associated with the disease.

The Muscular Dystrophy Association and Center for Disease Control and prevention suggest early screening, diagnosis, and intervention. A definitive diagnosis for MD is often difficult secondary to the fact that the clinical presentations for all MDs are similar in nature. Among the medical community, the gold standard is the muscle biopsy in which a small piece of muscle tissue is extracted and examined for changes in the structure of the muscle cells. If MD is present, changes are visible, and the biopsy can begin to detect the form of MD present in the tissue sample. The diagnostic criteria for nearly all MDs now incorporate genetic testing (see Genetic Connections: Muscular Dystrophy).

**Table 53.2 Subgroups of MD in the Adult Population and Clinical Presentation**

Type	Onset	Clinical Presentation
<b>Duchenne muscular dystrophy (DMD)</b>	2–4 years of age	<ul style="list-style-type: none"> <li>● Limb muscle weakness (proximal more than distal)</li> <li>● Positive Gowers' sign (muscle weakness of the proximal muscles, more commonly seen in lower limbs)</li> <li>● Calf enlargement</li> <li>● Leg pain</li> <li>● Progressive scoliosis</li> <li>● Equinovarus (clubfoot) deformities of the feet</li> <li>● Mental retardation</li> <li>● Progressive cardiomyopathy</li> <li>● Respiratory failure</li> </ul>
<b>Becker muscular dystrophy (BMD)</b>	Delayed onset, slower progression 5–25 years of age	<ul style="list-style-type: none"> <li>● Similar symptoms as DMD</li> <li>● Milder, slower progression</li> <li>● Muscle wasting affecting hips, pelvic area, thighs, and shoulders</li> <li>● Calves enlarged</li> <li>● Cardiac involvement less common, but if present more severe</li> <li>● Mental retardation less common</li> </ul>
<b>Emery-Dreifuss muscular dystrophy (EDMD)</b>	Delayed onset, slower progression Usually seen by 10 years of age	<ul style="list-style-type: none"> <li>● Wasting and weakness of muscles in shoulders, upper arms, and calf</li> <li>● Contractures in neck, elbows, and heels early in disease</li> <li>● Cardiac involvement that leads to need for pacemaker</li> </ul>
<b>Oculopharyngeal muscular dystrophy (OPMD)</b>	Usually seen mid-40s to 50 years of age French-Canadian families or family of French-Canadian descent and Hispanic residents of northern New Mexico Progression is slow	<ul style="list-style-type: none"> <li>● Ptosis</li> <li>● Weakness of the facial muscles and pharyngeal muscles</li> <li>● Dysphagia</li> </ul>
<b>Limb-girdle muscular dystrophy (LGMD)</b>	Progression variable Severe disability 10 years postdiagnosis Usually seen in mid-20s to 30s	<ul style="list-style-type: none"> <li>● Upper extremity and neck weakness</li> <li>● Lower extremity and hip muscle weakness</li> </ul>
<b>Facioscapulohumeral muscular dystrophy (FSH or FSHD) Also known as Landouzy-Dejerine</b>	Manifestations usually appear in adolescence, but onset and severity are widely variable	<ul style="list-style-type: none"> <li>● Weakness and deterioration around eyes, mouth, and upper shoulders</li> <li>● Lower extremity weakness with later signs of weakness to abdominal and occasionally hip muscles</li> </ul>
<b>Myotonic</b>	Most common form in adults	<ul style="list-style-type: none"> <li>● Prolonged spasm or stiffening of muscles after use</li> </ul>
<b>Congenital</b>	Present at birth Progress slowly	<ul style="list-style-type: none"> <li>● Severe contractures</li> </ul>
<b>Distal</b>	Rare Progresses slowly Affects fewer muscles	<ul style="list-style-type: none"> <li>● Muscle weakness and wasting in the distal extremities</li> </ul>

## Treatment

The medical management of MD focuses on the prevention of progressive deterioration of the disease, supportive measures to assist maximization of functional capacity, and pain management. There is no specific cure or pharmacological intervention. Glucocorticoid therapy is frequently the medication of choice in conjunction with supportive and collaborative care; however, practitioners need to be cognizant of the correlation of high dose steroid usage and increased propensity to obesity. Glucocorticoids such as prednisone have been shown to decrease the rate of muscle deterioration and increase restorative functional abilities. The pharmacodynamic principle of this therapy focuses on reduction of inflammation and regulation of metabolic pathways of proteins, carbohydrates, and fats, which thereby results in a decrease of enzyme activity and reduced muscle destruction. Many patients and healthcare providers support an integrative therapy regimen that includes the use of supplements such as coenzyme Q10, carnitine, amino acids (glutamine, arginine), anti-inflammatory medications, and antioxidants (fish oil, vitamin E, green tea extract) in addition to corticosteroid therapy. In addition to steroid therapy, pain management is primarily done with medications such as Tylenol, aspirin, or ibuprofen.

The psychosocial management of MD is even more complicated and intensive. Often, the stress associated with psychosocial management of MD exceeds that of the physical aspects of the disease. Supportive care is necessary on multilevel and multisystem perspectives. The focus is adapting to the deterioration of physical capacities and overall changes in roles and functional abilities. A referral to the Muscular Dystrophy Association (MDA) for supportive services and genetic counseling information is medically recommended.

## Complications

Spinal deformity and neuromuscular deterioration causing weakness of the trunk and lower extremities are severe complications of MD. With the development of **scoliosis** (curvature of the spine) and overall thoracic-lumbar changes, respiratory and cardiac compromise can develop. Total contact orthotic devices that support the trunk assist with minimization of spinal deformity and support cardiovascular function to prevent cardiac compromise that can occur with progressive MD. Ineffective cardiovascular and pulmonary functions are additional life-threatening complications that result with progressive MD.

## Nursing Management

### Assessment and Analysis

Many of the clinical manifestations observed in patients with MD are directly linked to the progressive muscle weakness and wasting that occur at a neuromuscular level. Common findings include:

- Weakness that affects the proximal before the distal limb muscles
- Difficulty with running, jumping, and walking up stairs

- Lumbar lordosis (excessive inward curvature of the lumbar spine)
- Calf enlargement
- Cardiomyopathy, especially involving the atrioventricular (AV) node
- Later cardiovascular disease associated with cardiomyopathy, such as heart failure (left ventricular)
- Respiratory compromise
- Falls leading to fractures
- Depression

## Nursing Diagnoses

- **Impaired physical mobility** associated with decreased muscle tone in the lower extremities as evidenced by the inability to walk independently
- **Risk for dysphagia** associated with decreased facial movement and/or cranial nerve VII dysfunction
- **Risk for falls** associated with decreased muscle tone in the lower extremities
- **Risk for decreased cardiac output** associated with AV node dysfunction
- **Risk for ineffective breathing patterns** associated with lumbar posture deformity

## Nursing Interventions

### Assessments

- Vital signs—heart rate, blood pressure, and pulse oximetry (SpO<sub>2</sub>)  
*Increased heart rate, decreased blood pressure, and decreased SpO<sub>2</sub> may indicate deterioration of cardiovascular and respiratory status.*
- Forced vital capacity  
*The amount of air exhaled during a forced exhalation, FVC, has a predictive value in assessing pulmonary function.*
- Chest x-ray  
*Changing chest x-ray indicates potential for respiratory compromises due to changes in skeletal structure.*
- Laboratory enzymes  
*Increased CK, LD, ALT, AST, and aldolase lactic levels indicate muscle deterioration and break down. Increased serum and 24-hour urine creatinine clearance levels indicate differential diagnosis and severity of muscle deterioration and disease progression.*
- Electrocardiogram  
*Atrioventricular node disturbances indicate changes in cardiac electrical activity and can be indicative of cardiac compromise.*
- Functional level  
*Decreases in functionality may indicate worsening progression of the disease, requiring more orthopedic and/or cardiovascular support.*
- Pain  
*Pain that is in control helps keep the patient active, which maximizes function and decreases immobility, which can lead to potential contractures or deformities*

*in the muscles that result from shortening of muscle tissue.*

### ■ Actions

- Administer corticosteroid therapy as ordered  
*Shown to decrease the rate of muscle deterioration and increase restorative functional abilities. The pharmacodynamic principles of this therapy focus on decreasing inflammation and regulating the metabolic pathways of proteins, carbohydrates, and fats, which thereby decreases enzyme activity and reduces muscle destruction.*
- Pain management—administer aspirin, ibuprofen, Tylenol as ordered for pain control  
*Managing pain is essential to maintaining mobility as much as possible.*
- Range-of-motion exercises  
*Maximize function and decrease potential contractures*
- Put patient on fall precautions  
*Because of increasing weakness, the patient is at increased risk for falls and fractures.*
- Collaborative care with occupational therapy, physical therapy, and rehabilitative medicine team  
*Coordinated care with an interprofessional team helps maximize comfort, mobility, and function.*

### ■ Teaching

- Reinforce exercises and physical and occupational therapy regimens  
*Assist with comfort and mobility and delay further deterioration and contractures*
- With family members, recognize signs of caregiver burden  
*Most patients with MD are cared for at home even as they progress to a very dependent ventilator dependent state as a result of cardiopulmonary compromise. Increasing dependency on family members can cause caregiver strain and burden. Family members should be taught to recognize these symptoms and recognize the need to contact supportive services such as the MDA to provide respite care when needed.*
- Genetic counseling (see Genetic Connections: Muscular Dystrophy)  
*Highly recommended by the MDA*

### Evaluating Care Outcomes

The ultimate outcome for the patient with MD is to promote and maintain optimal levels of function and comfort and a prescribed quality of life within the limitations of the disease (see Evidence-Based Practice). Supportive and collaborative care for both the patient and the family is an essential component of nursing care for the MD population, promoting maximal wellness in the patient and controlling caregiver burden. Disability is the greatest fear; thus, supportive and psychiatric care are essential to the holistic nursing approach for this patient population.

## Evidence-Based Practice

### Muscular Dystrophy Surveillance, Tracking, and Research Network

The Center for Disease Control and Prevention (CDC) supports the Muscular Dystrophy Surveillance, Tracking, and Research Network (MD STARnet) with the provision of funding in an effort to collect data about persons affected by MD. This surveillance and monitoring program is aimed at improving the quality of life and care for those living with the disease. Most programs collect information on persons with MD who are treated in hospitals, clinics or via medical specialists. MD STARnet is the only research-based program that monitors and gathers information from all persons affected with MD who live in the United States. This large-scale research program can provide more data and healthcare information based on the enormity of numbers which can help move the research for MD forward in the future.

Centers for Disease Control and Prevention, National Center for Health Statistics. (2018). MD StarNET Data and Statistics. Retrieved from [www.cdc.gov/ncbddd/muscular dystrophy/data.html](http://www.cdc.gov/ncbddd/muscular dystrophy/data.html)

## CASE STUDY: EPISODE 2

Eileen Doherty has returned to her healthcare provider with complaints of increasing pain in her lower back and the “feeling like I could fall” while walking. Her kyphotic posture appears to be worsening, and when her height is measured, it is noted that she has a decrease from 5 ft 3 in. to 5 ft 2.5 in. over the course of the year. She remains on her medication regimen of multivitamins and calcium and states she has begun to take Aleve (naproxen) for pain. She is very concerned about her fear of falling, increasing level of pain, and decreasing level of function...

## OSTEOPOROSIS

### Epidemiology

**Osteoporosis** is a chronic condition that results in deterioration of bone tissue and density, increasing a patient's risk for fractures. It is the most common bone disease in humans and creates a major public health concern for the future. The International Osteoporosis Foundation (IOF) estimates that osteoporosis affects 75 million people in Europe, United States and Japan. The National Osteoporosis Foundation (NOF) estimates that 9.9 million Americans have osteoporosis and approximately 43.1 million have a low

bone density. One in two women and one in five men older than 50 years of age will sustain an osteoporotic fracture and 50% of all postmenopausal women will sustain an osteoporotic fracture. Of these women, 25% will exhibit clinical signs of vertebral deformity and 15% will develop a hip fracture in their lifetime. Approximately one-third of men who experience a hip fracture as a result of osteoporosis will die within 1 year after sustaining the fracture. The NOF states that all ethnic backgrounds are affected by osteoporosis; however, 20% of non-Hispanic, Caucasian, and Asian women aged 50 years and older are estimated to have osteoporosis. Of these women, 52% have a low bone density score. The statistics for men are 7% of non-Hispanic, Caucasian, and Asian men aged 50 years and older are estimated to have osteoporosis, and 35% of these are estimated to have a low bone density. Additionally, 33.6 million Americans have low bone density of the hip, which increases the risk for osteoporosis. Caucasian small-framed women with a lower body weight have the highest risk factor for the development of osteoporosis.

The annual cost for osteoporotic fractures in the United States is \$19 billion, and in 2025 that cost is estimated to rise to \$25.3 billion. Those who sustain an osteoporotic hip fracture have an estimated mortality in excess of a 10% to 20% death rate within a year. Osteoporosis-related fractures are associated with a heavy economic burden, with more than 432,000 hospital admissions, 2.5 million medical office visits, and more than 180,000 admissions to long-term care facilities. These statistics and financial costs are estimated to continue to grow while the population continues to age.

The risk factors for osteoporosis are defined as primary and secondary. Primary risk factors are those that are non-modifiable, such as age or race, and lifestyle choices such as sedentary lifestyle, not enough calcium intake, or smoking. Secondary risk factors include other disease states that are associated with an increased risk such as Cushing's disease or medication use such as steroids (Table 53.3). Although not totally understood, Down's syndrome is also associated with an increased risk of osteoporosis, potentially associated with the accelerated aging associated with that syndrome.

### Connection Check 53.3

Which of the following is a risk factor associated with osteoporosis?

- A. African American
- B. Weight greater than 58 kg
- C. Hispanic
- D. Weight less than 58 kg

### Pathophysiology

Bone is a living, growing tissue that constantly forms new bone while replacing older bone through a process called **bone remodeling**. It is maintained by two types of bone

**Table 53.3 Primary and Secondary Risk Factors for Osteoporosis**

#### Primary Risk Factors

##### Genetics

- Age (older than 50 and postmenopausal)
- Gender (females greater than males)
- Race (Caucasian or Asian)
- Family history
- Smaller body frame (< 58 kg)

##### Nutrition

- Low calcium intake
- Low vitamin D intake
- High potassium intake
- Inadequate calories

##### Lifestyle

- Sedentary lifestyle
- Cigarette smoking
- Excessive alcohol consumption (more than three glasses per day)

#### Secondary Risk Factors

##### Medications

- Corticosteroid therapy for more than 3 months
- Anticonvulsants
- Heparin therapy
- Thyroid hormones

##### Disease pathology

- Cushing's disease
- Hypogonadism or premature menopause
- Malabsorptive issues (Crohn's, celiac disease, gastric surgery, etc.)
- Chronic liver disease
- Inflammatory bowel disease
- Rheumatoid arthritis
- Hyperthyroidism
- Hyperparathyroidism
- Previous fracture

##### Other

- Parental history of hip fracture
- Recurrent falls
- Prolonged immobilization

cells, osteoclasts, and osteoblasts. **Osteoclasts** break down bone by adhering to the surface of the bone and secreting acids and enzymes directly into the bone cavity; **osteoblasts** rebuild the bone by synthesis and mineralization of the new bony matrix within the bone cavity. It is thought to be a preventive measure by removing older bone and replacing with newer bone. Bone loss (**osteopenia**) occurs when bone resorption or **osteoclastic** activity is greater than bone rebuilding or **osteoblastic** activity, which ultimately results in a decreased bone mineral density (BMD). The resulting bone loss causes changes in the skeletal structure and results in an increased risk for fractures.

**Bone mineral density (BMD)** peaks between 25 and 30 years of age; then, as a result of aging and other associated risk factors, bone remodeling is altered. Some important factors to note that occur with aging are 1) a decrease in calcitonin levels, a hormone that decreases osteoclastic activity; 2) a decrease in estrogen levels, which results in the inhibition of bone formation; and 3) an increase in the parathyroid hormone, which increases osteoclastic activity

and bone turnover. All of these changes produce a decrease in the BMD; hence, the bones become more porous, brittle, and fragile, thereby increasing the risk for fractures (Fig. 53.2). Trabecular, or cancellous (spongy), bone loss is thought to occur first, which is then followed by loss of the compact (cortical) bone. Most frequently noted areas of bone loss are associated with vertebral changes of the lumbar spine and hip fractures, and Colles' fracture of the wrist.

## Clinical Manifestations

Osteoporosis is also frequently referred to as the “silent disease” secondary to the fact that patients are not diagnosed until a fracture occurs after an unremarkable fall or strain. Fragility fractures most often occur in the spine, hip, and distal radius. Because of this, it is important to understand the risk factors of this disease. Prevention is the key modifying factor to incorporate into the medical care for patients at risk for osteoporosis.

## Management

### Medical Management

#### Diagnosis

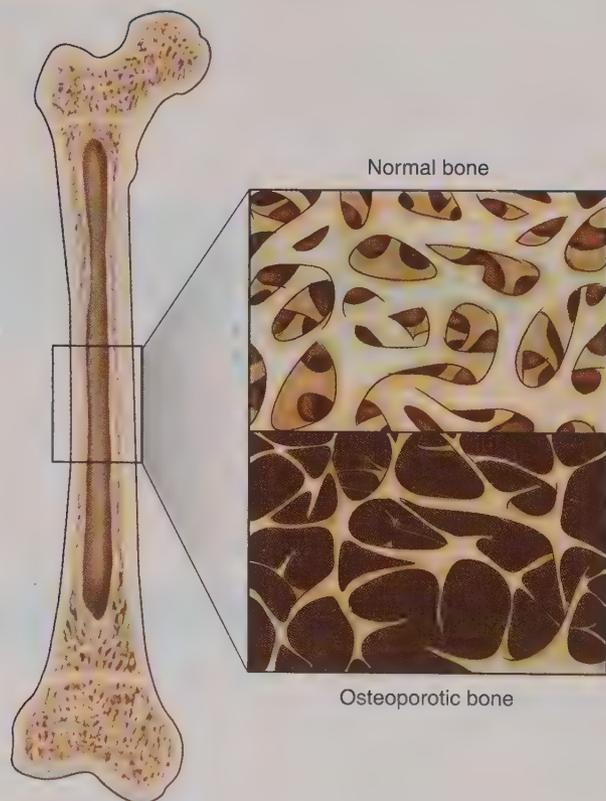

Universal recommendations call for annual height measurements with a preferred wall-mounted stadiometer. The gold standard assessment for osteoporosis is BMD measurements for women over the age of 65 or men over 70 and for

postmenopausal women and men 50 to 69 with a high risk-factor profile. They are obtained through a **dual-energy x-ray absorptiometry (DEXA) scan**. A DEXA scan gives precise measurements at clinically relevant skeletal points within the body, which highlight areas for future fracture risks. The DEXA scan reports T scores of the standard deviation above or below the mean for healthy young individuals. A low BMD, one that is 2.5 standard deviations or more below the mean for a young adult person, is highly correlated with an increased risk for fractures. A BMD that is low but not at the level of osteoporosis is indicative of **osteopenia**, a precursor to osteoporosis (Table 53.4).

Another assessment tool, quantitative computed tomography (QCT) measures volumetric bone density of the spine and hip and can identify cortical and trabecular bones distinctly. This tool is not recommended for screening but for research and diagnostic management. The literature also supports the use of ultrasonography as a good predictor for fractures and osteoporosis risk for both men and women. The major limitation with this diagnostic tool is associated with limited precision.

Although there is no definitive laboratory test to confirm osteoporosis, biochemical markers are helpful in providing insightful information associated with the status of bone remodeling. Biochemical markers of bone remodeling reflect the overall rate of bone resorption and formation. Some of the biochemical markers that are used to monitor effectiveness of treatment are bone-specific alkaline phosphatase, osteocalcin, N-telopeptide (NTX), and C-telopeptide. Numerous other laboratory studies (serum and/or urine calcium, vitamin D, phosphorous, serum alkaline phosphatase, hematocrit, erythrocyte sedimentation rate (ESR), and urine hydroxyproline excretion) can be used to rule out secondary osteoporosis and/or other metabolic bone disorders such as Paget's disease or osteomalacia. Additionally, tests such as protein measurements can be done to rule out hyperthyroidism.

Another important step in assessing osteoporosis is fracture risk assessment screening. The most widely used tool is the Fracture Risk Assessment Tool, or FRAX, which was

**FIGURE 53.2** Bony changes indicative of osteoporosis.

**Table 53.4 WHO Criteria for Diagnosis of Osteoporosis**

Classification	Score
Normal	BMD within 1 SD of young normal adult, T-score $\geq -1.0$ or higher
Low bone mass, or osteopenia	BMD between 1 and 2.5 SDs lower than that of a young normal adult, T-score between $-1.0$ and $-2.5$
Osteoporosis	BMD more than 2.5 SDs lower than that of a young normal adult, T-score $\leq -2.5$ or lower

WHO, World Health Organization; BMD, bone mineral density; SD, standard deviation.

developed by the World Health Organization's Collaborating Centre for Metabolic Bone Disease. The FRAX uses clinical risk factors with or without BMD to assess a person's 10-year risk for the development of fractures. This tool collects information on numerous key issues and associated clinical risk factors and then calculates a 10-year probability for hip and any one of four major osteoporotic fractures. The medical convenience of the FRAX tool is the ability to link directly to the National Osteoporosis Guideline Group algorithms and guidelines for clinical management. The FRAX tool is not used for patients under the age of 40 and over the age of 90 years.

Because of the silent nature of the disease, x-rays are not commonly used for osteoporosis screening and assessment. It is estimated that a change of greater than 25% to 40% in demineralization of the bone would need to be evident to be detected via x-ray.

### Treatment

Prevention and early screening are the treatment focus for osteoporosis. The NOF advocates for a comprehensive approach to the management of osteoporosis. Weight loss and muscle-strengthening exercises to reduce the incidence of falls and fractures are highly recommended. Additionally, a healthy lifestyle that includes weight bearing exercise that helps build and maintain strong bones, and avoidance of smoking and excessive alcohol intake (more than three drinks per day) are endorsed by the surgeon general as a means for prevention of osteoporosis.

### Medications

Pharmacological intervention is focused on preventing and slowing the progression of bone loss. The first line of prevention is safe and inexpensive with the use of calcium and vitamin D. The recommended dose of calcium either via dietary consumption or via supplements varies by age; however, 1,200 mg/day is the recommended daily intake for adults 51 years of age or older. The average person ingests between 600 and 700 mg per day; therefore, supplementation is necessary to maintain serum calcium levels required to support and maintain skeletal function. Higher doses of calcium (1,200 to 1,500 mg per day) have been shown to have limited benefit and are correlated with a higher incidence of the development of kidney stones and cardiovascular disease. Vitamin D helps with calcium absorption within the intestines and assists with the maintenance of adequate serum calcium levels that are imperative for bone health, muscle performance, and decreased risk for falling. The recommended intake for vitamin D is 800 to 1,000 international units (IU), which can be ingested from dietary sources such as vitamin D–fortified milk, cereals, egg yolks, saltwater fish, and liver. Sunlight for 15 minutes per day also helps with vitamin D and calcium absorption. Other pharmacological options for prevention and/or treatment of osteoporosis are listed in Table 53.5. The NOF endorses the Food and Drug Administration (FDA)–approved medications for the prevention of osteoporosis and decreased fracture risks; however, the organization does encourage practitioners to assess the potential

**Table 53.5 Pharmacological Interventions for Treatment of Osteoporosis**

Class and Mechanism of Action	Generic/Trade Name	Method of Administration	Special Considerations
<i>Bisphosphonate</i> Impedes bone resorption by inhibiting osteoclastic activity, thereby absorbing calcium phosphate in bone	Alendronate (Fosamax or Fosamax Plus D)	Daily or weekly tablet (must be taken on empty stomach)	All bisphosphonates can cause GI disturbance, dysphagia, and inflammation of esophagus
	Ibandronate (Boniva)	Monthly tablet (on an empty stomach) or IV infusion every 3 months	
	Risedronate (Actonel or Actonel with Calcium)	Daily or weekly tablet (must be taken on empty stomach)	
	Zoledronate (Reclast, zoledronic acid)	Annual IV infusion	Zoledronate has been shown to have higher risk for development of atrial fibrillation
<i>Calcitonin</i> Decreases osteoclastic activity in bone, decreases mineral release and collagen breakdown in bone, and assists with renal excretion of calcium	Miacalcin or Fortical	Intranasal spray daily; subcutaneous injection available	Can cause rhinitis and rarely epistaxis

Continued

**Table 53.5 Pharmacological Interventions for Treatment of Osteoporosis—cont'd**

Class and Mechanism of Action	Generic/Trade Name	Method of Administration	Special Considerations
<b>Estrogen/Hormone therapy</b> Estrogen assists with bone remodeling and osteoclastic activity	Estrace, Estraderm, Premarin	Varied methods of administration	Risk for MI, stroke, breast cancer, PE, and DVT
<b>Estrogen agonist/antagonist (formally known as selective estrogen receptor modulators, or SERMs)</b> Assists with bone remodeling and osteoclastic activity	Raloxifene	Daily tablet	DVT
<b>Parathyroid hormone</b> Parathyroid hormone is thought to protect against gonadotropin-releasing hormone agonist-related bone loss	PTH (1-34), Forteo	Subcutaneous injection daily	Leg cramps, dizziness
<b>Parathyroid hormone analog</b> Increases bone density and strength	Abaloparatide (Tymlos)	Periumbilical subcutaneous injection daily	Dizziness or tachycardia
<b>Dual-acting bone agent</b> Decreases osteoclastic activity and increases osteoblastic activity, thereby balancing bone turnover, increasing bone formation/remodeling	Strontium ranelate	Daily soluble sachet	Non-FDA approved
<b>Monoclonal activity</b> Inhibits osteoclastic function, formation, and survival, thereby reducing osteoclastic bone resorption	Denosumab	Subcutaneous injection every 6 months	Non-FDA approved Can be used with patients that cannot take bisphosphonates or patient with reduced renal function Causes infections

DVT, Deep vein thrombosis; FDA, Food and Drug Administration; GI, gastrointestinal; IV, intravenous; MI, myocardial infarction; PE, pulmonary embolism.

benefits versus risk with each individual patient. The NOF recognizes but does not endorse those non-FDA-approved medications for the treatment and prevention of osteoporosis.

### Complications

The complications of osteoporosis surround the skeletal changes that occur as a result of bone loss and lack of bone remodeling. Patients with osteoporosis are more at risk for falls, which incurs a greater risk for fractures, specifically vertebral compression fractures and hip fractures. All fractures in older adults can result in a higher incidence of prolonged hospitalization and ultimately death.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with osteoporosis are directly associated with a decrease in

bone resorption and bone building, which lead to osteopenia (bone loss) and osteoporosis. Common findings include:

- “Dowager’s hump” (kyphosis of the dorsal spine)
- Loss of height (loss as great as 2 to 3 in. [5–7.5 cm])
- Back pain (sharp or acute)
- Pain increased with activity and relieved with rest
- Restriction of movement, especially in the thoracic and lumbar regions
- Fear of falling (known as “falophobia”) and/or history of previous falls
- Previous fractures

Other clinical manifestations such as constipation, abdominal distention, and reflux esophagitis are associated with the decrease in movement and spinal deformity. Potential respiratory complications are due to curvature of the spinal column and decreased chest excursion.

## Nursing Diagnoses

- **Risk for trauma** associated with bone loss and the potential for falls and/or fractures
- **Impaired physical mobility** associated with pain and musculoskeletal changes

## Nursing Interventions

### ■ Assessments

- **Fall risk**  
*Age and change in skeletal structure (bone loss and decrease in BMD) can result in deformity and disability, which are correlated with the potential for falls and resulting fractures*
- **Pain**  
*The presence of pain decreases mobility and optimal functioning.*
- **Nutritional status**  
*Adequate ingestion of protein, magnesium, vitamin K, calcium, vitamin D, and trace elements is essential for bone formation and remodeling.*
- **Assess level of activity and exercise**  
*Exercise is an integral part of prevention and management for osteoporosis and pain control. Strive for an active lifestyle.*
- **Body image disturbance**  
*Skeletal changes can cause issues associated with posture (kyphosis), decrease in limb length (specifically lower extremities), and difficulty with clothing fitting appropriately. Physical appearance can change and cause issues associated with self-esteem.*

### ■ Actions

- Administer one of the following medications as ordered
  - **Bisphosphonates**  
*Impedes bone resorption by inhibiting osteoclastic activity, thereby absorbing calcium phosphate in bone*
  - **Calcitonin**  
*Decreases osteoclastic activity in bone, decreases mineral release and collagen breakdown in bone, and assists with renal excretion of calcium*
  - **Estrogen/Hormone therapy**  
*Estrogen assists with bone remodeling and osteoclastic activity*
  - **Estrogen agonist/antagonist**  
*Assists with bone remodeling and osteoclastic activity*
  - **Parathyroid hormone**  
*Parathyroid hormone is thought to protect against gonadotropin-releasing hormone agonist-related bone loss*
  - **Parathyroid hormone analogs**  
*Parathyroid hormone analog is thought to increase bone density and strength; thereby reducing fracture risk.*
  - **Dual-acting bone agent**  
*Decreases osteoclastic activity and increases osteoblastic activity, thereby balancing bone turnover, increasing bone formation/remodeling*
  - **Monoclonal activity**  
*Inhibits osteoclastic function, formation, and survival, thereby reducing osteoclastic bone resorption*

- Support exercise program/Implement steps to correct or supplement underlying physical and functional deficits  
*Exercises for strengthening abdominal and back muscles are essential to the promotion of function and safety. Low intensity weight bearing exercise such as walking is effective. Improved posture, balance, and strengthened muscle tone will enable the patient to move safely, promote functional capability, and decrease risk for falls.*
- Provide training for safe movement with activities of daily living  
*This patient population is at great risk for falls with transfers and lifting. Use assistive devices when appropriate.*
- Contact home health agency for a home environmental safety evaluation  
*High risk for falls and fractures, so home environment needs to be evaluated for environmental and safety hazards*

### ■ Teaching

- Take medication as prescribed  
*Many of the bisphosphonates need to be ingested first thing in the morning on an empty stomach. They can cause GI disturbances, esophagitis, and visual disturbances. These side effects need to be reported to provider as soon as possible.*
- Instruct patient in weight reduction if necessary  
*Weight loss has been shown to decrease stress on the skeletal structure.*
- Instruct patient to incorporate adequate ingestion of vitamin D and calcium  
*Medications may cause a decrease in calcium levels. Calcium helps with collagen synthesis and bone formation, thereby assisting with maintaining bone health. Vitamin D facilitates calcium absorption in the GI system.*

## Evaluating Care Outcomes

Patients with osteoporosis can live a functional and safe lifestyle if best practice standards are followed and maintained. The evaluative outcomes focus on early identification of the risk for fracture and/or osteoporosis. Education and support for patients with dietary and lifestyle issues, as well as education and discussion surrounding bone-sparing medications such as bisphosphonates are essential. Persistence with a healthy lifestyle and monitoring of the treatment regimen have been shown to be highly effective.

## PAGET'S DISEASE

### Epidemiology

Paget's disease is the second-most common bone disease with approximately 1% to 2% of the white adult male population older than 50 years of age being affected. Results obtained via autopsy approximate 3% to 3.7% of the patients older than 40 years of age were affected. Prevalence increases with age, with approximately 8% of the male gender and 5% of the female gender affected in their eighth decade of life. It is most commonly associated with men of

Caucasian, European, Dutch, and/or British descent. For reasons not completely understood, the disease is most common in the United Kingdom, specifically Lancashire towns.

Genetics have been linked to 15% to 40% of the known cases of Paget's disease. It is most commonly associated with an autosomal dominant trait that is more pronounced in the fifth to sixth decade of life. Also, research from the University of Pittsburgh School of Medicine has linked a gene from the measles virus with Paget's disease. It is thought that having measles during childhood is an environmental trigger for the disease.

## Pathophysiology

**Paget's disease of the bone (PDB)**, also referred to as *osteitis deformans*, is a bone metabolism disorder associated with accelerated bone remodeling, resulting in bone that is structurally abnormal. The skeletal areas most commonly affected are the skull, femur, tibia, pelvic bones, and vertebral column. Because of the insidious nature of the disease, a confirmed diagnosis is not known until a fracture develops or occurs.

As discussed in osteoporosis, bone is constantly renewed through the process of remodeling maintained by two types of bone cells, osteoclasts and osteoblasts. Osteoclasts break down bone by adhering to the surface of the bone and secreting acids and enzymes directly into the bone cavity; osteoblasts rebuild the bone by synthesis and mineralization of the new bony matrix within the bone cavity. With PDB, the osteoclasts increase in size and number, escalating resorption of bone. Consequently, osteoblasts add to new bone at an increased rate, which leads to enlarged bony structures that are disorganized in structure and reduced in mechanical strength, leading to patients at risk for the development of deformities and fractures. There are three characteristic phases of pagetic bone: initial (incipient-active), mixed, and inactive. In the initial phase, there is a hyperactive bone resorptive process in place that leads to architecturally disorganized bones and deformities. The mixed phase is classified with the coexistence of bone osteolysis (increased vasculature to bone) and sclerosis in which osteoblastic cells are more proliferative, resulting in lamellar (remodeled) bone that is functionally disorganized. Last is the inactive phase, which results in a disorganized bony structure that displays an increased fibrous connective tissue with increased blood vessels. This leads to a hypervascular state and ultimately osteosclerotic bone; bone that is disorganized and brittle.

## Clinical Manifestations

Paget's disease is initially asymptomatic. As it progresses, clinical manifestations of PDB vary according to the severity, extent, and site of bony involvement. The two main clinical characteristics of PDB are pain and deformity in the affected bony site. Additionally, fractures, bone tumors, neurological

disease, and cardiac disease, from related dysfunction with calcium and phosphate imbalance can also occur. Atypical clinical manifestations of PDB are an increase in pain with weight-bearing and an increase in nocturnal pain.

## Management

### Diagnosis

Diagnosis of PDB is difficult secondary to the asymptomatic nature of the disease. It is estimated that 80% of all PDB patients are asymptomatic. The diagnosis is made incidentally via radiographical examination or via routine laboratory chemistry screening that reveals an increase in serum alkaline phosphatase. Specific clinical indicators for the medical team to focus on are previous fractures, deformities, pain, and familial history of PDB. The pain may arise directly at the pagetic lesion but more commonly from the complications of the bone deformities, causing nerve impingement and/or degenerative issues associated with the disorganized bony structure.

The first step in clinical diagnosis of PDB is a comprehensive history and physical examination with measurements of serum concentrations of alkaline phosphatase, calcium, and urine hydroxyproline excretion. Diagnosis is highly speculative with an elevated serum alkaline phosphatase, normal serum calcium, and no evidence of hepatobiliary disease. Biochemical assay of bone turnover is important for both diagnostic and treatment purposes. Radiographical and nuclear examinations are performed and reveal changes within the bony structure and deformities. Thermography, a noninvasive and painless imaging technique that uses an infrared camera to detect increased temperature variations on the body's surface, can be used to reveal increased blood flow, thus increased temperature in the affected bony area. A bone scan is the most sensitive test for pagetic bone, revealing focal areas of increased activity ("hot spots") that are highly suspect of PDB. Computed tomography is most helpful in a differential diagnosis, especially when associated with **osteosarcoma** (primary bone tumor). A bone biopsy may be ordered in the event that osteosarcoma is suspected in a pagetic bone; however, it is not reliable for the diagnosis of PDB.

### Medical Management

Medical management of PDB is dependent on the following factors: presence or absence of symptoms of active disease, distribution of the pagetic bone, metabolic activity of a pagetic lesion, and potential consequences of bony overgrowth at the site of diagnosis. On the basis of these findings, management is either surgical or nonsurgical. The goal of treatment is focused on reduction of pain and increased functional mobility with a decreased risk for fractures.

### Medications

There is no effective treatment of Paget's disease. Medication therapy is focused on pain management and functional outcomes. Analgesic therapy is needed for pain control and

can span from mild to moderate with the use of aspirin-based products to nonsteroidal analgesics such as ibuprofen. Opioid analgesia is used with severe pain.

Calcitonin was the first therapeutic treatment used for PDB. Calcitonin decreases osteoclastic activity in bone, decreases mineral release and collagen breakdown in bone, and assists with renal excretion of calcium. Unfortunately, long-term management of Paget's disease is difficult with this medication alone. Problems include medication side effects (nausea, flushing, and rash) and the need for regular subcutaneous injections. Patients also may develop resistance to this medication.

The development of oral and IV bisphosphonates has improved the medical outcome for patients with Paget's disease. Treatment with bisphosphonates is recommended for patients with bone pain or other symptomatic active bone disease such as PDB. Bisphosphonates decrease osteoclastic activity, thereby suppressing bone resorption. The bisphosphonates have been shown to suppress bone resorption within days to weeks as evidenced by a decrease in urine hydroxyproline, as well as a decrease in serum alkaline phosphatase, which reveals a suppression of bone formation. Oral etidronate (Didronel) was the first bisphosphonate used with a 50% reduction in disease activity noted. Presently, it is used less, secondary to the fact that the therapeutic doses required for effective management have been linked to side effects such as bone demineralization. The six newer nitrogen-containing bisphosphonates (zoledronic acid, pamidronate, risedronate, alendronate, ibandronate, and neridronate) are the primary agents used for the initial treatment of PDB. These medications suppress bone remodeling without causing demineralization of the bone (see Table 53.5). Zoledronic acid is the preferred medication of choice and is administered via an intravenous infusion over 15 to 20 minutes in a secluded line not to be mixed with other medications. The rationale for this choice is due to the medication tolerance and a documented prolonged remission of Paget's disease. Zoledronic acid is not recommended by the United States FDA for patients who have a creatinine clearance less than 30 to 35 mL/min. Major issues with the oral bisphosphonates, risedronate (Actonel) and alendronate (Fosamax), medications also used in the treatment of osteoporosis, are the poor absorptive issues and mild (GI) issues with oral ingestion. Patients must be instructed to take these medications on an empty stomach and monitor for symptoms such as diarrhea, nausea, and dyspepsia. Additionally, because of the renal toxicity of these medications, any patients with renal dysfunction are not eligible candidates for this therapeutic intervention. IV therapy such as with pamidronate (Aredia) and zoledronic acid (Reclast) has been shown to be highly effective; however, serum calcium, phosphorus, and 25-hydroxyvitamin D (calcidiol) should be monitored during treatment. To reduce the risk for hypocalcemia, it is recommended enhanced supplementation with calcium and vitamin D be given 8 weeks before initiating this therapy in patients whose 25-hydroxyvitamin D level is 20 ng/mL (50 nmol/L)

or less. Supplementation of calcium and vitamin D is warranted post treatment on the basis of serum laboratory results. Pamidronate is well tolerated and easy to administer in a hospital and/or outpatient setting; however, recent studies have shown that some patients develop a resistance to the medication, resulting in treatment inefficacy.

### Surgical Management

Surgical management of PDB is focused on the secondary degenerative changes of the bony structure such as in the case of osteoarthritis (OA). Surgical intervention can span from joint replacement to spinal decompression and stabilization. Another option is **osteotomy**. Osteotomy is a surgical removal of damaged or deformed bone. This procedure can be corrective for skeletal deformities such as bowleg knee (varus) or knock-knee (valgus) (Fig. 53.3) that occur naturally or as a result of PDB. Surgical spinal decompression, removal of bony substances that are causing nerve impingement, and **spinal stabilization** (surgically inserted rods, pins, and pedicle screws that maintain spinal column structure) can be used with the ultimate goal of maintaining skeletal structure and function and preventing vertebral column pain and/or possible paralysis and/or paresthesias. The primary goal for surgical intervention is reduction of pain and maximizing functional outcome. Nonsurgical management is recommended before surgical intervention.

### Complications

In patients with advanced PDB, deformities and pain occur. Frequently, there are skeletal changes such as bowing of long bones (especially in the tibia, "saber tibia") and enlargement of the skull, which can cause impingement on the auditory nerve resulting in deafness, enlargement of the mandible leading to a protrusion of the chin (prognathism), and enlargement of the maxilla and cheekbones causing dental problems. The ultimate effect of PDB is to structurally weaken bones, which puts the patient at an increased risk for fractures. These fractures are most commonly seen in the tibia and femur as small stress fractures. Secondary degenerative changes are associated with PDB.

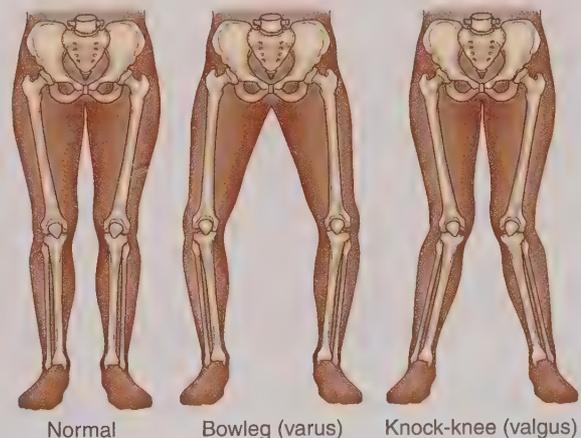

FIGURE 53.3 Bow-leg and knock-knee.

The most serious complication of PDB is the development of primary bone tumors, such as the rare but serious osteosarcoma. The prevalence of osteosarcoma in PDB is estimated to be less than 1%; however, it can be found in those patients aged 70 years or greater. The nature of the correlation between the two diseases is unknown but is thought to be linked to aggressive osteoblastic activity that is found most commonly in those patients affected by Paget's disease.

### Connection Check 53.4

Medical management for Paget's disease is based on which of the following characteristics? (Select all that apply.)

- A. Presence of symptoms of active disease
- B. Distribution of the pagetic bone
- C. Metabolic activity of a pagetic lesion
- D. Absence of symptoms of active disease
- E. Decreased calcium and phosphorous levels

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with Paget's disease are directly associated with an increase in bone loss affected by excessive or overactive osteoclasts, which leads to disorganized skeletal structure. Common findings include:

- Generalized pain, especially in the lower back, and bone pain
- Inclination or deformity of long bones and cranial bones
- Spinal curvature
- Spinal cord compression and neurological impairment
- Fissures of the cortex
- Complete or incomplete fractures
- Deafness and/or paralysis of other cranial nerves
- Increased heat in the skin overlying the affected bone
- Osteosarcoma

Other clinical manifestations such as hyperparathyroidism, gout, urinary and renal stones, and heart failure may be seen because of secondary issues associated with the disease pathology.

#### Nursing Diagnoses

- **Risk for trauma** associated with bone loss and potential for falls and/or fractures
- **Acute/chronic pain** associated with skeletal changes, vertebral compression on spinal nerves/muscles, and bone deformity
- **Impaired physical mobility** associated with pain and musculoskeletal changes

### Nursing Interventions

#### Assessments

- **Pain**  
*Pain control helps keep the patient comfortable and promotes optimal levels of functioning and mobility.*
- **Weight**  
*Weight reduction helps with reduction of stress on bones that might be weakened or misaligned.*
- **Serum calcium levels**  
*Serum calcium levels may be lowered due to the treatment with some bisphosphonates.*
- **Fall risk and gait disturbances**  
*Assess for varus (bowlegged) knees and valgus (knock-knee) knees, which put patients at greater risk for gait disturbances and falls.*
- **Body image disturbance**  
*Skeletal changes can cause issues associated with hearing and eating as well as bowing of the tibia, which result in difficulty with activities of daily living. Physical appearance can change and cause issues associated with self-esteem.*

#### Actions

- **Administer bisphosphonates as ordered**  
*Bisphosphonates disable osteoclasts, thereby slowing bone resorption and increasing bone-building activity.*
- **Administer supplemental calcium and vitamin D as ordered**  
*Calcium levels may be lowered with treatment with bisphosphonates. Supplemental calcium is suggested as well as vitamin D to facilitate GI absorption of calcium.*
- **Administer analgesic therapy as prescribed**  
*Controlling pain within tolerable levels assists with maximal level of function.*
- **Apply thermal therapy as ordered from rehabilitative services**  
*Thermal therapy (hot and/or cold) has been shown to reduce pain and increase functionality.*
- **Support exercise program/Implement steps to correct or supplement underlying physical and functional deficits**  
*Exercises for strengthening abdominal and back muscles are essential to the promotion of function and safety. Improved posture, balance, and strengthened muscle tone will enable the patient to move safely, promote functional capability, and decrease risk for falls.*
- **Provide training, orthotic shoes, braces, and other supportive measures including a physical therapy consult for safe movement with activities of daily living**  
*Patient population is at great risk for falls with transfers and lifting; use assistive devices when appropriate.*
- **Contact home health agency for a home environmental safety evaluation**  
*High risk for falls and fractures, so home environment needs to be evaluated for environmental and safety hazards*

## Teaching

- Take pain analgesic medication as prescribed  
*Adequate pain control facilitates active participation in daily activities. Caution: Opioids are highly addictive and can cause constipation, drowsiness, and respiratory depression. Patients should not drink alcohol or operate heavy machinery (car) while taking opioids.*
- Take bisphosphonate medication as prescribed  
*Many of the bisphosphonates need to be ingested first thing in the morning on an empty stomach. They can cause GI disturbances, esophagitis, and visual disturbances. These side effects should be reported to provider as soon as possible.*
- Instruct patient to incorporate adequate ingestion of vitamin D and calcium  
*Medications may cause a decrease in calcium levels. Calcium helps with collagen synthesis and bone formation, thereby assisting with maintaining bone health. Vitamin D facilitates calcium absorption in the GI system.*

## Evaluating Care Outcomes

Typically Paget's disease is found in the gerontological patient population; however, an accurate, inclusive family and personal history, in combination with a comprehensive history and physical examination, is the first line of assessment for this metabolic bone disease. Careful management of pain and discomfort is essential to a well-managed plan of care. Additionally, overall fracture reduction is maintained with careful screening by both physical and occupational therapies. This screening is essential for identification of gait disturbances, assessment of fall risk, and completion of a home safety assessment.

## OSTEOMYELITIS

### Epidemiology

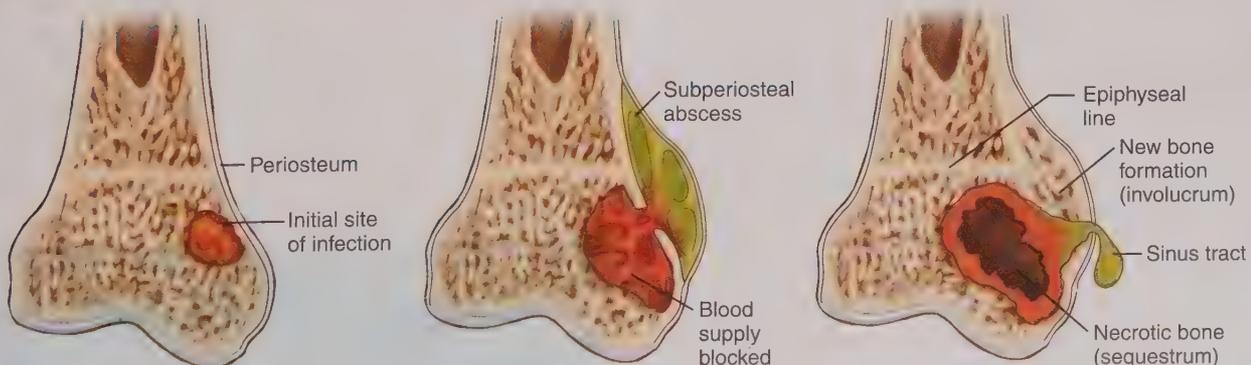

The incidence and prevalence for osteomyelitis are directly linked to the mechanism of infection; hematogenous or nonhematogenous. Hematogenous, or endogenous, osteomyelitis is a result of infectious spread from another area of the body via the bloodstream. Nonhematogenous, or exogenous, osteomyelitis is a result of an open fracture and/or

trauma to the bone. Acute hematogenous osteomyelitis is more commonly seen in children and those less than 1 year of age, accounting for approximately 85% of all documented cases. Nonhematogenous osteomyelitis is more commonly associated with adults and open surgical fractures or trauma. Open fracture or trauma is reported to have between a 2% and 16% incidence of osteomyelitis. It is most common with metaphysis of long bones, such as within the femur, tibia (19%–26%), or humerus, with the lower more commonly affected. Trauma is the leading causative factor, which tends to affect males between the ages of 18 to 30 years; however, osteomyelitis can be linked to other causative factors such as implanted surgical devices and puncture wounds.

Osteomyelitis is classified into one of three categories: 1) acute infection, which is less than 2 weeks; 2) subacute infection, which is from 2 weeks to 3 months; or 3) a chronic infection, which lasts longer than 3 months. The prevalence of chronic osteomyelitis averages 5% to 25% for patients undergoing treatment for an acute osteomyelitic infection. Diabetes and foot puncture prevalence statistics for chronic osteomyelitis can range as high as 30% to 40%. The overall incidence of osteomyelitis is approximately 2%.

### Pathophysiology

The pathophysiology for acute and/or chronic osteomyelitis is complex and not clearly understood; however, the principles of virulence of a bacterium, patient immune status, underlying patient pathology and type, and location and vascularity of the bone are highly correlated. In both acute and chronic osteomyelitis, the process begins with an invasion of the bone and surrounding tissue by one or multiple bacterial pathogens. This leads to inflammation and an increase in the vascularity to the region that ultimately results in edema. Within days to weeks, a thrombus occurs in the vessel, which leads to ischemia and slow necrosis of the affected area and bone. Once necrotic bone is present, the healing is delayed, and a superimposed infection or abscess is highly probable. This results in a cycle of more inflammation and infection. The ultimate clinical hallmark is bone necrosis and the development of sinus tracts between the bone and skin (Fig. 53.4).

**FIGURE 53.4** Abscess and sinus tract formation in osteomyelitis.

Exogenous osteomyelitis can be from trauma and/or surgery in which the spread is via direct inoculation from a fracture or open wound or contagious spread from a contiguous wound. Endogenous is caused by the spread of an infection from one area of the body to another because of infections in adjacent soft tissue and joints or indirect inoculation. Older adults are affected by contiguous osteomyelitis in which skin infections spread to bone. This can be polymicrobial or monomicrobial and is seen in such cases of decubitus ulcer, affected total joint arthroplasties, and other vascular insufficiencies. They account for approximately 34% of the documented cases. *Staphylococcus aureus*, coagulase-negative staphylococci, and aerobic gram-negative bacilli are the most common pathogens found in contiguous osteomyelitis.

## Clinical Manifestations

Clinical manifestations of acute osteomyelitis include pain not relieved by rest, swelling, tenderness and warmth at the site, fever, nausea, chills, and a general feeling of being unwell or malaise. Manifestations of chronic osteomyelitis include constant bone pain, edema, tenderness, erythema, and warmth at the site. Occasionally, especially in children, there is an absence of the classic osteomyelitis manifestation of fever, pain and increased inflammatory markers. The absence of these symptoms does not rule out osteomyelitis, which warrants a more aggressive diagnostic evaluation.

## Management

### Medical Management

#### Diagnosis

Diagnosis of osteomyelitis can be difficult secondary to the fact that many serum laboratory tests are nonspecific. Also, radiographical studies often show normal function rather than pathology. A white blood cell (WBC) count, ESR, blood cultures, and C-reactive protein (CRP) levels are the initial steps for diagnosis of osteomyelitis. White blood cells are elevated in infection. The ESR and CRP level are indicators of inflammation. The WBC count and ESR are commonly elevated in osteomyelitis. The CRP level is normally elevated in the first 7 days of infection as a direct response to the inflammatory response. As the initial inflammation decreases, CRP levels may trend down to a normal level. Approximately 50% of all patients with a confirmed diagnosis of osteomyelitis have positive blood cultures. A positive blood culture with evidence of soft tissue edema, bone degeneration, and a positive periosteal elevation (enlarged bone due to pus formation) is considered enough conclusive data to confirm a diagnosis for osteomyelitis.

X-rays are not generally ordered for an acute onset of osteomyelitis secondary to the fact that bony deformities are not commonly noted until 14 to 21 days after onset. A bone scan is the test of choice for acute osteomyelitis when

the x-ray is negative for definitive changes. An increased uptake of a radioisotope to the infected bone can detect an infection within 2 to 3 days of onset. A bone scan can result in a false-positive result of osteomyelitis due to many confounding variables (increase or decrease in bone metabolism, bone injury, decreased blood flow, septic arthritis, cancer). Therefore, multiple tests are performed for a definitive diagnosis. Computed tomography scans and magnetic resonance imaging (MRI) are useful tools to evaluate the diagnosis, but bone biopsy is the gold standard for conclusive diagnosis for osteomyelitis. An open (preferred) approach or needle aspirate can be used for this procedure. A positive biopsy (infectious bone) is conclusive for both acute and chronic osteomyelitis.

### Medications

Due to the complex nature of osteomyelitis, a collaborative medical management team is highly recommended. The medical management of osteomyelitis requires clinically appropriate antibiotic therapy and surgical debridement and incision of the infected and/or necrotic tissue and bone. The antibiotic regime is based on culture and sensitivity results. Age, renal function and health status are important criteria in the antibiotic selection. In the event that laboratory and diagnostic data is not available, a broad spectrum antibiotic should be initiated. The initial line of treatment is antibiotic IV infusions over a course of 4 to 6 weeks from the time of the final surgical debridement or surgical cleaning of the wound. Betalactam antibiotics, such as penicillin and cephalosporin, are the first-line options unless Methicillin-resistant staphylococcus aureus (MRSA) is suspected. In the event that MRSA is present, or an allergy to penicillin is present, intravenous vancomycin is the medication of choice. Fluoroquinolones are an alternative choice for staphylococcus infections and have been shown to be highly successful because of their high bone-penetrating ability. The IV infusion is typically started in the hospital and is often managed in the home post initial treatment. Dependent on laboratory results, some patients can move from IV infusions to oral antibiotic therapy, but IV infusion is strongly supported. Additional intraoperative antibiotic bead placement with severe and/or chronic osteomyelitis has been shown to be therapeutic and effective.

Opioid analgesia is indicated to manage the pain. Nutritional support focuses on a high-protein diet to support and aid in wound healing. Supplements such as vitamin C, zinc sulfate, iron, thiamine, folic acid, and a multivitamin are recommended dependent on the patient's baseline nutritional status.

### Surgical Management

Surgical intervention with debridement is required when a patient with osteomyelitis demonstrates one of the following: failure to respond to antibiotic therapy, evidence of soft tissue abscess or subperiosteal collection, suspected or confirmed joint infection, and/or progressive neurological deficits or spinal instability in the case of vertebral osteomyelitis. In the

event that a patient has known or suspected infected orthopedic hardware, surgical removal is often warranted. In the most extreme cases, a surgical amputation is performed to promote healing and vascular supply to healthy tissue and bone proximal to the infection.

### Complications

In the absence of appropriate therapy and medical management, osteomyelitis is associated with disabling and life-threatening complications such as sepsis, potentially resulting in amputation. Squamous cell carcinoma has been reported with chronic osteomyelitis, along with other tumors such as fibrosarcoma, myeloma, lymphoma, plasmacytoma, angiosarcoma, and rhabdomyosarcoma. Prompt diagnosis and early treatment with antimicrobial therapy are essential.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with osteomyelitis are directly associated with the pain and the extent of the infection within the bone and the surrounding tissue. Common findings include:

- Fever ( $> 101^{\circ}\text{F}$  [ $38.3^{\circ}\text{C}$ ]), especially when a blood-stream-borne infection is present
- Pain, defined as constant, localized, and pulsating tenderness, swelling, erythema, and warmth at the affected area
- Irritability, general malaise, lethargy
- Difficulty moving joints near the affected area
- Difficulty bearing weight on the affected area
- Poor perfusion to the area as demonstrated by venous stasis ulcers
- Stiff back (vertebral involvement)

#### Nursing Diagnoses

- **Acute/chronic pain** associated with inflammation
- **Impaired physical mobility** associated with pain and inflammation
- **Peripheral neurovascular dysfunction** associated with impaired perfusion to affected extremity
- **Risk for disturbance to body image** associated with skeletal changes and bone deformities.

### Connection Check 53.5

John, a 28-year-old man, has been recently diagnosed with osteomyelitis following an open reduction internal fixation to his tibia fracture. What is the most appropriate nursing diagnosis for John?

- A. Hypotension associated with tibia fracture
- B. Infection associated with tibia fracture
- C. Fear associated with tibia fracture
- D. Pain associated with tibia fracture

### Nursing Interventions

#### Assessments

- Temperature, pulse, and blood pressure  
*Elevated heart rate, decreased blood pressure, and febrile (fever) state may indicate an infection.*
- Pain  
*Increased pain may indicate activation of the inflammatory process. Pain unusual to the illness can be indicative of infection. Additionally, difficulty moving joints, stiffness, and overall pain near the affected joint area are signs of infection.*
- Wound assessment  
*Redness, heat, purulent drainage, pain, and edema are all signs of wound infection.*
- Neurovascular assessment  
*Weak pulses, pallor, pain, paresthesia, and/or paralysis indicate impaired circulation, which requires prompt intervention to avoid disabling complications due to decreased blood flow to the affected area.*
- Laboratory tests—WBC, ESR, CRP  
*Increased WBC, ESR, and CRP are indications of infection and inflammation.*
- Blood cultures, wound cultures  
*Positive blood cultures and/or wound cultures definitively diagnose infection and determine the appropriate antibiotic coverage.*

#### Actions

- Administer IV antibiotics as ordered  
*Because of the severity of the infection and the potentially disabling complications, IV antibiotics are indicated and continued for 4 to 6 weeks.*
- Administer analgesic therapy as prescribed  
*Pain that is controlled within a tolerable level helps the patient achieve a maximal level of function.*
- Apply thermal therapy as ordered  
*Thermal therapy (hot and/or cold) has been shown to reduce pain and increase functionality.*
- Apply gentle range-of-motion exercises to the joints above and below the affected site  
*Exercises for strengthening and flexibility help promote function and prevent contractures*
- Provide training for safe movement with activities of daily living  
*Patient population is at great risk for falls with transfers and lifting; use assistive devices when appropriate.*
- Provide nutritional support  
*Adequate ingestion of vitamin C, zinc, iron, thiamine, folic acid, and protein can help with wound healing and eliminating infection.*
- Contact home health agency for home infusion antibiotic therapy  
*Long-term antibiotic infusion therapy can safely be managed in the home with the assistance of a home infusion nurse.*

### Teaching

- Take pain analgesic medication as prescribed  
*Pain control is essential to encourage mobilization. Caution: Opioids are very addictive and can cause constipation, drowsiness, and respiratory depression. Patients should not drink alcohol or operate heavy machinery (car) while taking opioids.*
- Take prescribed antibiotics  
*Complete a full prescription to avoid a rebound or resistant infection.*
- Instruct patient on nutritional therapy to incorporate high-protein diet  
*A high-protein diet helps with tissue and wound healing.*

### Evaluating Care Outcomes

Overall evaluation of care outcomes for osteomyelitis is focused on control of pain, resolution of infection, and limb preservation. Adherence to the IV antibiotic regimen is essential to avoid complications such as bone abscess, fracture, bacteremia, delayed bone healing, gangrene, and ultimately amputation. Early recognition and prompt treatment are essential for effective clinical management and reduction of potential complications. A well-managed patient has pain and infection under control and retained limb functionality.

## SCOLIOSIS

### Epidemiology

Scoliosis is not a diagnosis but rather a description of the structural alteration that is noted by a curvature of the spine greater than a  $10^\circ$  curvature that is normally associated with rotation and compression; identified through the measurement of Cobb's angle (described below). While the median age of the population rises, so does the incidence of lumbar scoliosis in those 40 years of age and older. Caucasians have a higher incidence (11.1%) than African American (3.14%), and gender does not seem to be a factor, with males equal to females. The prevalence of adolescent idiopathic scoliosis, which is defined as greater than a  $10^\circ$  Cobb's angle, is 2% to 3%. Risk factors associated with scoliosis are smoking; obesity; older age; occupations that require heavy physical work; sedentary lifestyle; psychologically strenuous work; and persons who have a lower educational level.

### Pathophysiology

There are three main categories of scoliosis: neuromuscular, congenital, and idiopathic. Neuromuscular scoliosis occurs in patients with neurological musculoskeletal problems such as cerebral palsy, myelomeningocele, muscular dystrophy, or leg discrepancy. Congenital scoliosis is asymmetry in the vertebral column secondary to a congenital anomaly. Idiopathic scoliosis has no distinct etiology and is defined by exclusion and age of presentation. The actual cause is unknown; however, the pathophysiological process is rather clear in its presentation. As the degree of curvature in the vertebral column increases, damage to the vertebral bodies occurs. A curvature of greater than a  $50^\circ$  Cobb's angle causes instability within

the spinal column. Greater than a  $60^\circ$  angle causes significant compromise to the thoracic region, resulting in cardiopulmonary compromise.

### Clinical Manifestations

In scoliosis, there is a sideways curvature of the spine greater than 10%. Pain may be present, but other causes of pain should be ruled out before being attributed to scoliosis. Clinical manifestations of scoliosis include:

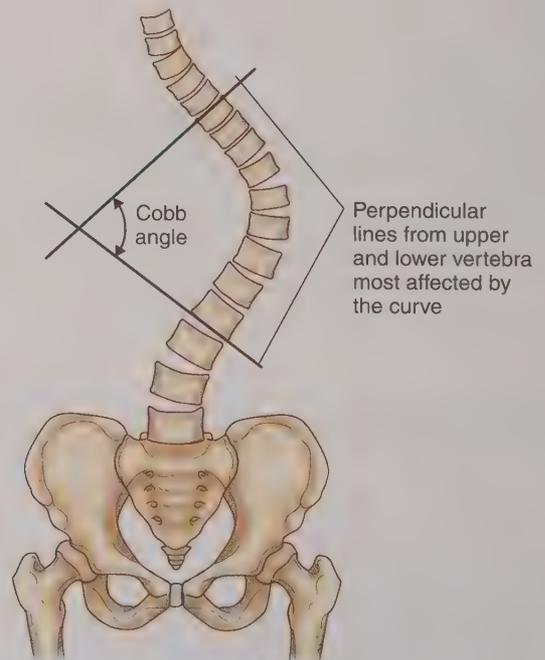

- Sideways curve in the spine
- Uneven shoulders
- One shoulder blade that appears more prominent than the other
- Uneven waist
- One hip higher than the other
- Signs of cardiopulmonary compromise with severe scoliosis such as tachypnea, tachycardia, shortness of breath, and decreased oxygen saturation

### Management

#### Medical Management

#### Diagnosis

Clinical diagnosis of scoliosis is done with visible inspection, radiographical imaging, and quantifying the curvature. **Cobb's angle** is the measurement used to evaluate the amount of curvature in the spine. This is done by identifying the upper and lower vertebra most affected by the curve, drawing perpendicular lines from each, and measuring their angle of intersection (Fig. 53.5).

**FIGURE 53.5** Cobb's angle; diagnostic for scoliosis. The intersection of perpendicular lines drawn from the upper and lower vertebrae most affected by the curve.

The first step in diagnosis is the identification of the underlying etiology and assessment of the severity of the curvature and the risk for progression. A comprehensive history and physical examination include when the deformity was first noted, rate of progression, pain, associated symptoms, and cardiopulmonary dysfunction. For the adolescent and adult populations, assessment of asymmetry of the iliac crest and posterior inferior iliac spines is palpated bilaterally. This is done with the patient in the standing position with hips and knees fully extended. Leg discrepancy is noted on palpation and many times on visual inspection. Simple inspection while standing behind the patient may reveal subtle differences such as discrepancy in shoulder height or scapulae, waistline asymmetry, and a difference in arm length. The patient's head may not appear aligned over the sacrum while leaning to one side or another. The Adams forward bend test (observe the patient from the back as he or she bends forward until the spine is parallel to the horizontal plane) reveals a thoracic or lumbar prominence on one side. Kyphosis, spinal curvature making the patient seem hunched over, may be visible when standing to the side of the patient. A scoliometer is used to determine the quantification of trunk rotation. Lastly, radiographical studies are required to confirm the diagnosis, type, and severity of scoliosis; Cobb's angle, and to evaluate skeletal maturity.

### Treatment

Medical treatment for scoliosis in the adult population with a curvature of less than a 50° Cobb's angle is treated conservatively with thermal therapy, physical and occupational therapies, a progressive exercise regimen, and pain management. Pharmacological intervention is focused on comfort and pain relief. Pain management ranges from mild (aspirin) to moderate (nonsteroidal analgesia) to severe (opioid analgesia). Thermal therapy is used to reduce pain, promote comfort, and assist with spinal flexibility. A growing body of research has shown that exercise can reverse the signs and symptoms of spinal deformity and prevent further progression within adolescents and adults.

### Surgical Management

Surgical intervention may be required with a Cobb's angle greater than 50°. It is considered only after conservative treatment has been shown to be unsuccessful. Surgery is done via **spinal instrumentation** and/or spinal fusion. Spinal instrumentation involves placing steel rods on either side of the spine. They are attached to the spine with hooks or pedicle screws in an effort to straighten the curve both side to side and front to back, decrease pain, and promote skeletal flexibility. The latest evidence supports the insertion of pedicle screws based on the primary advantages of improved coronal correction: correction of the sideways curve, decreased rates of pseudarthrosis, lower failure rate for surgical implants, and the overall ability to correct the curvature of the spine in three planes.

Postoperatively, a total contact orthotic (TCO) device, a **thoracic-lumbar spinal orthotic (TLSO)**, is worn by

the patient for stabilization purposes. The TLSO brace is a custom-fitted orthotic device that stabilizes the spine to prevent instability and flexion or rotation that could subsequently injure the thoracic-lumbar column.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with scoliosis are linked to the curvature of the vertebral column. Common findings include:

- Pain from degenerative changes within the vertebral column (usually thoracic and/or lumbar region)
- Kyphosis
- Asymmetry of hip and shoulder height
- Prominence located on the thoracic rib or scapula region on one side
- Asymmetry in leg length
- Cardiopulmonary compromise with a severe Cobb's angle

#### Nursing Diagnoses

- **Acute/chronic pain** associated with curvature of the thoracic and/or lumbar column
- **Impaired physical mobility** associated with lumbar pain
- **Risk for impaired cardiopulmonary dysfunction** associated with compromise to the thoracic cavity
- **Risk for falls** associated with impairment of the vertebral column
- **Risk for pathologic fractures** associated with destruction of the bony matrix
- **Body image disturbance** associated with change to posture

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Tachypnea, tachycardia, shortness of breath, and decreased oxygen saturation may indicate cardiopulmonary compromise with severe scoliosis.*
- Pain  
*Pain frequently accompanies scoliosis. Increased pain indicates inadequate pain interventions or further progression of the disorder.*
- Assess safety hazard during ambulation and transfers  
*Increased curvature of the vertebral column can cause balance and gait disturbances.*

##### ■ Actions

- Administer pain medication as ordered  
*Adequate pain management helps the patient achieve maximal functional mobility.*
- Maintain orthotic device  
*Orthotic devices such as a TCO/TLSO may be used with/without spinal instrumentation to help with posture and pain relief.*

- Apply thermal therapy as ordered  
*Thermal therapy (hot and/or cold) has been shown to reduce pain and increase functionality.*

### ■ Teaching

- Information on analgesic medication  
*Pain control is essential to encourage mobilization. Caution: Opioids are addicting and can cause constipation, drowsiness, and respiratory depression. Patients should not drink alcohol or operate heavy machinery (car) while on opioids.*
- Teach patient and family how to care for TCO/TLSO brace  
*The patient must wear the brace at all times, unless prescribed differently by the practitioner. The patient generally needs help with washing and changing clothes because of brace limitations.*
- In the event of a fall, report to provider immediately  
*For the patient postspinal instrumentation, subluxation or misalignment can occur with falls.*
- Maintain level of activity and exercise as prescribed by provider and physical therapy  
*Exercise is an integral part of the prevention and management of scoliosis and pain control. Strive for an active lifestyle.*

### Evaluating Care Outcomes

Overall evaluation of care outcomes for scoliosis is focused on pain control and reduction in curvature and rotation of the spinal column. A well-managed patient has pain under control and has functional mobility. This patient wears a TLSO brace as prescribed, and exercises and pursues weight reduction to decrease disease progression.

### Connection Check 53.6

What is considered a nursing priority for a patient with scoliosis?

- Maintain bedrest
- Encourage exercise
- Restrict fluids
- Restrict pain medication

## JOINT REPLACEMENT

### Epidemiology

Total joint replacement (TJR), also referred to as arthroplasty, is most commonly associated with the joints of the hip and the knee but may also include any and all joints within the body. Other common areas are the shoulder, elbow, ankle, and wrist. This is a surgical procedure designed to repair articulating surfaces with a synovial joint. A new smooth surface is restored. The life span for the replacement is typically 10 to 15 years.

According to the Centers for Disease Control and Prevention (CDC), due to the aging population and the increased

incidence of overweight Americans (one-third of all Americans), the need for joint replacement surgery is expected to grow exponentially. The CDC revealed that from 2000 to 2010 the number of joint replacements increased from 138,700 to 310,800 in the 45 and older population with approximately 310,800 total hip replacements. Additionally, the incremental increase was seen in younger age groups and a decrease was evident in the older population. The largest age group was that of the 55 to 64 years of age, with an increase of triple over this period of time. Financially, the average length of stay in the hospital for joint replacement surgery decreased from 5 days to 4 days from 2000 to 2010, which equates to a financial cost saving. From a gender perspective, approximately 18.1% of men and 20.1% of women have joint replacement surgery. *Healthy People 2020* focuses on prevention of disorders that increase the need for joint replacement by stressing weight reduction and smoking cessation.

### Pathophysiology and Clinical Manifestations

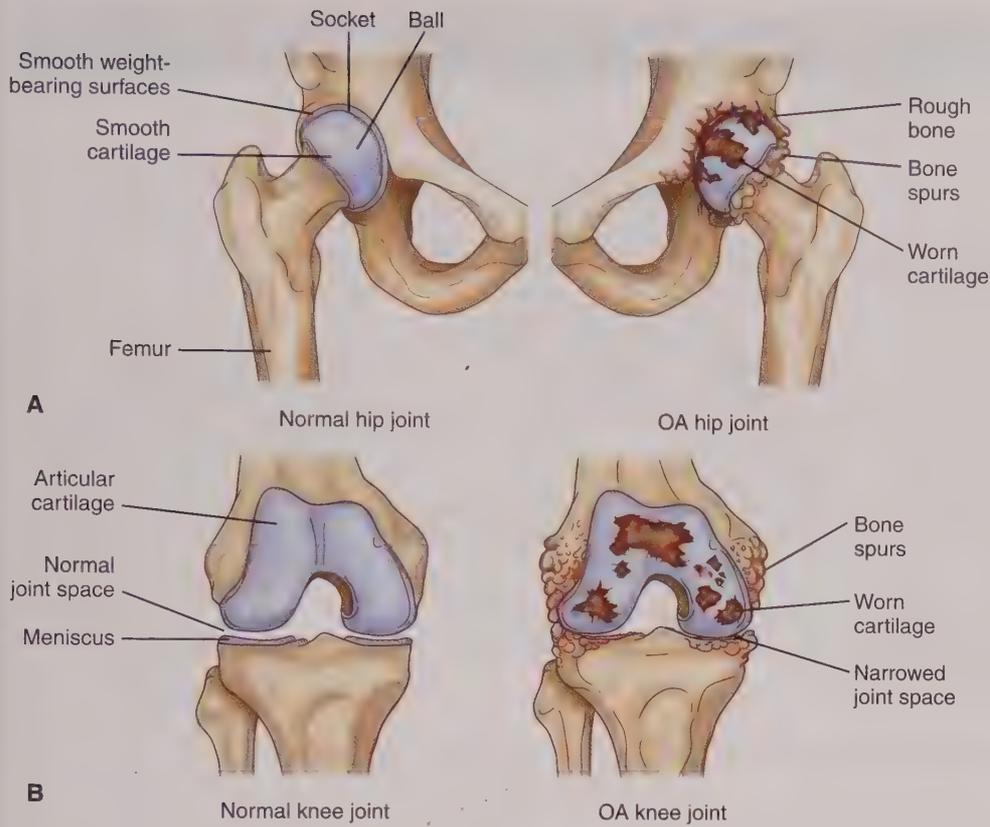

Osteoarthritis (OA) is the leading clinical indication for TJR (Fig. 53.6). Joint cartilage consists of a matrix of proteoglycans and collagen. In OA, there is a decrease in the proteoglycans, which are responsible for the management of the fluid within the joints. The result is a loss of cartilage strength and functionality. Normal cartilage is bluish-white in color. With OA, there is a slow change to translucent color to opaque to yellow-brown in appearance. The result of these changes is the erosion of cartilage and bone with a reduction and narrowing of the joint space and a production of bone spurs (osteophytes). With progression of the disease, fissures, pitting, and ulcerations develop, and there is an increase in the thinning of the cartilage. The inflammatory response produces cytokines (enzymes) such as interleukin-1, which enhance the deterioration. The normal body compensatory mechanisms cannot overcome the rapid degeneration. The result is joint destruction, dysfunction, and deformity, which leads to immobility, pain, muscle spasm, and localized inflammation. Joint replacement involves the removal of the damaged area of the bones with replacement prosthesis. The replacement joint may be a partial or complete prosthesis.

### Management

#### Medical Management

#### Diagnosis

Diagnosing or determining the need for TJR is based on deformity, tissue destruction, and loss of function of a specific joint. Joint changes, stiffness, pain that limits normal activities, and associated muscle atrophy are common indicators to be evaluated. The need for joint replacement is confirmed through radiographical studies such as an x-ray (Fig. 53.7) and MRI that reveal structure and joint pathology associated with the clinical indices for a joint replacement.

**FIGURE 53.6** Osteoarthritis of the hip joint (A) and the knee joint (B).

Narrowed joint space due to loss of cartilage

**FIGURE 53.7** X-ray of severe osteoarthritis of the hip.

### Treatment

The initial medical management before joint replacement is focused on weight management, activity modification, nonsteroidal therapy, and the use of joint supplements such as glucosamine and chondroitin. When the conservative approach is unsuccessful, joint replacement is frequently recommended. The National Institute for Health and Care Excellence states that a total hip replacement (THR) or a total knee replacement (TKR) can be considered once self-management, exercise, and analgesia are no longer effective in relieving pain during activities of daily living. Other clinical indicators for THR and TKR surgeries are described in Table 53.6.

### Surgical Management

Surgical management of joint replacement includes resurfacing of the joint and/or a complete or partial replacement of the joint. Today, most prostheses are made of a cobalt-chrome polished ball with a polyethylene cup or socket on the corresponding surface area (ball and socket). For both THR and TKR, the procedure can be done utilizing an uncemented or a cemented approach with the use of polymethylmethacrylate cement. The cemented approach uses glue or cement to attach the prosthesis to the bone and is usually used for older patients with a life expectancy of 20 years and who are unlikely to require revision surgery.

**Table 53.6 Indications for THR/TKR Surgery**

Clinical Condition	Indication
<i>Osteoarthritis</i>	Degenerative wear of articular cartilage and bony cyst formation
<i>Rheumatoid arthritis</i>	Destruction of articular cartilage and bony erosions
<i>Previous injury or surgery to joint or adjacent to joint</i>	Abnormal wearing of joint surfaces due to changes in anatomical alignment of joint following injury or surgery
<i>Previous childhood hip disease (THR)</i>	Conditions affecting normal development of hip joint in childhood: developmental dysplasia of hip; Perthes disease, slipped capital femoral epiphysis (misalignment of the femur and hip)
<i>Avascular necrosis of femoral head (THR)</i>	Death of femoral head due to trauma (up to 8 years after traumatic event), or alcohol disease
<i>Intracapsular fractured neck of femur (THR)</i>	For patients with underlying osteoarthritis in the fractured hip, a THR may be used instead of hemiarthroplasty (replacement of femoral head but not relining of acetabulum)
<i>Ankylosing spondylitis (THR)</i>	Bony ankylosis (loss of movement) of hip joint

THR, Total hip replacement; TKR, Total knee replacement.

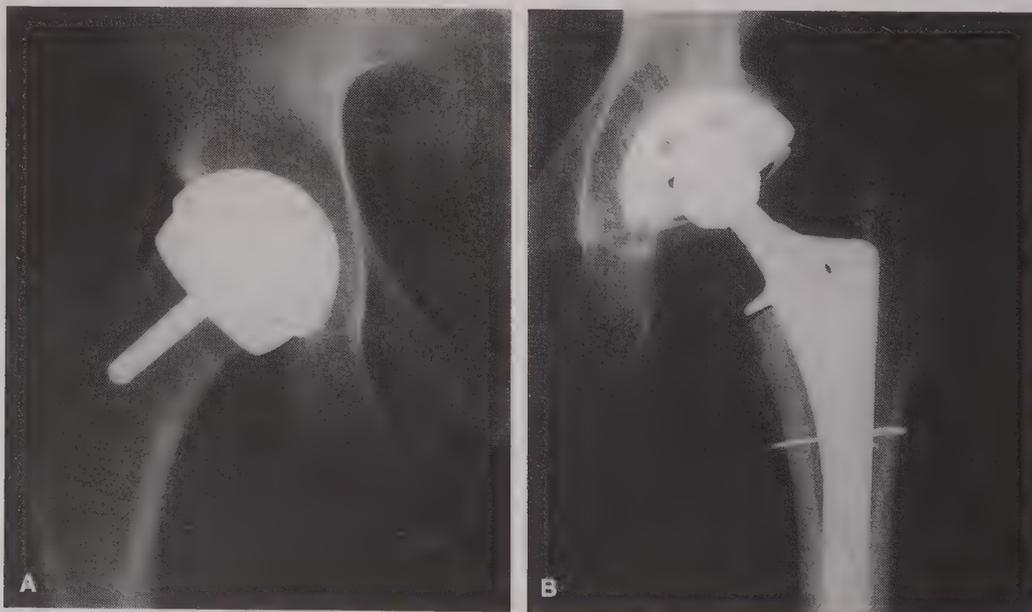

The cement acts as a filler in between bone and prosthesis providing a stable fixation.

Uncemented prosthetics are secured by placing a hole in the bone(s) that is anatomically correct to hold the device in place. The prosthetic joint is coated with hydroxyapatite, which allows for bone ingrowth into the surface of the prosthesis creating a stable bond. This type of surgical approach is used for the younger, more active patient population, allowing for an increase in joint movement and subsequent ease of removal in the event that a revision is required at a later date.

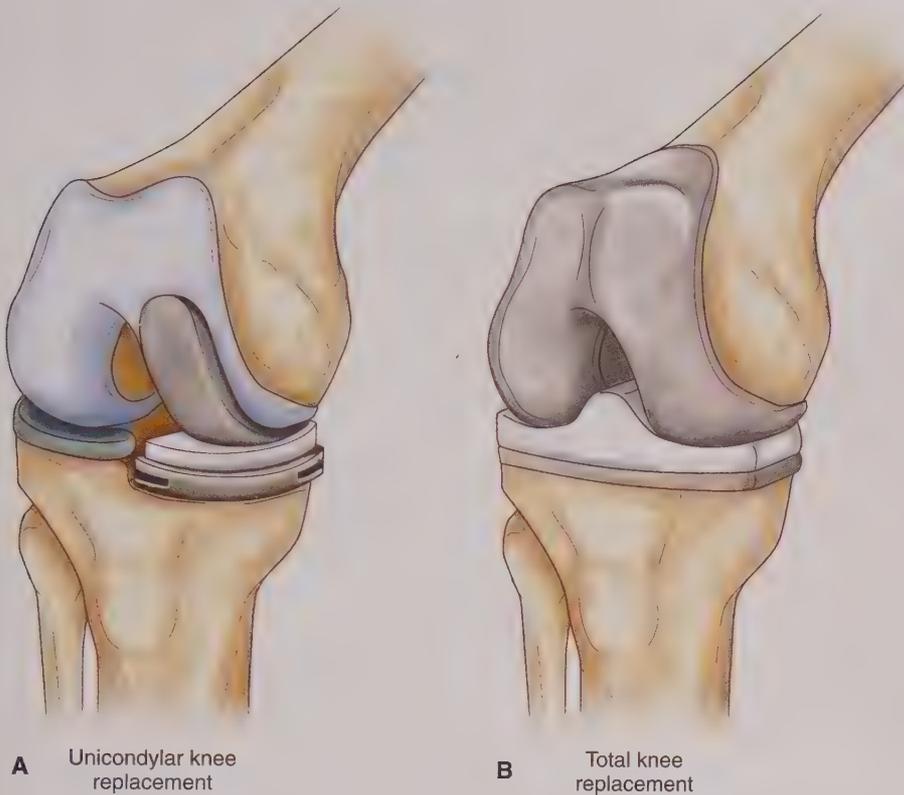

A newer alternative approach for the younger, more active patient population is referred to as *joint resurfacing*

(Fig. 53.8). This approach is used mostly for patients with hip pathology; however, it can be used for other joints such as a knee and shoulder. For patients with hip pathology, the surgical approach involves shaving the femoral head with preservation of the femoral neck and the insertion of a metal cup and metal socket. Surgical and recovery times are greatly reduced, and patient functionality and outcomes are optimized. This approach can also be done with the knee with a unicondylar or partial knee replacement (Fig. 53.9).

Joint replacement has a traditional or minimally invasive surgical approach. The approach varies according to the surgeon. The traditional surgical approach is an incision of

**FIGURE 53.8** Hip replacement. A, Hip resurfacing; preserving the femoral bone; B, Total hip replacement.

**A** Unicondylar knee replacement

**B** Total knee replacement

**FIGURE 53.9** Knee replacement. A, Unicondylar or partial knee replacement; B, Total knee replacement.

approximately 20 to 30 cm in length with staples and/or sutures postoperatively. A longitudinal versus lateral approach causes less damage to the muscle and a shorter incision. Staples are more frequently used for hip surgery because of faster rates of closure and improved wound healing time. The use of a semipermeable dressing rather than tape has been shown to decrease the incidence of skin blistering, promoting optimal conditions for healing and reduction in surgical site infections. A drain is placed during surgery to prevent hematoma formation and allow for autologous blood donation within the first 6 hours of surgery. Because of the potential of a large amount of blood loss during TJR surgery, the addition of this autologous transfusion device has been of great clinical benefit.

A minimally invasive surgical approach is an incision of approximately 10 cm or less. The major advantage of this surgery is reduction in complications such as tissue trauma, which promotes faster healing and quicker recovery. Recent studies have shown an increase in patient satisfaction with this approach; however, the visualization of the joint is limited from a surgical perspective. Because of the relative newness of this surgical approach, outcome statistics are limited. Independent of the surgical technique used, the overall goal for joint replacement remains to allow the patient's bone to grow into the joint and keep the prosthesis securely in place.

### Complications

The most immediate postoperative complications are hypotension, bleeding, and hypovolemia due to excessive blood loss during surgery. Wound site infection is another

potential complication. Intraoperative and postoperative adherence to asepsis with washing hands, proper emptying and cleaning of the drain, and monitoring of temperature and WBC count are simple measures to help prevent wound site infection. Additionally, prophylactic antibiotic therapy is considered protocol until the drain has been removed. The critical complication that is of concern in TJR is dislocation and/or subluxation or partial dislocation. This is where the prosthesis has become loose and is no longer in alignment within the joint. This condition is immediately recognizable because of asynchrony in leg length or abnormal rotation of the hip. This causes severe pain and the inability to bear weight on the affected joint and/or extremity. The most lethal complication is that of a deep vein thrombosis (DVT) and potential pulmonary embolism (PE).

### Connection Check 53.7

Which symptom is an appropriate indication for TJR?

- A. An inability to perform activities of daily living without pain
- B. A desire to participate in contact sports without pain
- C. A knee injury that may restrict aggressive skiing
- D. A hip injury that restricts a prior running routine

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient requiring a joint replacement are associated with the

degenerative changes within the joint. Common findings include:

- Pain from deterioration and structural changes within the affected joint and extremity
- Loss of mobility and joint function

### Nursing Diagnoses

- **Acute/chronic pain** associated with the destruction and/or deterioration of the affected joint
- **Activity intolerance** associated with limited physical mobility and progressive pain
- **Risk for infection** associated with surgical site complication

### Nursing Interventions: Preoperative and Postoperative Nursing Management

#### ■ Assessments

##### Preoperative Assessments

- Presurgical screening; ECG, metabolic profile, coagulation studies, complete blood count  
*Ensuring that patients have been adequately screened for anaesthesia risk correlates with a decreased level of cardiopulmonary compromise and improved pain satisfaction postoperatively.*
- Pain management  
*Assessment of pain tolerance and acceptable level of pain is crucial to early mobilization and ambulation in the early postoperative period.*

##### Postoperative Assessments

- Vital sign assessment  
*Hypertension, tachycardia, and tachypnea postoperatively may indicate problems with perfusion and oxygenation. Hypotension and tachycardia may signal hypovolemia and blood loss.*
- Temperature  
*Increased temperature may indicate a postoperative infection, which may compromise the new prosthetic joint.*
- Pain level  
*Assessment and management of pain is crucial to early mobilization and ambulation in the early postoperative period.*
- Laboratory assessment  
*A decrease in hemoglobin and hematocrit postoperatively due to blood loss hinders oxygen-carrying ability. The patient may require a blood transfusion.*
- Neurovascular assessment  
*Weak pulses, pallor, paresthesia, paralysis, pulselessness, and pain indicate neurovascular dysfunction compromising the new joint.*
- Monitor wound drainage  
*Excessive bloody drainage may indicate a “bleeder” that needs to be evaluated. Thick, purulent drainage may indicate infection.*

#### ■ Actions

##### Postoperative Actions

- Administer pain medication as ordered—Patient-controlled analgesia with a 24- to 48-hour weaning

program with the introduction of opioids and nonsteroidal therapy is most commonly used.

*Pain relief is essential for mobilization and ambulation in the immediate postoperative period.*

- Wound care—Ensure that the dressing and drain are secure; change dressing as ordered utilizing aseptic technique  
*Effective wound care helps decrease the incidence of postoperative wound infections.*
- Mobilization  
*Early movement postoperatively from bed to chair, possibly within 6 hours, is needed to improve and strengthen the muscles in the affected extremity. Early movement facilitates recovery.*
- Antiembolic stocking or compression stocking with sequential compressions device (SCDs)  
*Aids in venous return, which prevents venous stasis and reduces potential for blood clots.*
- Administer anticoagulant therapy as ordered—Some patients may remain on this therapy for as much as 4 to 6 weeks.  
*Anticoagulant therapy in conjunction with early ambulation and antiembolic stockings and SCDs help with venous return, prevention of venous stasis, which reduces potential for DVT and PE.*
- Continuous passive motion (CPM) machine with TKR  
*Some physiotherapists use a CPM machine, which gently flexes and extends the knee (TKR) continuously. The CPM is thought to slowly help increase range of motion, but the evidence does not support its routine use.*
- Maintain proper positioning and turning schedule  
*Abduction pillows prevent dislocation and internal rotation of the affected extremity with a THR. A turning schedule prevents pressure on heels and other bony prominences, which reduces the risk for decubitus ulcers for any type of joint replacement surgery.*
- Teaching
  - Preoperative education about the procedure  
*Research has shown that those patients who have a greater understanding of the procedure and the level of importance report a higher level of outcome and lower level of pain postoperatively.*
  - Postoperative education
    - Take pain analgesic medication as prescribed  
*Pain control is essential to encourage mobilization. Caution: Opioids can cause constipation, drowsiness, and respiratory depression. Patients should not drink alcohol or operate heavy machinery (car) while on opioids.*
    - Anticoagulation teaching
      - Administration of anticoagulant therapy and signs and symptoms of DVT  
*Low molecular weight heparin subcutaneous injections are most commonly used in the home setting. Patient and family teaching should focus on the need to continue the prescribed medication until further notice to prevent DVT. Signs and symptoms of DVT such as pain, warmth, and tenderness at the*

site of the clot should be reported to the provider immediately.

- Bleeding precautions while on anticoagulation  
*Avoid use of electric razors, use soft toothbrushes, no flossing, and avoid high risk for injury activities such as football.*

- Diet

*If on warfarin for anticoagulation limit or maintain consistent intake of foods high in vitamin K such as green vegetables; these foods interfere with the efficacy of warfarin*

- Home management

*Need to reinforce teaching for hip flexion less than 90 degrees for approximately 2 to 3 months. Encourage usage of a raised toilet seat and pull bar in the bathroom (toilet and shower) to prevent flexion of 90 degrees and to prevent falls. Remove scatter rugs around the house and encourage use of slip socks or shoes at all times to prevent patient falls. Avoid crossing the leg over midline to prevent hip abduction and venous stasis as DVT prophylaxis. Use assistive walking devices such as a walker or crutches if recommended by physical therapy.*

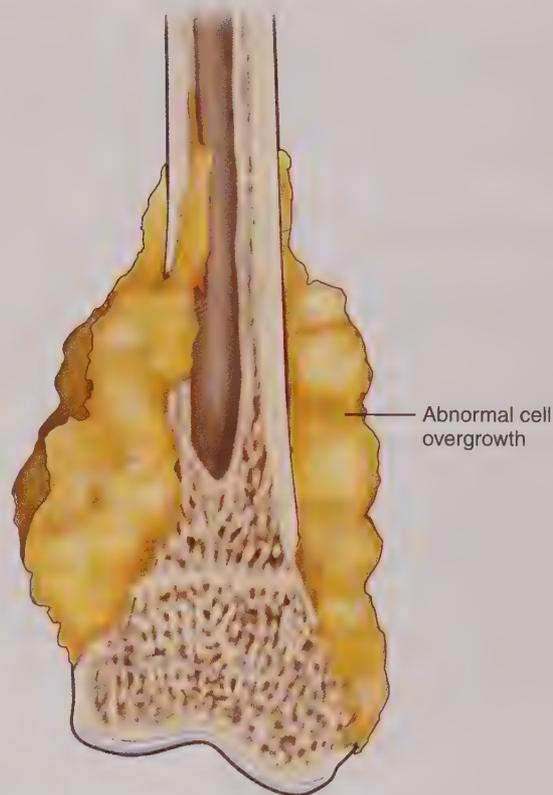

### Evaluating Care Outcomes

Total joint replacement therapy and outcomes are focused on reduction in pain and restoration of functional outcomes. With adequate assessment, wound care, positioning, and careful movement, the immediate postoperative goals of prevention of hypovolemia, surgical site infection, and dislocation of the prosthesis can be achieved. A return to independent activity without limitation in movement and functionality is possible by strictly following activity restrictions, then exercising as directed by the provider and physical therapist. Weight loss and a healthy diet are also necessary for a good result.

## BONE CANCER

Bone cancer is subdivided into two classifications: benign bone cancers, which are noncancerous and often asymptomatic, and malignant, which are cancerous in nature and originate either from a primary or secondary source. Primary bone tumors are more prevalent between the ages of 10 and 30 years and are generally seen only in a small percentage of the population. Secondary or metastatic lesions are more often diagnosed in the older patient population.

Osteochondroma, a benign bone tumor, is the most common form of bone cancer and is seen at the end of a long bone, such as the knee or shoulder. Ewing's sarcoma, a primary bone cancer, is most common in children and is the most malignant and deadly of all the bone cancers. Other bone tumors associated with the adult population are chondrosarcoma, fibrosarcoma, and rhabdomyosarcoma. Chondrosarcomas, tumors of the hyaline cartilage, affect the pelvis and proximal femur area. These neoplasms are generally characterized by dull pain and swelling of the lower extremity. Chondrosarcomas generally have a better prognosis than osteosarcomas and are found predominantly

**FIGURE 53.10** Osteosarcoma; abnormal and undifferentiated cell growth around the bone.

in people of middle to older years of age. Fibrosarcoma, a tumor of the fibrous connective tissue, is a rare primary malignancy in which there is abnormal fibroblast cell division, which leads to lack of cellular control and subsequent invasion of local tissue and migration to other sites in the form of metastasis. Rhabdomyosarcoma is a malignant tumor that originates from normal skeletal muscle cells. The cause is unknown. It is very rare in adults, and only 350 to 400 cases are diagnosed each year in children under the age of 21. This section on bone cancer will predominantly focus on osteosarcoma, which is the most prevalent primary malignant tumor in the adult population.

### Epidemiology

Osteosarcoma is rare, accounting for only 1% of all cancers diagnosed annually in the United States; however, it is the fifth most common malignancy among adolescents and young adults. Approximately 750 to 900 new cases of osteosarcoma (Fig. 53.10) are diagnosed yearly in the United States. Of these statistics, 400 cases arise in children and young adults less than 20 years of age. Osteosarcoma is found twice as often in males than in females between the ages of 10 and 30 years. Peaks for osteosarcoma are also seen in the older population because of a link between osteosarcoma and Paget's disease. The overall prognosis for that group is very poor. Metastasis of osteosarcoma is typically to the lungs and, if it occurs, can be seen within 2 years from the time of diagnosis and ultimately results in death.

Risk factors associated with osteosarcoma are prior radiation and/or chemotherapy, Paget's disease, other benign bone lesions, and other inherited conditions such as Li-Fraumeni's syndrome, Rothmund-Thomson's syndrome, and Bloom's and Werner's syndromes.

## Pathophysiology

The actual etiology of osteosarcoma is not exactly known. One theory is that osteosarcoma arises from rapid or abnormal bone growth and remodeling triggered by an oncogenic agent during a time of cell proliferation or growth. This may explain why it occurs commonly in children and adolescents. The underlying pathology of a tumor of the bone is a disruption in either the osteolytic response (bone destruction) or the osteoblastic (bone growth) activity within the bone tissue. Osteosarcomas are associated with a production of osteoid or immature malignant bone cells. They are typically seen where the bone is growing quickly, such as near the ends of the long bones in the distal femur, the proximal tibia, or the proximal humerus.

## Clinical Manifestations

Clinical manifestations of osteosarcoma are common to those of other musculoskeletal health problems, sometimes delaying diagnosis. The following manifestations may be present primarily at the tumor site:

- Pain worse with motion and unrelieved by rest
- Pain may result in a limp
- Swelling
- Redness
- Decreased range of motion
- Fracture

## Management

### Medical Management

#### Diagnosis

The primary evaluative tool is a comprehensive history and physical examination focusing on the musculoskeletal system. The past medical history focuses on exposure to previous radiation and/or chemotherapy. Following the history and physical, diagnostic studies including CT, bone scans, myelography, arteriography, MRI, bone biopsy, and biochemical analyses of the blood and urine are recommended. Serum alkaline phosphatase, LD, and ESR levels are frequently elevated with osteosarcomas due to the increased enzyme activity at the level of the muscle, the deterioration of bone, and the inflammatory response. With metastasis from the breast, kidney, or lung to the bone, elevated calcium levels are frequently noted. Computed tomography is not definitive in diagnosis but is helpful with assessing for metastasis. Magnetic resonance imaging is superior to CT due to the ability to define the extent of soft tissue involvement, neurovascular compromise, joint and marrow involvement, and the presence of

metastasis. The definitive diagnostic study is a bone biopsy done to determine cell histology and cancer stage and confirm the diagnosis.

### Treatment

The primary objective of medical management is to destroy or remove the tumor. The ultimate goal for treatment is limb salvation, survival, and maintenance of quality of life. Treatments can range from radiation therapy (if radiosensitive) to chemotherapy to surgical incision. Radiation therapy, such as brachytherapy (internal radiation) or external radiation treatment, is used if the tumor is radiosensitive. In the case of primary bone tumors, radiotherapy is used to destroy or to reduce the size of the tumor so that chemotherapy and/or surgical excision can be used for treatment. Radiation therapy can be scheduled for one session or for multiple sessions depending on the radioactive treatment response and the tumor's cellular structure.

Chemotherapy is another treatment alternative. Again, the goal is to reduce and/or destroy the bony tumor to prevent metastasis. Essential to the successful eradication of bone tumors via chemotherapy is early identification and treatment. Treatment must be initiated when the disease burden is low. Most osteosarcoma tumors, as well as other bone tumors, use a multimodality treatment approach: multiple chemotherapeutic agents and/or a combination of radiation and surgical intervention.

Pain control is another significant goal of treatment. Treatment includes nonsteroidal anti-inflammatories, such as acetaminophen, but commonly narcotics are necessary to manage pain.

### Surgical Management

Surgical management of bone cancers is focused on resection of the cancerous mass and limb salvation. For most bone cancers, radical resection, removal of the mass, the entire muscle, bone, and other surrounding tissues that have direct involvement with the lesion, is performed. The focus of this surgical approach is limb salvation and prevention of metastasis. In the event of large bone resection, TJRs with prosthetic implants as well as other surgical procedures (allograft, vascular grafting) may be required.

### Complications

In the absence of appropriate therapy and medical management, neoplasms of the bone are associated with disabling and life-threatening complications such as amputation and death. In the event that destruction of the tumor is not evident and tumor growth and spread are probable, resection of the entire bone is deemed medically appropriate. Other complications after surgery include delayed wound healing, osteomyelitis and wound infections, and hypercalcemia.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with bone cancer are directly associated with the pain and the extent of the cancer to the bone and surrounding tissues

and organs. Most common sites of involvement are the distal femur, proximal tibia, proximal humerus, and middle and proximal femur (occasionally the jaw with Paget's disease). Common findings include:

- Localized pain, typically over several months' duration
- Pain frequently noted with incurrence of injury (may come and go over time)
- Soft tissue mass that is large and tender on palpation

Other clinical manifestations such as fever, malaise, and weight loss are associated with metastasis and are not normally seen with primary bone cancer diagnosis.

### Nursing Diagnoses

- **Acute/chronic pain** associated with the destruction of bone
- **Impaired physical mobility** associated with pain and inflammation
- **Peripheral neurovascular dysfunction** associated with impaired perfusion
- **Ineffective tissue perfusion** associated with inflammation
- **Grieving** associated with impaired body image (possible loss of limb)
- **Risk for pathologic fractures** associated with destruction of the bony matrix

### Nursing Interventions

#### ■ Assessments

- Respiratory rate/level of consciousness  
*Bone cancer requires aggressive pain management; a decrease in respiratory rate or level of consciousness may indicate overmedication.*
- Pain assessment  
*Regular pain assessment provides a baseline and is an indicator of effective/ineffective pain management.*
- Neurovascular assessment  
*Weak pulses, pallor, pain, paresthesia, paresis, and/or paralysis indicates a compromise in neurovascular status that may be caused by compartment compromise (increased pressure in the tissues surrounding the mass) resulting in loss of muscle, tissue, nerves, and bone.*
- Palpation of mass  
*A palpable mass with swelling, pain, and tenderness may indicate a progression of tumor growth and metastasis.*
- Assess level of activity, exercise, and independent function  
*Independence versus dependence is a potential problem for patients with bone cancer. Pain and the disability caused by osteosarcoma may limit the ability to perform activities of daily living independently.*

#### ■ Actions

- Administration of pain medication as ordered  
*Pain is extensive and requires aggressive pharmacological intervention. Monitor vital signs of patient for opioid-induced respiratory depression.*

- Work with healthcare team to support long-term pain relief, pharmacological and nonpharmacological  
*The most effective pain management approach helps the patient maintain a functional status as well as provides a plan for procedures that may be necessary to manage increasing pain.*
- Prepare and support the patient for radiation treatment if warranted; be sure patient is free from moisture, deodorant, or creams  
*Moisture, deodorant, or creams may cause radiation skin irritations and burns.*
- Administer chemotherapeutic therapy as ordered  
*The goal of chemotherapy is to reduce or destroy tumor cells.*
- Support and position the affected extremities with gentle range of motion and exercises to the joints above and below the affected site  
*Bone tumors weaken the bone, causing extreme pain on movement. Exercises for pain relief and external supports are used for additional support, comfort and safety.*
- Apply thermal therapy as ordered from rehabilitative services  
*Thermal therapy (hot and/or cold) has been shown to reduce pain and increase functionality.*

#### ■ Teaching

- Take pain analgesic medication as prescribed  
*Adequate pain management is essential to promote maximal independent functioning. Caution: Opioids are addictive and can cause constipation, drowsiness, and respiratory depression. Patients should not drink alcohol or operate heavy machinery (car).*
- Teach patient about radiation therapy  
*Radiation therapy can cause localized skin irritation, blisters, and burns. No creams, talcum powder, or emulsion agents should be used before radiation treatment. Also, general malaise can be seen with some radiation treatments.*
- Teach patient to eat a diet rich in protein  
*A high-protein diet helps with tissue and wound healing.*
- Provide training for safe movement with activities of daily living  
*The patient population is at great risk for pathologic fractures causing falls. Use assistive devices when appropriate.*
- Patient understanding of disease process and symptom management, onset and course of injury and illness  
*Patient understanding of the disease process, course of illness, and symptom management is essential for early diagnosis and treatment of the disease.*

### Evaluating Care Outcomes

Limb salvation and prevention of metastasis are the essential components of a well-managed patient with osteosarcoma. Effective pain management facilitating an optimal level of independence are paramount for patient comfort. Early recognition of symptoms is of key importance because it allows early initiation of treatment with radiation, chemotherapy, and/or surgical excision.

### Connection Check 53.8

A patient is postoperative day 1 following a surgical procedure after a recent diagnosis of osteosarcoma to his tibia. The nurse recognizes the patient has good understanding of his diagnosis by which statement?

- "The doctors opened my bone to take a biopsy for the diagnosis."
- "The doctors opened my bone to take the tumor out and all the tissue around it."
- "The doctors opened my bone to remove dead bone."
- "The doctors opened my bone to clean out the infected area."

- The nurse understands which of the following is an important teaching point for Ms. Doherty?
  - Boniva must be taken on an empty stomach.
  - Boniva is taken once a week.
  - Boniva may cause joint pain.
  - Boniva is taken instead of calcium.
- The nurse understands which of the following is implicated in the development of osteoporosis?
  - An increase in calcitonin level
  - A decrease in estrogen level
  - A decrease in the parathyroid hormone
  - A decrease in phosphorus level

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Eileen Doherty demonstrates classic signs of osteoporosis (vertebral changes noted as kyphosis, or "dowager's hump"). She states she has noticed that her pants seem longer. She complains of back pain and increased difficulty with simple activities of daily living such as short walks. Initial diagnostic results for Ms. Doherty reveal an elevated ESR, decreased serum calcium level, and a  $-2.5$  T score for BMD study. These results are consistent with primary osteoporosis. The healthcare provider orders Ms. Doherty to begin bisphosphonate therapy with ibandronate (Boniva) by mouth.

#### Case Study Questions

- Ms. Doherty demonstrates the need for more teaching by which of the following statements?
  - "I don't need to take calcium or vitamin D anymore."
  - "I know I need to develop an exercise plan."
  - "I may need to remove a lot of the small throw rugs around the house."
  - "I know I will need to follow up on a regular basis."
- The nurse understands which screening tool will help evaluate home safety?
  - FRAX
  - Medication
  - Dietary
  - Activity
- Ms. Doherty's greatest risk factor for the development of osteoporosis is which of the following?
  - A low BMD
  - A high BMD
  - A low FRAX
  - A high QCT

## CHAPTER SUMMARY

Muscular dystrophies (MDs) are classified as an inherited group of progressive myopathic (muscle) disorders that are caused by defects in normal muscle function. The Duchenne and Becker muscular dystrophies (MDs) are caused by a mutation to the dystrophin gene; a gene responsible for muscle repair. In the absence or reduction of dystrophin, there is degeneration of the muscle fibers resulting in muscle weakness. The primary commonalities among all the MD disorders are progressive muscle weakness, muscle wasting, and increased muscle enzyme serum levels.

Osteoporosis is a chronic condition that results in deterioration of bone tissue and density, which results in an increased risk for fractures. The most widely used fracture risk assessment tool is the FRAX (Fracture Risk Assessment Tool). Assessment is primarily done through BMD measurements obtained through a dual-energy x-ray absorptiometry (DEXA) scan. Intervention is focused on preventing and slowing the progression of bone loss with the use of calcium and vitamin D. Although other medications are available, the primary treatment is the administration of bisphosphonates.

Paget's disease of the bone (PDB), also referred to as *osteitis deformans*, is a bone metabolism disorder that is associated with accelerated bone remodeling. Osteoclasts increase in size and number, escalating resorption of bone. Consequently, osteoblasts add to new bone at an increased rate, which leads to enlarged bony structures that are disorganized in structure and reduced in mechanical strength, leading to patients at risk for the development of deformities and fractures. The skeletal areas most commonly affected are the skull, femur, tibia, pelvic bones, and vertebral column. There is no effective treatment of Paget's disease. Medication therapy is focused on pain management and functional outcomes. Bisphosphonates are used to help manage the bone remodeling.

Osteomyelitis is defined as a localized infection of the bone. Hematogenous, or endogenous, osteomyelitis is a result of infectious spread from another area of the body via the bloodstream. Nonhematogenous, or exogenous, osteomyelitis is a result of an open fracture and/or trauma to the bone. Clinical manifestations include pain not relieved by rest, swelling, tenderness, erythema and warmth at the site, fever, nausea, chills, and malaise. Chronic osteomyelitis results in constant bone pain and swelling, tenderness, and warmth at the site. The initial line of treatment is antibiotics. Opioid analgesia is indicated to manage the pain. The priority nursing diagnosis is infection.

Scoliosis is not a diagnosis but rather a description of the structural alteration that is noted by a curvature of the spine greater than a  $10^\circ$  curvature (Cobb's angle) that is normally associated with rotation and compression. Conservative treatment includes thermal therapy, physical and occupational therapies, a progressive exercise regimen, and pain management. Pharmacological intervention is focused on comfort and pain relief. A Cobb's angle greater than  $50^\circ$  may be managed surgically via spinal instrumentation and/or spinal fusion. A nursing priority with scoliosis is to provide pain relief to enable the patient to maintain adequate exercise levels.

Total joint replacement (TJR) is most commonly associated with the joints of the hip and the knee. Our aging population and the increased incidence of overweight Americans (one-third of all Americans), is expected to exponentially increase the need for joint replacement surgery. Osteoarthritis is the leading clinical indication for TJR. A total hip replacement (THR) or a total knee replacement (TKR) can be considered once self-management, exercise, and analgesics are no longer effective in relieving pain during activities of daily living.

Bone cancer is subdivided into two classifications: benign bone cancers, which are noncancerous and often asymptomatic, and malignant, which are cancerous in nature and can originate from either a primary or secondary source. The cause of primary bone cancer, osteosarcoma, is not exactly known. One theory is that osteosarcoma arises from rapid or abnormal bone growth and remodeling triggered by an oncogenic agent during a time of cell proliferation or growth. Clinical manifestations include pain, redness, warmth, and deformity around the tumor site. The primary objective of medical management is to destroy or remove the tumor. Surgical management of bone cancers is focused on resection of the cancerous mass and limb salvation. Treatments can range from radiation therapy to chemotherapy to surgical incision.

# Chapter 54

## Coordinating Care for Patients With Musculoskeletal Trauma

*Susan Kulik*

### LEARNING OUTCOMES

Content in this chapter is designed to support the learner in:

1. Describing the epidemiology of various types of musculoskeletal trauma
2. Identifying the clinical manifestations in the pathophysiological processes of:
  - a. Strains and sprains
  - b. Fractures
  - c. Amputations
  - d. Meniscus injuries
  - e. Carpal tunnel syndrome
3. Describing the diagnostic results used to confirm the specific type of musculoskeletal trauma
4. Explaining the effective medical management of:
  - a. Sprains and strains
  - b. Fractures
  - c. Amputations
  - d. Meniscus injuries
  - e. Carpal tunnel syndrome
5. Developing a comprehensive plan of nursing care for patients with musculoskeletal trauma
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations based on patients with musculoskeletal trauma
7. Explaining the clinical presentation and management of complications associated with musculoskeletal trauma

### CONCEPTS

- Assessment
- Comfort
- Inflammation
- Medication
- Mobility
- Perfusion
- Perioperative
- Promoting Health

### ESSENTIAL TERMS

**Amputation**  
**Carpal tunnel syndrome (CTS)**  
**Closed reduction**  
**Compartment syndrome**  
**Dislocation**  
**External fixation**  
**Fat emboli**  
**Fracture**  
**Hypovolemia**  
**Internal fixation**  
**Malunion**  
**Neuromas**  
**Neurovascular compromise**  
**Nonunion**  
**Open reduction**  
**Phantom limb pain**  
**Rhabdomyolysis**  
**Sprain**  
**Strain**  
**Traction**  
**Traumatic amputation**  
**Venous thromboemboli (VTE)**

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Zachary White is a 29-year-old male driver involved in a head-on motor vehicle collision. He was ejected from his vehicle, and his right leg was trapped under the vehicle until the medics arrived on scene. He is awake, alert, and yelling because of the severe pain in his right leg. On closer inspection, he has an open right femur fracture that is bleeding profusely and is missing a chunk of muscle. The EMS placed Zachary's right leg in a Hare traction splint, start two large-bore IV lines, and transported him to the emergency department.

Zachary's breath smells of alcohol, and his family member states that he was at a college party. He has no medical history and is not allergic to any medications...

## INTRODUCTION

Musculoskeletal conditions and injuries are not just conditions of older age; they are relevant across the life span. Between 60% and 77% of unintentional injuries reported in the United States are due to musculoskeletal trauma. Approximately 20 to 27 million musculoskeletal injuries occur annually in the United States, with **strains** and **sprains** the most prevalent, followed by **fractures**. These injuries often yield negative effects on patients' mobility and sensation and subsequently impair their performance of activities of daily living (ADLs). Nurses must be knowledgeable and prepared to provide appropriate care for patients with musculoskeletal injuries.

## STRAINS AND SPRAINS

### Epidemiology

Strains and sprains consistently occur from sporting injuries in athletes of all ages, but they are also caused by accidents at home, at work, and during recreation. Ankle sprains are the most frequently occurring orthopedic injury and are responsible for 40% of all athletic injuries, totaling five million annually. The frequency of ankle sprains can be ranked highest among the sports of basketball, ice-skating, and soccer. Another common injury, an anterior cruciate ligament (ACL) tear, a severe strain, occurs mostly from noncontact injuries from sports that involve twisting and jumping. Basketball, football, soccer, and gymnastics generate the highest number of ACL tears. Women are nine times more likely than men to sustain an ACL tear because of several biomechanical and neuromuscular factors. Women have a greater degree of valgus knee torques (knock-knee),

have less muscular strength, and have more knee laxity (flexibility), which puts them at higher risk of ACL injury. There are an estimated 80,000 to 100,000 ACL repair surgeries annually in the United States.

### Pathophysiology and Clinical Manifestations

A strain is an injury to muscle or tendon tissue. Tendons connect muscles to bones. A strain is the tearing or stretching of a muscle or tendon, often resulting from overextension, overexertion, or overstretching. Strains can be categorized according to their severity:

- First-degree/mild strains demonstrate minimal inflammation and pain. Symptoms can last for several days, but range of motion (ROM) remains unaffected.
- Second-degree/moderate strains result from actual tearing of the muscle and tendon fibers. This injury is often painful, with severe muscle spasms, extensive inflammation, and ecchymosis that appear several hours or days after the initial injury. Symptoms can last for several weeks.
- Third-degree/severe strains include the rupture of the muscle or tendon, causing considerable internal bleeding, pain, inflammation, and ecchymosis. Surgical repair may be needed if there is extensive tearing in the muscle or tendon.

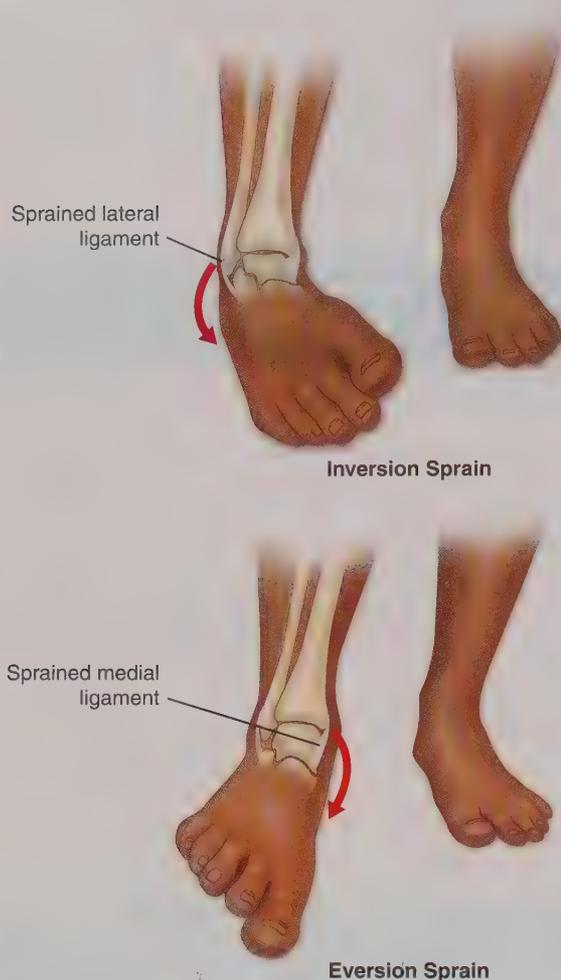

A sprain is an injury to ligaments. Ligaments are segments of connective tissue that secure bones to bones and bones to cartilage. As in tendons, a sprain is defined as the stretching or tearing of a ligament resulting from overextension, overexertion, or overstretching (Fig. 54.1). Sprains are also classified similar to strains on the basis of severity:

- First-degree/mild sprains demonstrate stretching and/or minimal tearing of ligament fibers. Edema and pain may be evident, but joint function remains intact, and patients are able to ambulate with slight discomfort.
- Second-degree/moderate sprains result from a moderate amount of tearing in the ligament fibers. The joint remains intact, and the ligament is not completely torn. Increased swelling, ecchymosis, pain, and altered weight-bearing mobility are evident in these patients.
- Third-degree/severe sprains include the complete tearing of a ligament, which renders the patient unable to ambulate because of joint instability. Symptoms include severe pain, ecchymosis, and edema.

### Connection Check 54.1

The nurse recognizes that the stretching or tearing of a muscle or tendon occurs in which condition?

- Strains
- Dislocations
- Fractures
- Sprains

**FIGURE 54.1** Inversion and eversion sprains caused by ankle rotation.

## Management

### Medical Management

#### Diagnosis

The diagnosis of sprains and strains is based on a thorough history and physical examination of the affected area and is often confirmed by radiography, ultrasound, or magnetic resonance imaging (MRI). Ultrasounds are low cost and highly effective in identifying strains and sprains, but an MRI may be more definitive in the final diagnosis.

#### Treatment

Treatment of first- and second-degree strains and sprains involves **RICE**, a common acronym referring to the treatment plan for strains and sprains:

- **R**est the injured extremity for as long as 72 hours to allow the ligaments or tendon time to heal.
- **I**ce applied for no longer than 30 minutes three to five times per day for 24 to 72 hours after injury. This promotes vasoconstriction and decreases bleeding and fluid collection in the injured area.
- **C**ompression by means of an Ace wrap or similar compression dressing to minimize further swelling,

which can delay healing. The dressing should be wrapped tightly but not enough to alter neurovascular function. Ensure that circulation, movement, and sensation remain intact.

- **E**levate the affected area to minimize dependent swelling.

Functional supports in the form of braces may be used for 4 to 6 weeks and are preferred versus immobilization. Exercise therapy programs may be prescribed and consist of neuromuscular and proprioceptive exercises. In addition to the therapies mentioned previously, NSAIDs are usually prescribed to minimize pain and inflammation.

Third-degree strains may require surgical repair of the torn tendon or muscle. Surgical repair typically involves an open incision and the use of thick suture material to reattach the torn muscle and tendons. Occasionally, either a graft from the patient's healthy tendon or a donor graft can also be used for surgical repair. Third-degree sprains may necessitate the need for arthroscopic surgical repair. Arthroscopic surgery uses small scopes to visualize and repair the injured area. Musculoskeletal allografts are gaining popularity for ligamentous reconstruction by orthopaedic surgeons while their safety and efficacy continue to improve. Postoperative treatment for strains and sprains involves immobilization of the affected extremity for 4 to 6 weeks and physical therapy.

### Complications

There can be numerous complications from strains and sprains, such as chronically unstable joints, bursitis, tendinitis (Box 54.1), and frequent reoccurrence. Strains and sprains

## Box 54.1 Bursitis and Tendinitis

### Definitions

Bursitis is an inflammation of the bursa, a sac located between bone or muscle or tendon that contains lubricating fluid to decrease friction with movement. Tendinitis is an inflammation of the tendon. Both are more common in people older than 40 because age makes tendons less elastic and more prone to tearing.

### Causes

Both conditions are typically caused by overuse, repetitive minor impact, or a sudden, more significant impact to the affected area. Areas typically affected include the elbow, hip, shoulder, or knee.

### Symptoms

Pain in the affected area occurs in both conditions.

### Treatment

Avoidance of activities that aggravate the irritation, rest for the affected area, and anti-inflammatory medications are methods of treatment for both conditions.

can cause significant alterations in patient mobility, limiting function and the ability to perform self-care. Additionally, patient noncompliance with therapeutic treatment regimens can cause future disability, increased risk for repeated injuries, and the need for surgical intervention. Although extremely rare, **compartment syndrome**, excessive pressure in a compartment of the body due to bleeding or edema which impedes blood flow resulting in severe tissue damage in the affected area, can develop in patients with sprains and strains.

### Nursing Management

#### Assessment and Analysis

Close examination of the affected extremity typically reveals swelling, ecchymosis, and deformity due to strain, tearing, or rupture of the ligaments, tendons, or muscles. Patients may also exhibit intolerance to palpation and be unable to bear weight on the injured side.

#### Nursing Diagnoses

- **Acute pain** associated with the physical injury
- **Altered peripheral tissue perfusion** associated with edema and vessel damage
- **Impaired physical mobility** associated with the injury

#### Nursing Interventions

##### Assessments

- Physical assessment of injured extremity via inspection and palpation: palpate the injured extremity noting the six Ps to include **p**ain, **p**ressure, **p**aralysis, **p**allor, **p**ares-thesis, and **p**ulselessness. Complete the neurovascular assessment by checking movement and sensation.  
*Inspection and palpation are done to assess circulation, movement, and sensation in the injured area. The presence of the six Ps may indicate neurovascular compromise of the injured area and may necessitate immediate medical intervention to prevent permanent damage. Extreme pain may indicate the presence of a fracture.*
- Patient history of injury  
*Appropriate medical management is dependent on an accurate patient history to include determination of a chronic versus acute injury.*

##### Actions

- Rest the injured extremity  
*Minimizing activity promotes healing.*
- Ice applied to the injury  
*Cryotherapy causes vasoconstriction, which decreases further bleeding and inflammation.*
- Compression via ace wrap  
*Compression reduces the inflammation that causes pain and delays healing.*
- Elevation  
*Elevation decreases edema, which eases pain and promotes mobility of the injured area.*
- Administer anti-inflammatory and analgesia medications as ordered

*Inhibit prostaglandin (mediators of pain and inflammation) formation, which can reduce pain and inflammation*

##### Teaching

- Immediately report any worsening symptoms in the injured area, to include continued pain, loss of function, loss of mobility, or loss of sensation  
*Alterations in circulation, movement, and sensation can signal the need for further medical intervention.*
- RICE therapy  
*Compliance with the prescribed treatment regimen ensures appropriate healing and the return of the injured limb to normal function.*

#### Evaluating Care Outcomes

Severe strains and sprains may require surgical intervention and lengthy postoperative treatment regimens that include physical therapy. Optimal recovery is possible with compliance with physical therapy–suggested exercises. A well-managed patient should return to normal function with compliance with the treatment protocol.

#### Connection Check 54.2

The nurse identifies which pathophysiological finding in a third-degree sprain?

- Stretched muscle or tendon fibers
- Torn/ruptured ligaments
- Torn/ruptured muscle or tendon fibers
- Stretched ligaments

#### CASE STUDY: EPISODE 2

Zachary demonstrates classic symptoms of an open, displaced femur fracture. The emergency department provider immediately consults with the orthopedic surgeon, and 45 minutes later, Zachary is taken to the operating room. After significant irrigation of the open right femur fracture, the surgeon conducts an open reduction with placement of an external fixator...

## FRACTURES

### Epidemiology

The incidence of fractures in the United States is on the rise, with an estimated six million fractures occurring annually. Fractures most often occur in the young and in the older population because both groups have bone that is porous and contains areas of weakness. Fragility fractures in older adults are a result of progressive decrease in bone density and bone strength. They also frequently suffer from chronic bone disorders that increase the risk of pathologic fractures. These chronic bone disorders are Cushing's syndrome, osteoporosis, osteogenesis imperfecta, neoplasms, anorexia, and Paget's

disease. These diseases significantly weaken bones, decrease load-carrying capacity and tolerance to force, increase the patient's susceptibility to fractures, and further prolong the healing process. Fractures in young people between the ages of 12 and 21 are typically the result of high-energy trauma. Examples of high-energy trauma include motor vehicle collisions, contact sports, and bicycle accidents. Fractures in people 65 years or older are usually caused by low-energy trauma, for example, fractures from falling.

## Pathophysiology and Clinical Manifestations

Bone is classified as dense, irregular connective tissue made up of osteoblasts and osteocytes. Bones provide support and structure, assist the body in movement, and protect vital organs. When excessive force is placed on bones, they fracture. A **fracture** is defined as a disruption, or break, in the continuity of a bone. There are numerous classifications of fractures that can occur throughout the body (Fig. 54.2).

### Types of Fractures

- **Complete.** The disruption spans across the width of the bone, causing bone fragments.
- **Incomplete.** The disruption occurs through part of the bone cortex; however, there is no displacement of bone fragments.
- **Closed (simple).** Fracture that is contained within the skin
- **Open (compound).** Disruption in which pieces of bone protrude through the skin, creating an external wound that exposes the fracture site. Open fractures are graded on the basis of their severity.
  - **Grade I.** Presence of a puncture wound, minimal injury to the soft tissues, and vasculature remains intact
  - **Grade II.** Puncture wound, fragments of broken bone, moderate skin and muscle contusions, and significant wound contamination
  - **Grade III.** Severe damage to soft tissues, nerves, muscles, and blood vessels. The open fracture site is considered extremely contaminated and contains numerous comminuted fractures.

### Fracture Patterns

- **Avulsion.** Caused by the overstretching and tearing of a tendon or ligament, separating a small segment of bone at the insertion site
- **Comminuted.** Fracture that has several disruptions producing shattered bone fragments within the fracture site
- **Compression.** Fracture caused by excessive force along the axis of cancellous (spongy internal layer of bone) bone, leading to the bone collapsing on itself; representative in vertebral compression fractures from falls of significant heights
- **Depressed.** Disruptions in which fragments of bone are forced inward; frequently seen in facial and skull fractures involving blunt trauma
- **Displaced.** Malalignment of bone fragments at the fracture site

- **Greenstick.** An incomplete disruption in which one side of the bone is bent and the other is fractured; generally seen in children because of the flexibility of their bones
- **Nondisplaced.** Bone fragments are well approximated within the site of disruption.
- **Oblique.** The fracture line occurs usually at a 45-degree angle across the cortex of the bone.
- **Spiral.** The fracture wraps around the shaft of the bone.
- **Impacted.** Segments of bone are wedged into each other at the fracture line.

## Management

### Diagnosis

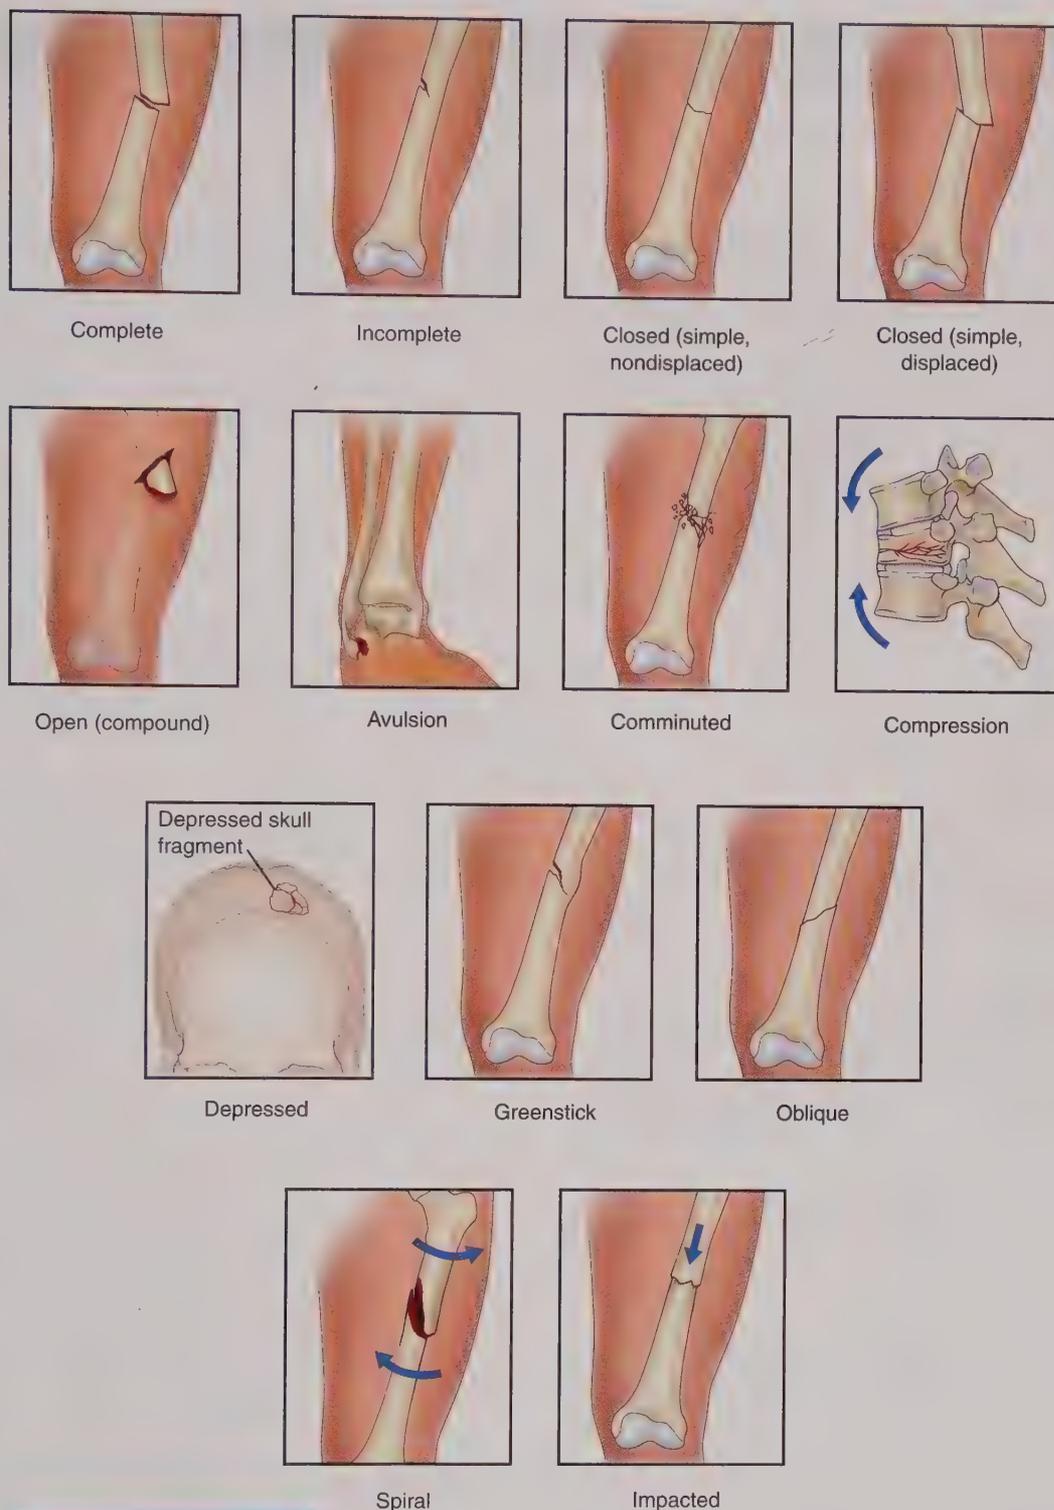

The diagnosis of fractures is based on a thorough history of how the injury occurred, a physical assessment, and is confirmed by radiography or computed tomography (CT). When the patient's history is obtained, it is important to note the specific mechanism of force that caused the injury. Other imperative information includes the patient's medical history and any chronic illnesses, medications, and potential substance abuse. Medications and substance abuse can impair mental judgment and function and contribute to motor vehicle accidents and falls, thus producing bone fractures and other traumatic injuries. If a chronic illness is suspected as having a major role in the injury, a bone scan and MRI may be needed to confirm the diagnosis.

### Treatment

Definitive treatment of fractures is highly dependent on their type and location and may require either surgical or nonsurgical intervention. Table 54.1 describes various fractures and their treatment. In the case of open fractures with contaminated wounds, antibiotics are implemented to prevent osteomyelitis and other wound infections. Effective pain management is an important aspect in treating fractures. Narcotics and anti-inflammatory medications are effective in controlling pain and inflammation. These medications allow the patient to gradually regain movement and function of the injured area. After definitive treatment, movement and function are key in preventing muscle atrophy and contractures.

### Nonsurgical Management

Nonsurgical treatment of a fracture, or a **closed reduction**, is the most frequent type of nonsurgical fracture treatment in which the fractured bone segments are manually manipulated and realigned while the patient is under general anesthesia. General anesthesia is needed to ensure complete muscle relaxation for proper bone realignment. After closed reduction, the realigned bone is typically placed in a cast or a splint. Splints are a form of nonrigid immobilization to maintain alignment of bone fragments. Casts are rigid immobilization devices constructed of fiberglass or plaster for use on weight-bearing extremities. Adjunctive therapies include ultrasound and electromagnetic stimulation. Percutaneous autologous bone marrow grafting has been used

**FIGURE 54.2** Types of fractures.

with nonunions, and treatment has demonstrated increased healing rates.

### **Surgical Management**

Surgical repair of fractures includes an **open reduction** with **internal fixation** or **external fixation**. Open reduction requires a surgical incision that enables the surgeon to

accurately visualize the wound and ensure proper realignment. Internal fixation requires the use of plates, screws, rods, and other hardware to realign the fractured bone segments. Irrigation and debridement might be needed for open fractures that are contaminated with dirt and foreign matter. External fixation is the application of a series of rods and pins to the area surrounding the fracture,

**Table 54.1 Fractures of Various Sites**

Type of Fracture	Mechanism of Injury	Treatment
<b>Skull</b>	Blunt force	If at risk for or showing signs of elevated pressure within the brain: Operative treatment via Burr holes (surgically created hole in the skull to relieve pressure), craniotomy (bone flap removed for access to brain tissue then replaced), or craniectomy (bone flap removed and not replaced) followed by ORIF with plates and screws No elevated brain pressure: Nonoperative observation
<b>Spinal</b>	Compression: Fall from significant heights Hyperflexion and hyperextension: Acceleration and deceleration injuries	Compromised neurological function or damage to spinal cord: Operative ORIF, fusion, cervical traction, immobilization No neurological compromise: Nonoperative immobilization with a stiff cervical collar, observation
<b>Clavicle</b>	Blunt force to the chest, falling on shoulder or outstretched hand	Nonoperative: immobilization with splint Operative: ORIF
<b>Humerus</b>	Direct blunt force, falling on outstretched hand	Usually nondisplaced and treated with closed reduction and immobilization Displaced: Operative ORIF
<b>Elbow</b>	Direct blunt force typically from a fall	Nondisplaced: closed reduction and immobilization with a cast Displaced: operative ORIF
<b>Forearm (radius and ulna)</b>	Trauma, direct force, and falling on outstretched hand	Nondisplaced: closed reduction and immobilization with a cast/splint Displaced: operative ORIF
<b>Wrist</b>	Fall on outstretched hand, direct blunt force trauma	Nondisplaced: closed reduction and immobilization with splint/cast, pressure dressing Displaced: operative ORIF with traction, pins/screws, or application on an external fixator
<b>Metacarpal/Phalanges</b>	Fall on outstretched hand, direct blunt force trauma	Typically nondisplaced: closed reduction, immobilization with splint/cast Displaced: operative ORIF with pins, plates, and screws followed by immobilization with cast/splint
<b>Rib</b>	Direct blunt force trauma	Observation, treat pain with analgesia/epidural, deep breathing exercises with use of incentive spirometry to maintain pulmonary hygiene
<b>Pelvic</b>	Crush injuries, motor vehicle crashes, and falls from significant heights	Dependent on type/degree of fracture Displacement: emergent placement of external fixator and/or ORIF Nondisplaced/Less severe: Observation, bedrest, analgesia, and ambulation as tolerated
<b>Hip</b>	Falls, blunt force trauma, motor vehicle and pedestrian accidents, chronic illnesses	Highly dependent on the specific location of the fracture within the acetabular/femoral region; commonly requires operative ORIF with nails, plates, and screws; potentially also requires partial and/or total hip replacement
<b>Femur</b>	Falls, blunt force trauma, motor vehicle and pedestrian accidents	Nonoperative: skeletal/skin traction and immobilization with cast/brace Operative: ORIF with intramedullary rod/nail
<b>Tibia/Fibula</b>	Direct blunt force trauma, stepping torsion/rotation of leg and ankle	Nondisplaced: Closed reduction and immobilization with cast/splint Displaced/open: application of external fixation and/or ORIF with plates and screws followed by immobilization with cast/splint
<b>Metatarsal/Phalanges</b>	Crush injuries and blunt force trauma	Typically nondisplaced: closed reduction, immobilization with splint/cast Displaced: operative ORIF with pins, plates, and screws followed by immobilization with cast/splint

ORIF = Open reduction and internal fixation.

creating an external frame to stabilize and align the displaced fragments. External fixators are frequently used when there is significant soft-tissue damage at the fracture site (Fig. 54.3).

### Traction

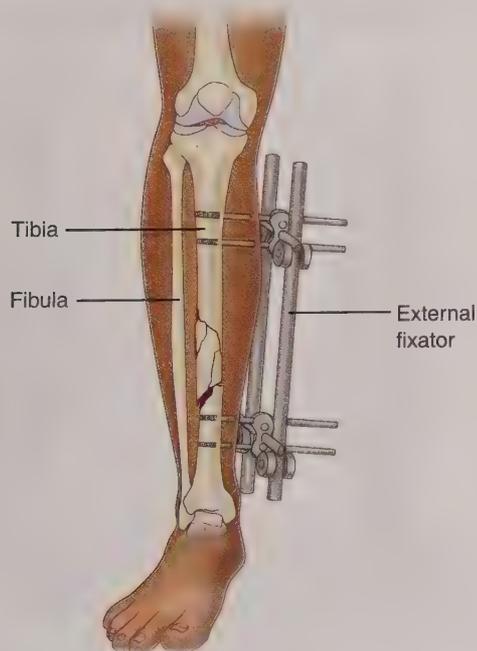

**Traction** can be used in conjunction with any of the other previously mentioned forms of fracture treatment. Traction involves the use of weights and force to reduce the fracture and relieve muscle spasms.

- **Skeletal traction.** Pins, tongs, screws, and wires are surgically secured to the bone, and weight is then applied to provide realignment (Fig. 54.4A). Cervical traction is an example of skeletal traction in which a halo device, or Crutchfield tongs, is applied to stabilize the cervical fracture.
- **Skin traction** uses a flexible harness, boot, or belt to secure the extremity while 5 to 10 lb of weight is applied to relieve muscle spasms and maintain the length of the bone (Fig. 54.4B). Buck's traction is a form of skin traction commonly used for femur and hip fractures.

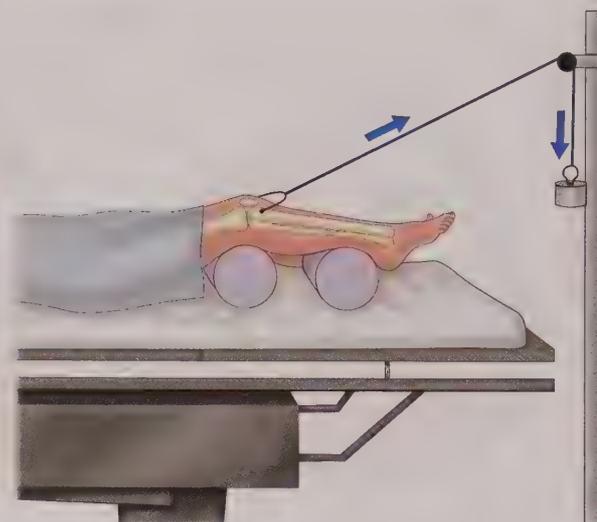

### Connection Check 54.3

The nurse correlates which diagnostic result for an older adult with a suspected pathologic fracture?

- Decreased bone density
- Increased osteocytes
- Hypertension
- Coagulopathy

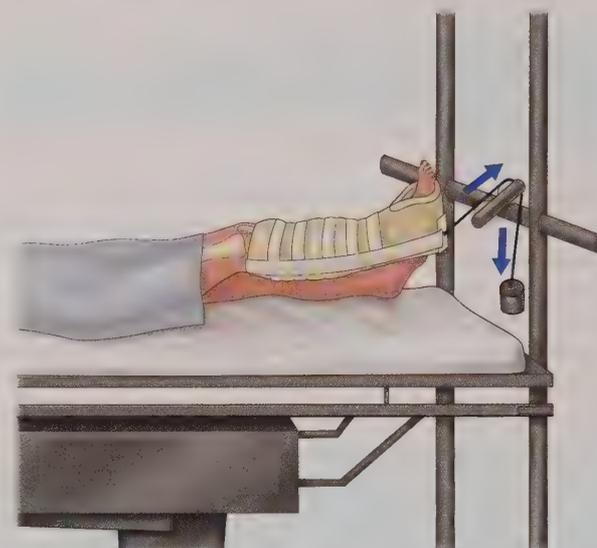

**FIGURE 54.3** External fixation for an open tibial fracture.

A

**Skeletal Traction**

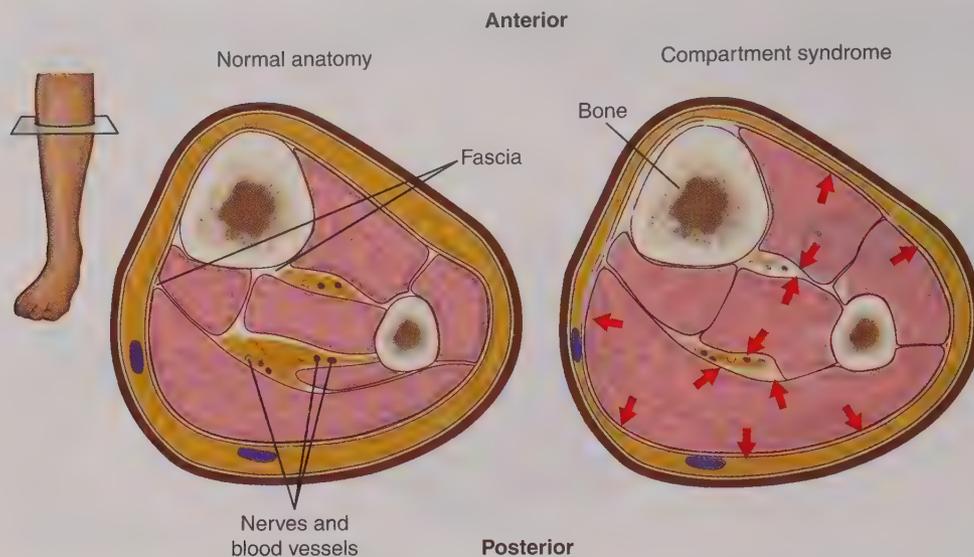

B

**Skin Traction**

**FIGURE 54.4** Types of traction. A, Skeletal traction; B, Skin traction.

### Complications

**Neurovascular compromise** is a complication due to any source of decreased blood flow and oxygenation to the tissues. One cause is the severing of blood vessels and nerves surrounding the bone by sharp bone fragments created by a fracture. The use of traction and immediate fracture reduction is vital in preventing further damage to the neurovasculature. Joint **dislocation** in which the displaced bones compress the nerves and vessels is another cause of neurovascular compromise, and the joint should be realigned as soon as possible. Compartment syndrome is a rare but serious complication which, when undetected, can cause permanent loss of the affected limb due to neurovascular compromise caused by increased pressure in the extremity (Fig. 54.5). Compartments are composed of muscles, nerves, and blood vessels. These compartments are surrounded by tough connective tissue linings called *fascia*.

**FIGURE 54.5** Compartment syndrome: increased pressure in the compartment causing compression of nerves and blood vessels.

Compartment syndrome occurs when there is increased edema and hemorrhage within the compartment space under the fascia. It can be caused by extended compression from casts and splints. Other possible sources of edema include hemorrhage from the initial injury, burns, venous thrombosis, and excessive exercise. Increased swelling compresses the blood vessels, restricting blood flow and oxygenation of the muscles and nerves, leading to tissue hypoxia. Hypoxia stimulates increased capillary permeability, causing more blood and fluid to leak into the already restricted compartmental space. The resulting effect is a vicious cycle of neurovascular compression that can progress to permanent damage and eventual loss of the extremity. The most common symptoms of compartment syndrome are the “six Ps”; passive pain at rest, along with pressure, paresthesia, pallor, paralysis, and pulselessness. Among the six Ps of compartment syndrome, pallor, paralysis, and pulselessness are considered to be late findings. Once compartment syndrome is suspected, the nurse should immediately notify the provider to relieve the pressure on the extremity (see Evidence-Based Practice). If caused by pressure from a cast, the provider will remove the cast immediately. An immediate fasciotomy is indicated in the case of internal pressure from edema. A fasciotomy is a procedure in which the surgeon makes incisions on both the medial and lateral aspects of the extremity down through the fascia, relieving the compartment pressure (Fig. 54.6).

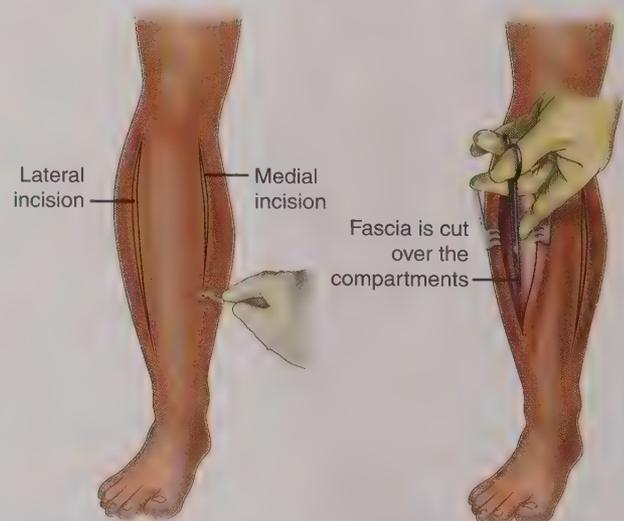

bleeding disorders, and bone fractures. The nurse must perform frequent neurovascular examinations that include the assessment of both the affected and unaffected limbs. Key findings indicative of compartment syndrome include pain out of proportion to the injury and pain with passive movement in the affected limb. Direct compartment pressure can be measured with a Stryker device. A pressure within 30 mm Hg of the diastolic pressure or an absolute pressure greater than 30 mm Hg is diagnostic for compartment syndrome. An immediate fasciotomy is indicated to preserve extremity function.

Kistler, J. M., Ilyas, A. M., & Thoder, J. J. (2018). Forearm compartment syndrome: evaluation and management. *Hand Clinics*, 34(1), 53-60.

## Evidence-Based Practice

### Compartment Syndrome

Compartment syndrome is a serious condition that, if untreated, can lead to the loss of the affected limb. Causes of compartment syndrome include burns, vascular injuries, penetrating trauma, insect bites, IV infiltration, animal bites,

**FIGURE 54.6** Fasciotomy: incisions through the fascia over the affected compartment to relieve pressure.

**Venous thromboemboli (VTE)** is another possible complication. VTE develop in the large vessels of the extremities because of extended periods of immobility, traumatic injuries, cardiac disease, long surgeries, obesity, smoking, and use of oral contraceptives. Venous thromboemboli can be perpetuated by musculoskeletal trauma, specifically fractures involving the upper and lower extremities. Clots can develop in large vessels and hinder circulation or can break apart and travel to the pulmonary arteries and become *pulmonary emboli* (Fig. 54.7). Pulmonary emboli clog the pulmonary vasculature hindering gas exchange, impairing oxygenation, and potentially leading to respiratory failure and patient death. Patients experiencing a pulmonary embolism exhibit dyspnea, tachycardia, abnormal breath sounds, pleuritic chest pain, cyanosis, anxiety, and altered mentation. Chapter 27 discusses pulmonary emboli in detail.

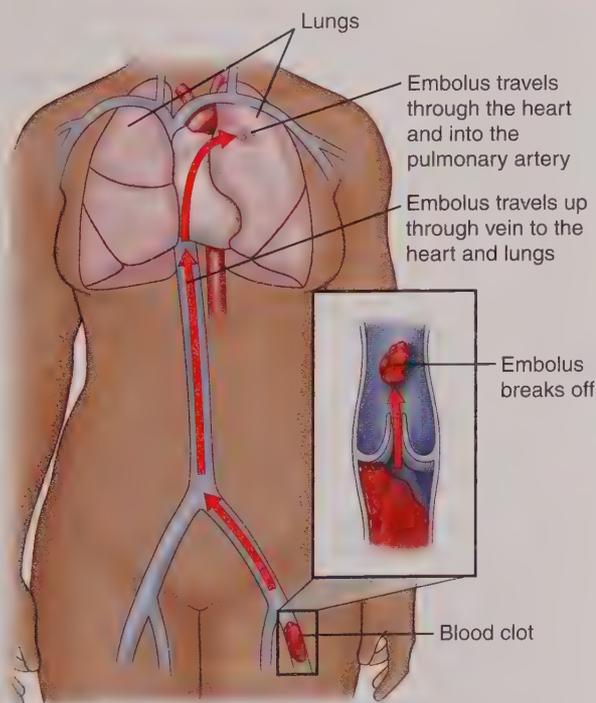

**Fat embolism syndrome** is a rare complication after orthopedic injury and surgery. **Fat emboli** frequently manifest in long bone fractures where particles of the exposed fatty bone marrow have migrated into the systemic circulation. The particles then mobilize throughout the body and clog smaller blood vessels, producing generalized petechiae: small or pinpoint round spots that appear red or purple on the skin. Much like VTE, fat emboli can travel to and lodge in the pulmonary artery and become pulmonary emboli. As a result, patients experience symptoms of respiratory distress, acute confusion, and restlessness potentially leading to respiratory failure and patient death.

**Safety Alert** It is imperative that the nurse immediately identify patients with long bone fractures and recognize that they are highly susceptible to developing life-threatening fat emboli. The nurse should conduct frequent assessments of the patient's respiratory status and report any abnormal findings immediately.

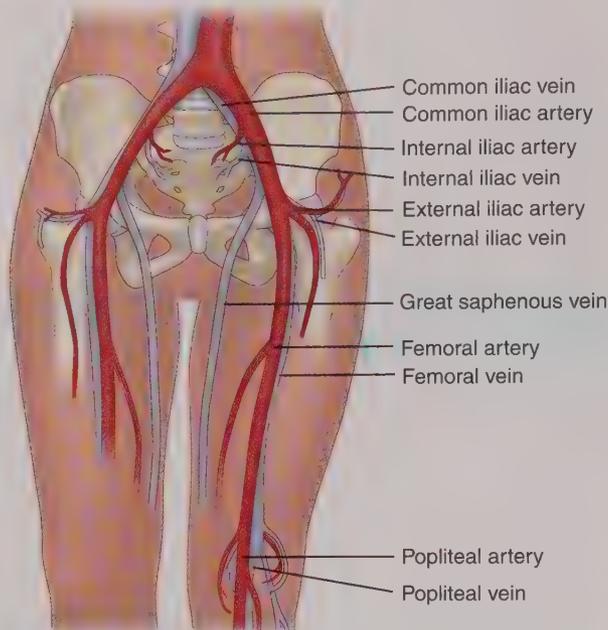

**Traumatic rhabdomyolysis** is a potential complication from injuries that result in compression and tissue ischemia, such as crush injuries. Crush injuries produce continued compression of muscle tissue that restricts blood flow and precipitates tissue ischemia. Tissue ischemia catalyzes a vicious cycle of further inflammation, increased capillary permeability, and the release of more fluid and intracellular contents into the compartment and circulatory system. Myoglobin is an intracellular oxygen-binding protein found in skeletal muscle. It is one of the many intracellular components that spill out of dead muscle cells. Once in the circulatory system, myoglobin travels to the kidneys and is lodged in the nephrons. As a result, the kidneys are unable to effectively filter the proteins and fall victim to acute tubular necrosis and renal failure. Symptoms of rhabdomyolysis include severe flank pain and dark tea-colored urine. Patients who have experienced crush injuries must have regular monitoring of their serum myoglobin and renal function levels. If rhabdomyolysis is present, fluid resuscitation is indicated to help “flush” the myoglobin through the kidney. Rhabdomyolysis is frequently complicated by multiple electrolyte disorders including hyperkalemia, hypophosphatemia, and hypo/hypercalcemia.

**Hypovolemia** is a potential complication due to the loss of blood that may occur with the fracture. Fractures produce sharp shards of bone that can sever adjacent blood vessels, causing severe exsanguination. Open fractures can generate significant amounts of blood loss that must be controlled as early as possible. Although not immediately visible, internal hemorrhaging from closed fractures must also be rapidly assessed and treated. The presence of large hematomas at the site of injury can signify internal bleeding. Close monitoring of vital signs is essential. The pelvis is highly vascular and a potential fracture site where patients can quickly hemorrhage and decompensate into hypovolemic shock (Fig. 54.8). Table 54.2 notes various fracture sites and their potential blood loss.

**Infection** is a common complication associated with fractures. All open fractures are deemed contaminated and can cause a bone infection called *osteomyelitis*. If undetected, bacterial infections can develop into gas gangrene and tetanus. Other potential sources of infection are external fixators, internal hardware from surgical repair, and hospital-acquired nosocomial infections. Patients with a wound/bone infection can exhibit delayed wound healing, purulent drainage, erythema, fever, and elevated white blood cell counts. Infection can be prevented through strict aseptic wound care and frequent assessments.

**FIGURE 54.7** Pulmonary emboli.

**FIGURE 54.8** Blood supply in the pelvis. The pelvis is highly vascular causing it to be a fracture site where there can be extensive blood loss.

**Table 54.2 Potential Blood Loss per Fracture Site**

Fracture Site	Potential Blood Loss (mL)
<b>Humerus</b>	500–1,500
<b>Elbow, radius, ulna</b>	250–750
<b>Pelvis</b>	750–6,000
<b>Femur</b>	500–3,000
<b>Tibia, fibula</b>	250–1,000

**Malunion** and **nonunion** are also possible complications of fractures. Both can cause significant impairment to mobility. Malunion occurs when fractures fail to heal in the correct anatomical alignment. It can be the result of inadequate fracture reduction and immobilization, misalignment during fracture reduction, or the premature removal of splints and casts. Severe traumatic fractures that are comminuted with many bone fragments are at high risk for malunion.

Nonunion refers to a fracture that has failed to heal. Nonunion is further categorized into septic nonunion and aseptic nonunion. Septic nonunion is precipitated by infection, whereas aseptic nonunion can be due to older age, anemia, use of tobacco and nicotine, diabetes, and medications that suppress healing such as NSAIDs, steroids, and aspirin. Surgical treatment of malunion and nonunion typically includes bone grafting, either from the patient or by using cadaver and donor bone, and/or the application of bone growth stimulators.

## Nursing Management

### Assessment and Analysis

Close examination of the affected extremity typically reveals swelling, ecchymosis, and deformity due to bone misalignment and the resultant bleeding and inflammatory process. Hemorrhage may be evident with an open fracture in which the bone fragments have severed the blood vessels. Pain may or may not be present at the fracture site, but patients frequently exhibit pain when the affected site is manipulated on examination.

### Nursing Diagnoses

- **Acute pain** associated with muscle spasms and trauma
- **Activity intolerance** associated with immobility
- **Impaired mobility** associated with limb immobilization
- **Impaired skin integrity** associated with the presence of a cast, splints, and traction

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Excessive bleeding leads to symptoms of hemorrhagic shock: low blood pressure, tachycardia, and tachypnea. Tachycardia, tachypnea, and decreased pulse oximetry with chest pain may indicate pulmonary embolus. An elevated temperature may indicate infection.*
- **Physical assessment of the site of injury via inspection and palpation.** Palpate the injured extremity noting the six Ps: **p**ain, **p**ressure, **p**aralysis, **p**allor, **p**aresthesia, and **p**ulselessness. Complete the neurovascular assessment by checking movement and sensation.  
*The presence of one or several of the six Ps may indicate neurovascular compromise that can lead to hemorrhage, compartment syndrome, infection, or permanent loss of function. The absence of the six Ps indicates that proper treatment is being provided and that there is no neurovascular compromise.*
- **Verify proper positioning, application, and stability of traction/splinting/immobilization devices**  
*Immobilization, traction, casts, and splints secure the fractured bone segments to promote healing. Occasionally, immobilization devices become loose, compromise circulation, or move out of position. Frequent assessment is needed to ensure that the devices are secure and are not hindering the healing process.*
- **Laboratory tests**
  - **Myoglobin**  
*Myoglobin is released from damaged muscle and may indicate the presence of rhabdomyolysis, which may lead to renal compromise or failure.*
  - **Creatine phosphokinase (CPK)**  
*CPK is released with any muscle breakdown, increased levels are seen with rhabdomyolysis*
  - **Complete blood count (CBC), metabolic profile, and renal studies**  
*Rhabdomyolysis is frequently complicated by multiple electrolyte disorders including hyperkalemia, hypophosphatemia, and hypo/hypercalcemia as well as renal*

failure. Blood loss and infection are potential complications of fractures. A complete blood count (CBC), metabolic profile, and renal studies are used to detect signs of infection (increased white blood cell count), blood loss (decreased hemoglobin and hematocrit), electrolyte disturbances (metabolic profile) and indications of renal failure (increased blood urea nitrogen [BUN] and creatinine).

- **Urine appearance**

Urine may be tea colored in rhabdomyolysis because of ruptured blood cells that clog the nephrons. Acute kidney injury is the most serious and even life-threatening complication of rhabdomyolysis.

- **Intake and output**

All fractures result in blood loss. Adequate volume replacement is necessary to prevent hypovolemic shock. Blood loss from drains, incisions, and wounds should be monitored closely. Also, hypovolemia and rhabdomyolysis may result in decreased urine output.

### ■ Actions

- **Maintain pulmonary hygiene**

Incentive spirometry exercises and coughing and deep breathing expands alveoli, helping maintain adequate alveolar gas exchange

- **Administer analgesia as ordered**

Administration of scheduled narcotic and anti-inflammatory medications inhibits prostaglandin formation, thus reducing pain and allowing the patient to reestablish function and mobility.

- **Administer antibiotics as ordered**

Reduce the risk of infection, especially in patients with open fractures

- **Administer anticoagulants as ordered**

Patients with fractures are highly susceptible to VTE and pulmonary emboli. Anticoagulants help prevent blood clots and emboli.

- **Wound/Pin care**

Providing daily pin site and wound care using strict aseptic technique reduces the risk of infection and promotes healing.

- **Elevation**

Elevating the affected extremity above the level of the heart minimizes pain and edema.

*\*If a crushing injury is suspected, do not elevate the limb because elevation reduces arterial pressure.*

- **Apply ice**

Promotes therapeutic vasoconstriction and decreases edema and pain

- **Range-of-motion exercises and ambulation using available assistive devices**

Ambulation and movement as soon as ordered prevent muscle atrophy and contractures, promote function and mobility, and promote healing and strength. Early ambulation as possible helps prevent VTE through the action of muscle contraction, which discourages blood from pooling. Assistive devices are very helpful in allowing the patient to perform self-care. (Box 54.2)

## Box 54.2 Assistive Devices

Assistive devices facilitate the patients' performance of activities of daily living, promote patient independence, prevent complications associated with immobility, and enhance the patient's feelings of self-esteem and self-worth. Some of the commonly used assistive devices related to mobility and ambulation include canes, walkers, wheelchairs, crutches, over-bed trapeze devices, and prosthetic limbs.

- **Repositioning**

Patients in traction, casts, and other immobilization devices have an increased risk of skin breakdown and decubitus ulcers. Provide the patient with a trapeze that is set up to encourage mobility while in bed.

- **Provide hydration and nutrition**

Metabolic demands increase during bone and wound healing. Extra protein, calcium, and vitamins A/D/C are needed for adequate bone repair. Adequate fluid intake is essential to ensure adequate "flushing" of the kidneys to prevent the complications of rhabdomyolysis. Iron supplements may be required for the treatment of anemia after surgery.

- **Positive feedback and encouragement**

Empower the patient to continue with treatment/rehabilitation and boost self-confidence

### ■ Teaching

- **Treatment process**

Providing a clear explanation of all available treatment options enables the patient to make knowledgeable healthcare decisions and take an active role in their care.

- **Overview of healing process**

Patient and supportive family members need to understand the healing process in order to be compliant with the treatment protocol. Healing may take months or years to complete (Box 54.3).

- **Consume adequate calories and vitamins to promote healing**

Metabolic demands increase during bone and wound healing. Extra protein, carbohydrates, calcium, and vitamins A/D/C are needed for adequate bone repair. Vitamin D supplementation promotes bone healing. Extra fiber and fluids are needed to avoid constipation caused by narcotic analgesics.

- **Appropriate use of analgesia**

Effective pain control enables the patient to perform self-care, ambulate, and reestablish independence.

- **Wound care via aseptic technique**

Prevents infection, promotes skin integrity, and expedites healing

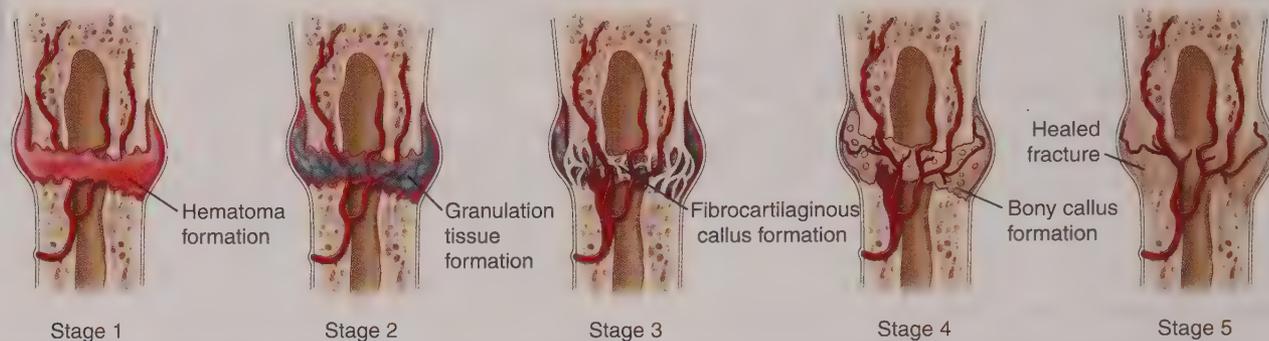

- **Exercise and ambulation using assistive devices**

Exercise and ambulation allows for the earliest return to normal activities and discourages muscular atrophy, contractures, and loss of function. Mobility may be dependent on the

## Box 54.3 Healing of Fractures

Fractured bones undergo a healing process that can extend from 6 months to a year. Healing is a five-stage process that begins within 24 hours of the initial injury.

- Stage 1: A hematoma forms around the fracture site within 24 to 72 hours of the initial injury.
- Stage 2: The hematoma undergoes a transformation to granulation tissue, which provides the basis for bone healing. This stage occurs 72 hours to 14 days after the initial injury.
- Stage 3: Granulation tissue develops into a callus (fibrocartilaginous tissue bridging the gap of the fracture) at 2 to 6 weeks. During this stage, the callus initiates the fusion of the bone segments.
- Stage 4: The callus is reabsorbed and converted into bone tissue 3 weeks to 6 months from the initial injury.
- Stage 5: Final stage of bone repair for mechanical function; this typically happens at 4 to 6 weeks and can last as long as a year.

*proper use of assistive devices such as canes, walkers, and wheelchairs.*

- Proper use of slings, splints, casts, and traction devices  
*Fosters bone healing, minimizes complications that can cause malunion or non-union (see Box 54.4)*
- Self-care activities  
*Patient, family, and support members need to collaborate to allow patient to perform self-care with the least assistance needed.*

### Connection Check 54.4

A patient has returned from the postanesthesia care unit after having surgery to have an external fixator placed for an open tibia fracture with extensive soft tissue damage. What should the nurse do immediately?

- Conduct a neurovascular assessment
- Elevate the extremity
- Perform pin site care
- Remove the dressing and assess the wound

### Evaluating Care Outcomes

The ultimate goal for the patient with a bone fracture is to return to normal activity and function as soon as possible. Most patients are able to return to their preinjury status and regain normal function within 6 to 12 months of the initial injury. This may be dependent on the severity of the fracture and need for surgery, presence of fracture-related

complications, and compliance with the treatment regimen. A well-managed patient:

- Is free from infection
- Uses analgesic intervention as prescribed
- Does not exhibit any neurovascular compromise such as compartment syndrome or VTE
- Complies with and actively participates in nutrition, activity, and exercise protocols
- Maintains stable vital signs, intake and output, and perfusion

## AMPUTATIONS

### Epidemiology

Amputations occur for various reasons in people of all ages. They can be traumatic or elective in nature. Risk factors for traumatic amputations include blunt force trauma obtained in motor vehicle crashes, motorcycle crashes, accidents where the patient is caught between two objects, and pedestrian versus vehicle injuries. This accounts for 1% of all trauma patients. Risk factors also include engaging in risk-taking behaviors, gunshot wounds, industrial jobs requiring the use of power tools, and the use of lawn mowers and snow blowers. The conflicts in Iraq and Afghanistan precipitated thousands of traumatic amputations among military professionals because of improvised explosive devices. Amputations of the upper extremities are more frequently seen in motor vehicle crashes, whereas lower extremity amputations generally occur because of motorcycle crashes and pedestrian injuries.

## Box 54.4 Cast Care

### Cast Care Dos and Do Nots

#### DO

Do keep the cast clean and dry at all times.

Do cover the cast with a plastic bag or cast cover for bathing or showering.

Do use a hair dryer on cool air setting to dry the cast if it gets wet by blowing air under the cast.

Do contact the provider if there is any red skin irritation, blisters or sores around the edges of the cast or inside the cast.

Do cover rough edges of the cast with tape to prevent skin irritation.

Do elevate the cast above the heart if increased swelling, pain, numbness, tingling or change in color or circulation are noted. If this does not relieve the symptoms, notify the provider.

Do contact the provider if the cast is damaged, cracked, or extremely wet. The cast will need to be changed.

#### DO NOT

Do not pull out any padding from under the cast.

Do not get the cast wet. For casts that were applied using water resistant cast padding, you may shower or swim in a pool only, but must dry the lining of the cast after you finish with a cool air hair dryer to prevent skin breakdown.

Do not allow the patient to place any objects inside the cast.

Do not apply powder or deodorant to itching areas. Notify the provider if there is persistent itching.

Do not trim or break off any rough edges around the cast.

Do not rest the heel of the leg cast on a pillow or bed. Keep the heel floating off the surface by elevating the leg with a pillow or blanket roll under the calf to prevent sores.

immediately after injury to preserve life. Elective amputations are caused by disorders that lead to ischemia and eventual cell death. This lack of tissue perfusion prevents distribution of oxygen throughout the affected extremity. Cell death occurs from lack of oxygenation; necrotic tissue begins to form and creates an open wound. The open wound acts as a portal of entry for bacteria that thrive in low-oxygen environments, such as *Clostridium perfringens*. While the bacteria spread and migrate through the body, they secrete toxins that stimulate a systemic response leading to gangrene (an anaerobic infection caused by *C. perfringens*) and sepsis. Without immediate amputation, tissue ischemia migrates proximally through the limb and ultimately leads to overwhelming sepsis and multiple organ dysfunction.

## Management

### Medical Management

#### Traumatic Amputations

Due to the life-threatening nature of traumatic amputations, it is imperative to immediately control the bleeding and replace the blood lost from the injury. A tourniquet should be applied to the remaining portion of the limb to stop both arterial and venous bleeding. The tourniquet can remain in place for as long as 6 hours before the tissue becomes necrotic. Typically, patients with traumatic amputations also demonstrate polytrauma based on the same mechanism of injury. As a result, a rapid but thorough injury assessment should be conducted on the patient's arrival to the hospital. A coagulation panel and CBC can establish the need for immediate blood transfusion. A serum lactate level, an indicator of anaerobic metabolism, helps determine the level of hypoxemia and gauge the success of resuscitative efforts. To preserve life and maintain limb function in traumatic amputations, salvage surgery may be required to control hemorrhage, reattach limbs (Box 54.5), or remove/reconstruct the damaged tissue.

#### Elective Amputations

All possible medical interventions to reestablish perfusion are used before performing elective amputations. Radiography is used to determine the extent of bone damage or infection, whereas venograms and arteriograms are done to assess the level of peripheral circulation. Cultures and sensitivities isolate infective organisms in the wound and allow for accurate implementation of antibiotics. Medical interventions include hyperbaric therapy (100% oxygen administered under pressure in a hyperbaric chamber), percutaneous transluminal angioplasty (insertion of a balloon-tipped catheter into the affected artery that can be expanded to open the artery and restore blood flow), and anticoagulant therapy. In the case of neoplasms of the bone, resection of the tumor and bone grafting can often eliminate the need for surgical amputation. Once all other efforts have been exhausted, elective amputations are performed to salvage the remaining function of viable tissue.

Elective amputations are typically due to vascular compromise secondary to chronic illnesses such as peripheral vascular disease, diabetes, neoplasms, and infections. Risk factors for elective amputations include noncompliance with the diabetic treatment regimen, smoking, and venous stasis ulcers.

## Pathophysiology and Clinical Manifestations

**Amputation** is the severing, or removal, of part of the body, generally involving the extremities. In traumatic amputations, high-energy trauma mutilates and destroys soft tissues, blood vessels, nerves, and bones of the extremities. The amputation can occur at the time of injury or is necessary

## Box 54.5 Care for Limb Reattachment

Recent advances in microsurgery have improved patient outcomes in the reattachment of severed extremities. Successful reattachment is highly dependent on the proper care of the amputated body part. Warm ischemia time, the time the severed extremity remains at body temperature after the loss of blood supply, should be limited. The limb should be cleansed with isotonic fluids (normal saline or lactated Ringer's solution), wrapped in a clean towel, and placed in a container then placed on ice. It is important to not place the extremity directly in ice. For a major traumatic amputation, replantation is not recommended if warm ischemia time is more than six to eight hours. For a digit, more than 10-12 hours is generally considered to be too long, but successful digit transplantation has been seen after a delay of 94 hours.

Prosthetic devices now allow amputee patients to resume near-normal function. Current prosthetic technology and design use state-of-the-art muscle and nerve sensors that allow the patient to perform both fine and gross motor movements. Patients are often fitted and sized for a prosthesis before their elective amputation surgery.

**Safety Alert** Traumatic amputations cause serious disruptions in muscle, bone, and blood vessels.

As a result, these patients have a significant risk of succumbing to hemorrhagic shock. The nurse should:

- Immediately assess the wound for active hemorrhaging
- Place a pressure bandage or tourniquet and monitor for effectiveness
- Obtain a CBC and type and crossmatch for immediate blood transfusion according to the provider's orders
- Prepare the patient for surgery to repair the severed extremity

### Connection Check 54.5

The nurse correlates which of the following critically low laboratory results with a traumatic amputation?

- A. Hemoglobin (Hgb): 7.0 g/dL
- B. Glucose: 60 mg/dL
- C. BUN: 10 mg/dL
- D. WBC: 4,000  $10^3/\text{mm}^3$

### Complications

Hemorrhage in traumatic amputations is caused by the destruction of large blood vessels within the extremity, leading to severe bleeding and consequent hypoperfusion. If the bleeding is not immediately controlled with a pressure

bandage or tourniquet, the patient further decompensates into hypovolemic shock and death.

Infection in older patients with peripheral vascular disease who are undergoing elective amputations is a potential complication. These patients are at an increased risk for developing infections of the tissue and bone. Osteomyelitis is an infection of the bone that can quickly progress to sepsis in geriatric patients. Infection is also a problem in traumatic amputations because large open wounds are often contaminated with dirt and debris.

Contractures may occur in the residual limb because of the loss of bone, nerves, and muscle. Contractures are most often seen in patients with lower-extremity amputations and are manifested by lack of movement and exercise in the residual limb. These can be avoided by encouraging the patient to perform active ROM exercises and participate in physical therapy.

**Phantom limb pain** is a common complication of amputations which produces numbness, tingling, and a sharp burning pain perceived as manifesting in the removed limb or in the distal aspect of the remaining limb. The pain typically weakens over time but can be exacerbated by touching the residual limb. Weather changes, stress, nervousness, exhaustion, and further sickness can also exacerbate the pain. Different theories exist on the exact mechanism behind phantom limb pain. A frequently cited theory is that inflamed nerve fibers in the stump of the amputated extremity still send pain signals to the brain. The most prevalent theory presently is that when the nerves are severed during the amputation process, sensory function of the lost limb relocates to the spinal cord and brain cortex, causing the continued sensation of pain from the amputated extremity. The administration of antidepressant and anticonvulsant medications such as gabapentin has demonstrated effectiveness in treating phantom limb pain. Mirror therapy has also been successful in treating phantom limb pain by reversing the relocation of sensory nerve function through visual feedback.

**Neuromas** are clumps of nerve axons in the distal end of the residual limb that have regenerated after surgical amputation. Neuromas mostly occur in upper-extremity amputations but can develop in any residual limb. The development of neuromas is often inevitable and interferes with the proper fit and use of prosthetic devices, frequently requiring additional surgery for removal.

### Nursing Management

#### Assessment and Analysis

In traumatic amputation, close examination of the affected extremity typically reveals extensive damage to blood vessels, bone, nerves, muscles, and other soft tissue due to high-energy blunt force trauma. Massive blood loss before hospital arrival leads to signs of shock such as tachycardia and hypotension. Patients with traumatic amputations also experience polytrauma, which can cause life-threatening issues with the airway and breathing. Because of the severity of the injury, patients often experience significant pain.

Preoperatively, elective amputations often exhibit signs of infection, absent circulation, severe pain, and lack of movement because of necrotic muscle and tissue.

### Nursing Diagnoses

- **Acute pain** associated with surgery and phantom limb pain
- **Chronic pain** associated with surgery and phantom limb pain
- **Ineffective tissue perfusion** associated with edema and impaired arterial circulation
- **Impaired skin integrity** associated with delayed healing and prosthesis rubbing
- **Ineffective coping** associated with change in body image
- **Impaired physical mobility** associated with amputation, weakness, and musculoskeletal impairment
- **Grieving** associated with loss of the body part and future lifestyle changes
- **Self-care deficit** associated with deficient knowledge of stump care and rehabilitation
- **Risk for:**
  - **Infection** associated with invasive surgery
  - **Fluid volume deficit** associated with surgical disruption of hemostasis
  - **Bleeding** associated with the vulnerable surgical site

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Hypotension and tachycardia may occur secondary to hemorrhage and sepsis. Increased temperature is an indication of infection. Decreased SpO<sub>2</sub> indicates problems with oxygenation.*
- CBC  
*Hemorrhage in traumatic amputation causes loss of red blood cells (RBCs), and low hemoglobin and hematocrit.*
- Pulses, temperature, color, movement, and sensation of affected extremity  
*Weak pulses, pale color, a cool temperature, and limited movement or sensation indicate inadequate blood flow and tissue perfusion in the affected limb that may indicate the potential need for elective amputation.*
- Pain  
*Phantom limb pain is a common side effect due to remapping of impulses from the amputated extremity to the spinal cord, causing continued pain sensations.*
- Wound/incision site  
*Warm, red tissue with purulent drainage is a sign of wound infection.*

#### ■ Actions

- Insert large bore IV  
*The massive blood loss associated with traumatic amputation necessitates IV blood and fluid resuscitation.*
- Transfusion of IV fluids and blood products as ordered  
*Replace fluid and blood lost in traumatic amputation*

- Administer analgesia as ordered  
*Improved pain control promotes movement, function, increasing the ability to participate in rehabilitation.*
- Alternative pain management techniques  
*Alternative pain management modalities such as TENS unit or CAM therapies are synergistic in conjunction with analgesic medications.*
- Refrain from using a pillow under the remaining portion of the lower extremity  
*Prevents the development of flexion contractures that can occur if a pillow is left under the extremity*
- Application of ice for no longer than 15 to 20 minutes  
*Promotes vasoconstriction and decreases painful edema*
- Nutrition: maintain adequate intake and output  
*The increased metabolic demands of healing require additional protein and carbohydrates.*
- Range of motion  
*Strengthens muscles and prevents contractures in the residual limb fostering improved self-care*
- Application of rigid splint  
*Minimizes edema by compressing residual limb for a better fit into the prosthesis*

#### ■ Teaching

- Medication regimen  
*Adequate pain control allows the patient to ambulate and perform self-care. Taking antibiotics as prescribed promotes wound healing and decreases the risk of superinfection and the development of antibiotic-resistant organisms.*
- Nutrition and hydration  
*Sufficient dietary intake of proteins and carbohydrates allows for adequate healing of bone, muscle, and skin. Increasing dietary fiber and maintaining hydration prevents narcotic-associated constipation.*
- Wrap limb with compression dressing (Fig. 54.9)
  - Figure-eight technique
  - Start 1 to 3 days postoperatively
  - Wrap from distal to proximal position
  - Start with minimal tension, then increase gradually
  - Rewrap two to three times per day
  - Keep wrapped unless bathing
  - If pain occurs, the wrapping is probably too tight  
*Limb wrapping decreases edema and aids in the correct fitting of the prosthesis on the residual limb.*
- Wound care  
*Wound care often continues after discharge from the hospital. Using the aseptic technique minimizes the risk of infection.*
- Signs and symptoms of infection  
*Patients need to know and identify early signs of infection: increased or purulent drainage, redness, warmth, or increased temperature, and seek medical attention as necessary.*
- ROM exercises  
*Prevent contractures and strengthen muscles for movement and function*
- Community support resources  
*A case manager or social worker can coordinate resources to allow the patient to resume rehabilitation and self-care*

**FIGURE 54.9** Procedure for wrapping the residual limb to prevent edema and provide compression.

1. Hold the bandage roll at your waist with one hand. Use the other hand to roll the bandage all the way around your waist.
2. Turn the bandage so that it goes down toward the floor. Roll it diagonally down your thigh, and continue to the back of your limb. Stretch the bandage slightly while you wrap your limb.
3. Roll the bandage around to the front of your limb. Roll it diagonally up your thigh, to your waist. Roll it all the way around your waist again, in the same direction as the first time.
4. Repeat these steps until the bandage covers the top of your thigh to the end of your limb. Overlap the bandage as you wrap so you cover new skin each time. If you need to use more than one bandage, secure each bandage with a clip or tape before you apply another one.
5. When you are finished, secure the last bandage. Try to end the bandage in a place that is not in a skin fold or at your hip.

*activities at home with the use of various assistive devices. Organizations composed of other amputee patients can offer additional encouragement and emotional support.*

- Collaborate with the physical therapist and prosthetist-orthotist  
*These professionals can promote adaptation to new lifestyle and help ensure prosthesis fit. They can also serve as a resource for any prosthesis-related issues.*

### Connection Check 54.6

A patient with diabetes who had an elective below-the-knee amputation returns to the unit for IV antibiotic care on post-operative day 3. On closer examination, the nurse notices the patient has a pillow under the residual limb. What should the nurse do in this situation?

- A. Leave the pillow in place to prevent dependent edema
- B. Remove the pillow to prevent contractures
- C. Remove the pillow to prevent VTE
- D. Leave the pillow to promote circulation

### Evaluating Care Outcomes

Patients with amputations who are compliant and actively participate in home care and rehabilitation can expect to lead productive lives once discharged from the hospital. Adjusting to a traumatic amputation is more difficult than adjusting to a planned one. The nurse can help to provide anticipatory counseling to help prepare for an emotional reaction. The presence of strong family and support systems is instrumental in helping the patient make a smooth transition home from the hospital. A well-managed patient is free from evidence of infection, has acceptance of body image and limits of physical mobility, and is knowledgeable in the use of prosthetic devices to ambulate and function as independently as possible.

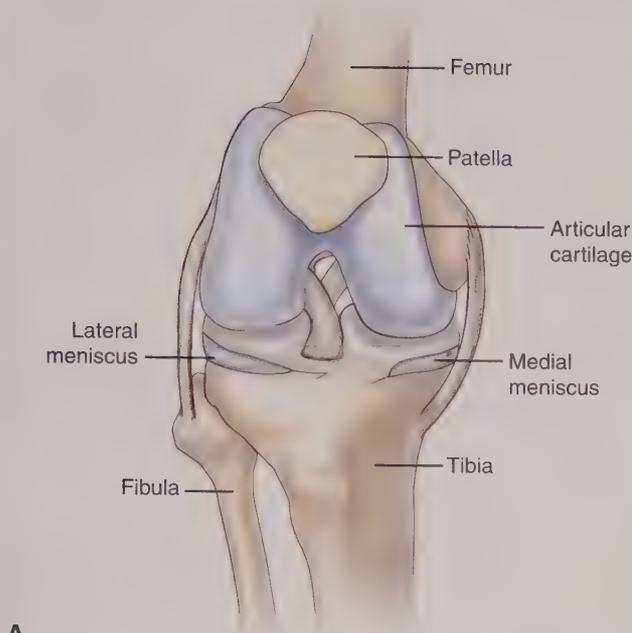

## MENISCUS INJURIES

### Epidemiology

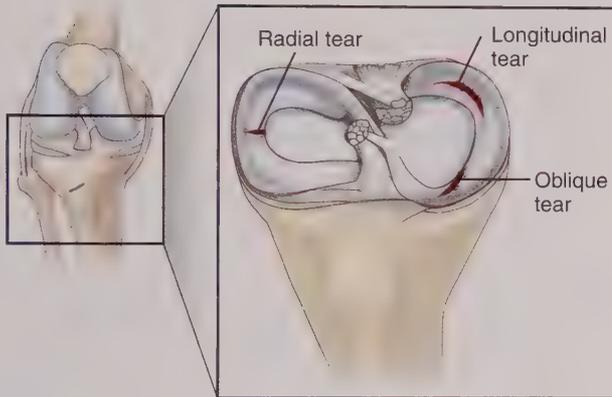

Meniscus injuries occur in patients of all ages and genders. Acute meniscus injuries occur on average in 61 out of 100,000 people. Men are more than twice as likely as women to sustain a meniscus injury of the knees. Risk factors for meniscus injuries include congenital abnormalities, chronic joint diseases such as rheumatoid arthritis and osteoarthritis, ligament deficiencies, and insufficient quadriceps muscle control. Athletes participating in football, soccer, skiing, basketball, and baseball have an increased risk of developing meniscal injuries. Contributing factors of meniscal tears include overuse of the joint, failure to stretch and warm up, poor quadriceps muscle development, and abnormal alignment of the knee joint.

### Pathophysiology

The menisci are semilunar-shaped wedges of cartilage positioned between the tibia and femur of both knee joints (Fig. 54.10A). They serve to cushion, protect, and stabilize the knee joint from shock during flexion and movement. There is a lateral and a medial portion of each meniscus. Medial menisci are “C” shaped and positioned on the medial aspect of the knee. They are torn when excessive twisting, or rotational, force is applied to a knee that is bent. The medial aspect is larger in size and more apt to tear than the lateral meniscus. The lateral meniscus is more “U” shaped and is located on the lateral aspect of the knee joint. Lateral meniscus tear when the lateral compartment of the knee slides or subluxates forward, which impinges the meniscus between the tibia and femur. Meniscus tears (Fig. 54.10B) frequently accompany more severe knee injuries such as ACL tears.

A

B

**FIGURE 54.10** Menisci. A, Normal menisci; B, Radial, longitudinal, and oblique meniscal tears.

## Clinical Manifestations

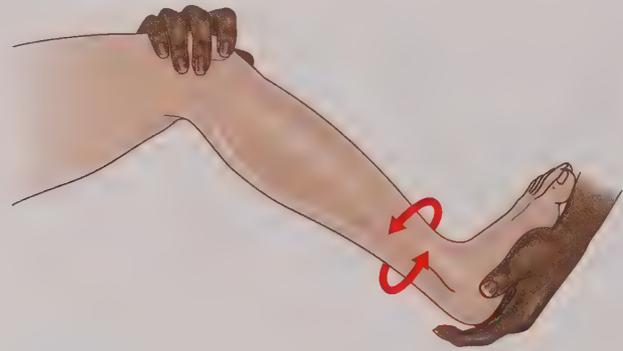

Pain experienced at the time of menisci injury is variable and is typically followed by an insidious onset of effusion, increased fluid in the joint, during the next day. Patients may experience mechanical symptoms, such as catching, locking, clicking, or instability, and usually report medial or lateral pain. An effusion combined with joint line tenderness is one of the most sensitive and reliable signs of meniscal tear.

## Management

### Medical Management

### Diagnosis

The diagnosis of meniscus injuries is based on physical examination using either the McMurray's test, in which the knee is supported and flexed while the lower leg is rotated internally and externally (Fig. 54.11), or Steinman's test, in which the knee is flexed and extended. A positive result is indicated when either test reveals an audible/palpable

**FIGURE 54.11** McMurray's test. With the knee supported and flexed, the lower leg is rotated internally and externally. An audible/palpable "click," an inability to extend the knee, or the presence of pain is a positive test.

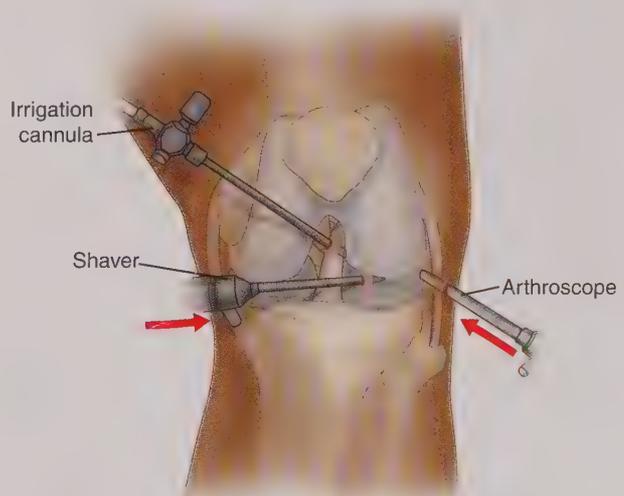

"click," an inability to extend the knee, or the presence of pain. Radiography may be needed to rule out degenerative joint diseases. An MRI can further help isolate and characterize the extent of the tear.

### Treatment

Treatment of meniscus tears is dependent on the size and severity of the tear. Smaller tears often heal within a few months and are treated with limited rest, ice, and administration of NSAIDs. Total immobility and resting of the affected joint is not recommended because it may cause muscle atrophy, stiffness, and further movement problems. Patients are encouraged to continue daily activities as tolerated.

### Surgical Management

Surgery in the form of an arthroscopic surgical repair of meniscus tears, or meniscectomy, may be indicated for small tears that have not healed with conventional treatment or for large unstable tears. Arthroscopic surgery involves the insertion of small fiber-optic scopes through small incisions in the knee (Fig. 54.12). The joint is insufflated or irrigated

Arthroscopic instruments are inserted through small incisions in the knee; the knee is infused with saline and the damaged tissue is removed with small grinding or shaving instruments.

**FIGURE 54.12** Arthroscopic surgical repair.

with saline to enhance visibility. The damaged meniscus is then either removed with small grinding/rotating instruments or repaired with bioabsorbable sutures. This is done on an outpatient basis, allowing the patient to ambulate with crutches immediately after surgery. Patients often return to normal function within 6 to 8 weeks after surgery and may undergo physical rehabilitation to strengthen the quadriceps and prevent further meniscus injuries.

### Complications

Patients with meniscus injuries frequently experience pain, immobility, and the inability to carry out everyday activities. If left untreated, meniscus tears can lead to permanent joint damage and immobility.

### Connection Check 54.7

The nurse prioritizes which nursing diagnosis in the patient immediately after arthroscopic surgical repair of the medial meniscus injury?

- High risk for ineffective airway clearance associated with general anesthesia
- High risk for ineffective breathing associated with intubation
- Self-care deficit associated with pain, edema, and immobility
- Pain associated with inflammation

### Nursing Management

#### Assessment and Analysis

Patients often present complaining of “popping” or “clicking” when they bend their knee. They may also describe pain to the anterior or posterior aspect of the knee joint. Close examination of the affected knee may reveal swelling, warmth, and an accumulation of fluid within the joint. Mobility is impaired because of pain and swelling.

#### Nursing Diagnoses

- **Impaired physical mobility** associated with musculoskeletal impairment
- **Acute pain** associated with musculoskeletal trauma

#### Nursing Interventions

##### Assessments

- Physical assessment of injured extremity via inspection and palpation  
*An assessment revealing adequate pulses, color, and temperature ensures that there is no emergent or permanent damage to circulation, movement, and sensation.*

##### Postoperative

- Vital signs  
*Tachycardia and hypotension may result because of hypovolemia due to hemorrhage. Increased temperature is an indicator*

*of infection. Tachycardia and hypertension may indicate increased pain.*

- Neurovascular check  
*Poor pulses, pallor, and cool extremities indicate problems with increased swelling, which can compress the nerves, blood vessels, and muscle.*
- Wound site/dressing  
*Blood on the dressing indicates bleeding. Purulent drainage and/or a red, warm incision indicate postoperative infection.*
- Pain  
*Increased pain may indicate further injury or edema. Well-controlled pain indicates effectiveness of pain interventions.*

##### Actions

- Apply ice or cold compress to wound  
*Cryotherapy causes vasoconstriction, which decreases further bleeding and inflammation and helps manage pain.*
- Elevation  
*Elevation decreases edema, which eases pain and promotes mobility of the injured area.*
- Exercise/ROM therapy as tolerated  
*Prevents atrophy, strengthens muscles, and promotes mobility*
- Administer anti-inflammatory and analgesia medications as ordered  
*Inhibits prostaglandin (mediators of pain and inflammation) formation reducing pain and inflammation*

##### Teaching

- Immediately report any worsening symptoms to the injured area to include infection, continued pain, loss of function, loss of mobility, or loss of sensation  
*Alterations in circulation, movement, and sensation can signal the need for further medical intervention.*
- Pain management  
*Compliance with the prescribed treatment/medication regimen supports the ability to participate in activities of daily living (ADLs) and rehabilitation facilitating the return of the injured limb to normal function.*
- Wound care  
*Wound care often continues after discharge from the hospital. Using aseptic technique minimizes the risk of infection.*
- Exercise/Physical therapy/Rehabilitation therapy  
*Promotes ambulation, muscle strength, and return to pre-injury functioning*

### Evaluating Care Outcomes

A well-managed patient has pain under control and actively participates in the prescribed rehabilitation plan, promoting a return to preinjury functioning. Patients may occasionally exhibit some long-term stiffness or soreness dependent on weather and activity.

## Connection Check 54.8

The nursing diagnosis “ineffective peripheral tissue perfusion associated with deficient knowledge of aggravating factors” applies to which fracture patient with the highest risk of developing VTE?

- A 30-year-old female on oral contraceptives who smokes one pack of cigarettes per day
- A 40-year-old male who ambulates four times a day with a walker
- A 70-year-old diabetic female who attends rehabilitation once a day
- A 20-year-old male who smokes 10 cigarettes per day and ambulates with crutches

## CARPAL TUNNEL SYNDROME

### Epidemiology

**Carpal tunnel syndrome (CTS)** is the most frequent compression neuropathy of the hands. Risk factors for CTS include age, type of employment, and gender. Higher occurrences are noted in patients who have jobs requiring repetitive motions of the hands and wrists such as computer operators, musicians, construction workers, and factory workers. Women are four to five times more likely to get CTS than their male counterparts, partially because of the smaller size of the carpal tunnel in women. Factors that precipitate CTS include pregnancy, congenital malformations, hormone therapy, trauma to the hand or wrist, and other idiopathic causes. This syndrome usually occurs in adults.

### Pathophysiology and Clinical Manifestations

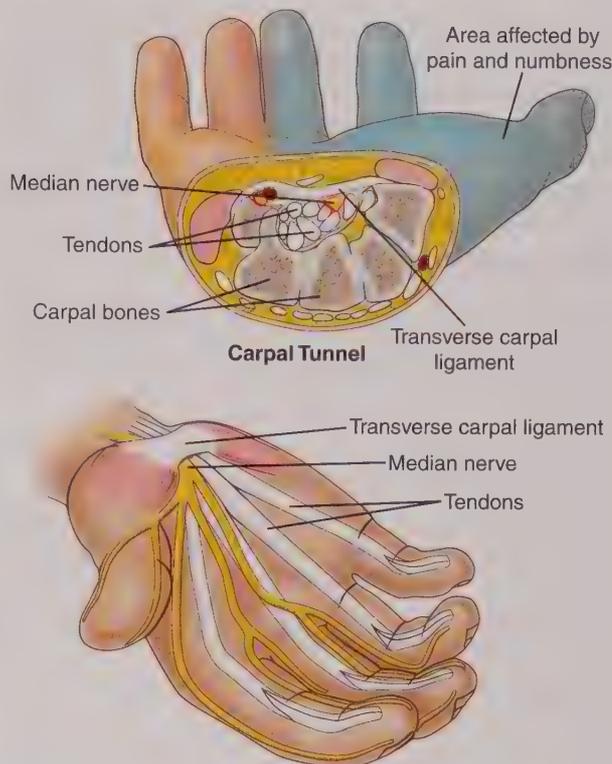

The carpal tunnel is an area located between the carpal bones of the wrist. The tunnel contains the median nerve, tendons, and ligaments. Repetitive motions of the wrist elicit inflammation of the tendons and ligaments (Fig. 54.13). Inflammation compresses the median nerve causing sharp pain, numbness, and tingling of the hand. Grip strength may be decreased, and over time there is atrophy of the muscles. Symptoms initially occur intermittently at night, then progress if not treated.

### Management

#### Medical Management

#### Diagnosis

Diagnosis starts with a detailed patient history. The history includes the patient’s occupation, factors responsible for generating the wrist pain, and medical history. The Phalen’s test aids in diagnosis of CTS and is performed by having the patient relax his or her hand in the flexed position for

**FIGURE 54.13** Carpal tunnel syndrome: inflammation in the carpal tunnel produces pressure on the median nerve causing pain, numbness, and tingling.

60 seconds or by placing the back of the hands together while flexing both wrists. This compresses the median nerve. Patients with CTS experience numbness and tingling during the Phalen’s test. Tinel’s sign, tapping the median nerve over the carpal tunnel at the wrist, will also elicit paresthesia over the median nerve region of the wrist. Nerve conduction studies and electromyographies are frequently ordered to determine the severity of CTS and rule out any potential spinal cord lesions or tumors. Cervical spine radiography eliminates any possible cervical disorders that could cause radiating pain in the hands. Occasionally, MRI and ultrasound may be used to isolate the cause of CTS.

#### Treatment

Treatment of CTS can be done with conventional nonoperative measures such as modifying the work environment to eliminate repetitive motion and promote ergonomics. Ultrasound therapy, NSAIDs, steroid injections, night splinting, and acetaminophen are other treatment options.

#### Surgical Management

Surgical intervention called *carpal tunnel release surgery* is often performed as an outpatient procedure to decrease pressure on the median nerve. There are two types of surgical decompression of the median nerve: open release and endoscopic. Open release is a procedure that creates a 2-inch incision in the wrist, allowing visualization. The transverse carpal ligament is then cut to enlarge the carpal tunnel. The

endoscopic procedure creates two half-inch incisions to allow visualization via an endoscopic camera. As in the open release, the ligament is cut to enlarge the carpal tunnel. Studies have not been conclusive in determining which surgical method is the most beneficial. A synovectomy to remove excess synovium can be performed when CTS is exacerbated from rheumatoid arthritis.

### Complications

Untreated CTS can lead to chronic pain, immobility of the hands, and loss of sensory and motor functions. Postoperative complications include infection, further nerve injury, and hematoma formation.

### Nursing Management

#### Assessment and Analysis

Patients with suspected CTS complain of pain in the wrist and numbness and tingling in the fingers; mostly the thumb and first two fingers. These symptoms are due to the compression of the median nerve because of inflammation caused by repetitive motions. Patients may notice that the symptoms diminish, or weaken, a few hours after the repetitive motion is stopped.

#### Nursing Diagnoses

- **Alteration in rest: sleep pattern disturbance** associated with pain
- **Acute/chronic pain** associated with inflammation and pressure on the median nerve
- **Impaired physical mobility** associated with neuromuscular impairment

#### Nursing Interventions

##### Assessments

- Patient work or activity history  
*A work or activity history of repetitive movements such as computer or assembly-line work puts patients at risk for CTS.*
- Physical assessment of injured extremity via inspection and palpation  
*Numbness and tingling during the Phalen's test or paresthesias with a Tinel's test may indicate CTS caused by compression of the median nerve.*
- Pain, paresthesia  
*Pain is caused by inflammation and edema, resulting in compression of the median nerve.*

##### Actions

- Splinting at night or with symptoms  
*Immobilizes the joint, decreasing irritation and inflammation on the median nerve*
- Exercise/ROM therapy as tolerated  
*Prevents atrophy, strengthens muscles, and promotes mobility*
- Administer anti-inflammatory medications as ordered  
*Inhibits prostaglandin (mediators of pain and inflammation) formation reducing pain and inflammation*
- Collaborate with occupational therapist  
*An occupational therapist can evaluate the work area and make recommendations for modifications to eliminate causative factors.*

### Teaching

- Immediately report any worsening symptoms to the injured area to include infection, continued pain, loss of function, loss of mobility, or loss of sensation  
*Alterations in circulation, movement, and sensation can signal the need for further medical intervention.*
- Exercise/physical therapy  
*Promotes movement, muscle strength, and return to preinjury functioning*
- Pain management  
*Compliance with the prescribed treatment/medication regimen supports the ability to participate in activities of daily living (ADLs) and rehabilitation facilitating the return of the injured limb to normal function.*
- Work/activity modifications; stop the activity responsible for CTS or modify how activity is performed  
*Eliminates the cause of CTS, prevents further recurrences*

### Evaluating Care Outcomes

A well-managed patient is compliant in their treatment protocol, which includes their medication regimen, use of splints, workplace modification, and undergoing surgical intervention if necessary. This patient is often successful in obtaining symptomatic relief of CTS and is able to return to normal preinjury functioning.

## Making Connections

### CASE STUDY: WRAP-UP

Zachary is admitted to the ward from the operating room at 0600 in the morning. Frequent nursing assessments noting the six Ps are performed to assess neurovascular function. Laboratory testing to include serum myoglobin and CPK are ordered. His urine remains clear yellow, ruling out the presence of rhabdomyolysis. His pain is controlled with PO oxycodone. His provider's orders include the provision of adequate hydration and nutrition and an order for physical therapy to evaluate his readiness for exercise and ambulation using assistive devices. If he continues to improve, he will be discharged to home soon.

#### Case Study Questions

1. Zachary has undergone placement of an external fixator for an open displaced femur fracture. Immediately following surgery, he begins to exhibit dyspnea, pleuritic chest pain, anxiety, and tachycardia. The nurse suspects which complication?
  - A. Pneumothorax
  - B. Deep vein thrombosis
  - C. Fat embolism
  - D. Myocardial infarction

2. Following the surgical procedure for an open displaced femur fracture, what action does the nurse frequently perform?
  - A. ROM exercises
  - B. Neurovascular assessments
  - C. Dressing changes
  - D. Pain assessments
3. The nurse monitors for which common symptom of compartment syndrome?
  - A. Passive pain at rest
  - B. Pain with movement
  - C. Pallor
  - D. Paresthesia
4. Because Zachary has lost a significant amount of blood, what complication should the nurse monitor for?
  - A. Bradycardia
  - B. Hypotension
  - C. Metabolic alkalosis
  - D. Hyperkalemia
5. The nurse monitors Zachary for which signs of rhabdomyolysis?
  - A. Bloody urine and abdominal pain
  - B. Anuria, nausea, and severe flank pain
  - C. Low serum myoglobin, fever, and severe headaches
  - D. Elevated serum myoglobin, tea-colored urine, and severe flank pain

of fractures that can occur throughout the body. Types of fractures include complete, incomplete, closed (simple), or open (compound). Effective pain management and definitive surgical or nonsurgical treatment is indicated depending on the type and location of the fracture. Venous thromboemboli, fat emboli, neurovascular compromise, and compartment syndrome are complications of fractures. Neurovascular assessments should be completed frequently on these patients.

Amputation is the severing, or removal, of part of the body, generally involving the extremities. There are two types of amputations, traumatic and elective. In traumatic amputations, high-energy trauma mangles and destroys soft tissues, blood vessels, nerves, and bones of the extremities. Traumatic amputations involve massive hemorrhage due to the high-energy destruction of blood vessels. Elective amputations are due to disease, diabetes, peripheral vascular disease, and neoplasms that hinder tissue perfusion and lead to ischemia and eventual cell death. Hemorrhage and infection are complications to be monitored for in these patients.

Medial menisci are torn when excessive twisting, or rotational, force is applied to a knee that is bent. Lateral menisci tear when the lateral compartment of the knee slides or subluxates forward, which impinges the meniscus between the tibia and femur. Contributing factors of meniscal tears include overuse of the joint, failure to stretch and warm up, poor quadriceps muscle development, abnormal alignment of the knee joint, and congenital abnormalities. Small tears can be treated with limited rest, ice, and administration of NSAIDs. Small tears that have not healed with conventional treatment or large unstable tears require arthroscopic surgical repair.

The carpal tunnel is an area located between the carpal bones of the wrist. The tunnel contains the median nerve, tendons, and ligaments. Repetitive motions of the wrist elicit inflammation of the tendons and ligaments. Inflammation compresses the median nerve causing sharp pain, numbness, and tingling of the hand. Treatment of CTS can be done nonoperatively with measures such as modifying the work environment to eliminate repetitive motion and promote ergonomics. Surgical intervention, carpal tunnel release surgery, is performed to decrease pressure on the median nerve.

## CHAPTER SUMMARY

A strain is the tearing or stretching of a muscle or tendon. A sprain is defined as the stretching or tearing of a ligament. Strains and sprains are categorized according to their severity. Treatment of first- and second-degree strains and sprains involves RICE: rest, ice, compression, and elevate. NSAIDs are usually prescribed to minimize pain and inflammation. Third-degree injuries may require surgical repair.

A fracture is defined as a disruption, or break, in the continuity of a bone. There are numerous classifications

## Promoting Health in Patients With Gastrointestinal Disorders

### Chapter 55

## Assessment of Gastrointestinal Function

*Jana Goodwin*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the gastrointestinal system
2. Discussing the function of the gastrointestinal system
3. Describing the procedure for completing a history and physical assessment of gastrointestinal function
4. Correlating relevant diagnostic examinations to gastrointestinal function
5. Explaining nursing considerations for diagnostic studies relevant to gastrointestinal function
6. Discussing changes in gastrointestinal function associated with aging

#### CONCEPTS

- Assessment
- Digestion
- Medication
- Metabolism
- Nutrition

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Martin Jhanes is a 70-year-old male patient who presents to his healthcare provider complaining of worsening heartburn that has persisted over the last 3 months. He also reports nausea, decreased appetite, abdominal bloating, frequent belching, and gas. He states that there is “burning pain” in his stomach until he eats. Symptoms persist despite dietary changes and treatment with over-the-counter antacids and H<sub>2</sub> antagonists, which have worked in the past. He reveals that his last bowel movement was several days ago. He reports having difficulty with bowel movements since he retired last year. He noticed that his stool was darker than usual but thought it was from the Pepto-Bismol that he had taken. He denies laxative use or abuse. Mr. Jhanes also reports feeling tired and complains of light-headedness when moving from a sitting to a standing position. The patient has a past medical history significant for hypertension, myocardial infarction, and hypercholesterolemia. He reports drinking a glass of wine with dinner every night and being a former smoker. Mr. Jhanes states that he smoked about one pack of cigarettes per day for 20 years. He currently takes lisinopril (Zestril) 20 mg PO daily, clopidogrel (Plavix) 75 mg PO daily, and atorvastatin (Lipitor) 10 mg PO daily. He has not taken any medication in 2 days...

## INTRODUCTION

The gastrointestinal system is responsible for intake, digestion, and elimination of food and fluids, and proper functioning is key to adequate nutrition. Consisting of two divisions, it is divided into the alimentary tract and accessory organs. Normal intake is through the mouth; however, in patients with disorders that affect the ability to eat or swallow, nutrition may be delivered directly to the stomach or small intestine. Digestion begins in the mouth and continues in the stomach and small intestine. The large intestine is primarily responsible for reabsorption of fluids and electrolytes and elimination of waste products. Equally important to the normal function of the gastrointestinal system is the role of the accessory organs that include the teeth, tongue, salivary glands, liver, gallbladder, and pancreas. Normal functioning of the gastrointestinal system also includes actions of the nervous and endocrine systems.

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

The gastrointestinal tract, also known as the alimentary tract, begins with the esophagus and ends with the anus

(Fig. 55.1). Responsible for the digestion and absorption of nutrients and expelling of metabolic wastes, the tract consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine. Additionally, the teeth, tongue, salivary glands, liver, gallbladder, and pancreas are involved in the digestive process.

### The Mouth

The process of digestion begins in the mouth, where the mechanical and chemical breakdown of food occurs. The mechanical breakdown of ingested food occurs through the process of **mastication** (chewing). Saliva, which contains amylase, lipase, and lysozyme, is excreted from a group of glands: parotid, sublingual, and submandibular glands (Fig. 55.2). Amylase is responsible for the chemical breakdown of carbohydrates, whereas lipase chemically digests fat. Digestion of protein actually occurs in the stomach. Lysozyme has antimicrobial properties that destroy the cell wall of bacteria in the mouth. **Deglutition**, or swallowing, consists of two phases and involves the pharynx, esophageal muscles, and the following cranial nerves (CNs), CN V (trigeminal), CN VII (facial), CN IX (glossopharyngeal), and CN XII (hypoglossal). The **buccal** (mouth) phase involves the tongue and the pharyngeal muscles, and the esophageal phase involves the palate and esophageal muscles. Peristaltic movement of the esophagus moves the bolus of food into the stomach.

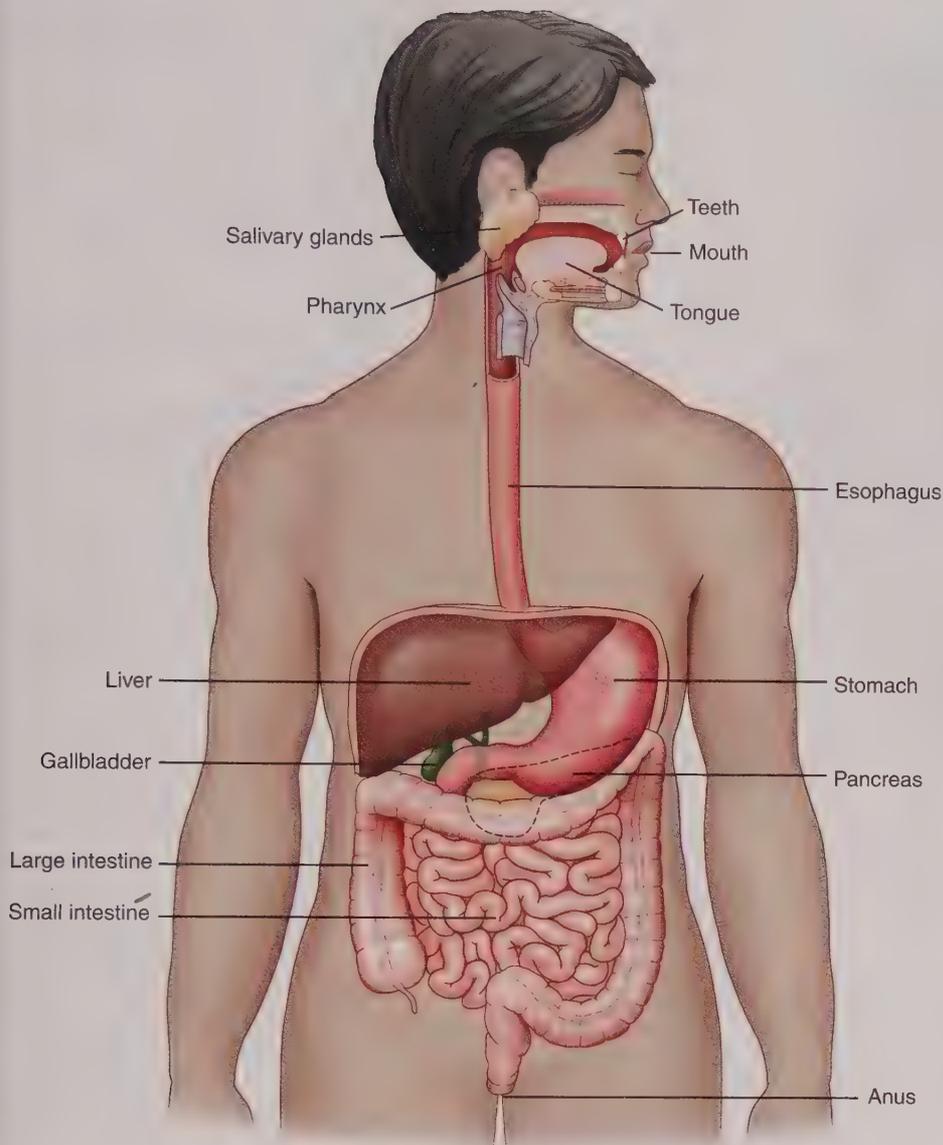

### The Esophagus

The esophagus (Fig. 55.3) is a hollow muscular tube that extends from approximately the vertebral levels of C6 to T7. It is positioned inferior to the pharynx and posterior to the trachea and passes through the diaphragm via a space known as the esophageal hiatus and then connects to the stomach. The external musculature of the esophagus is skeletal muscle in the upper one-third, skeletal/smooth mix in the middle third, and smooth muscle in the lower third. The mucosa of the esophagus consists of nonkeratinized stratified squamous epithelium. The peristaltic movements push the food bolus downward as the esophagus constricts above the bolus and dilates below the bolus.

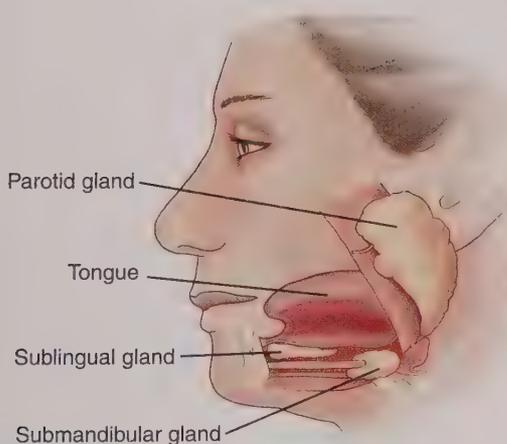

### The Stomach

The esophagus extends through the diaphragm and connects to the stomach. In normal digestion, the lower esophageal sphincter protects the esophageal mucosa from the regurgitation of partially digested food and the acid produced in the stomach. Specialized cells secrete chemicals essential to the digestive functions of the stomach:

- **Mucous cells:** Secrete mucus that protects the stomach lining
- **Parietal cells:** Secrete hydrochloric acid that aids in the conversion of food to **chyme** (partly digested semiliquid food), as well as convert gastric lipase and pepsinogen

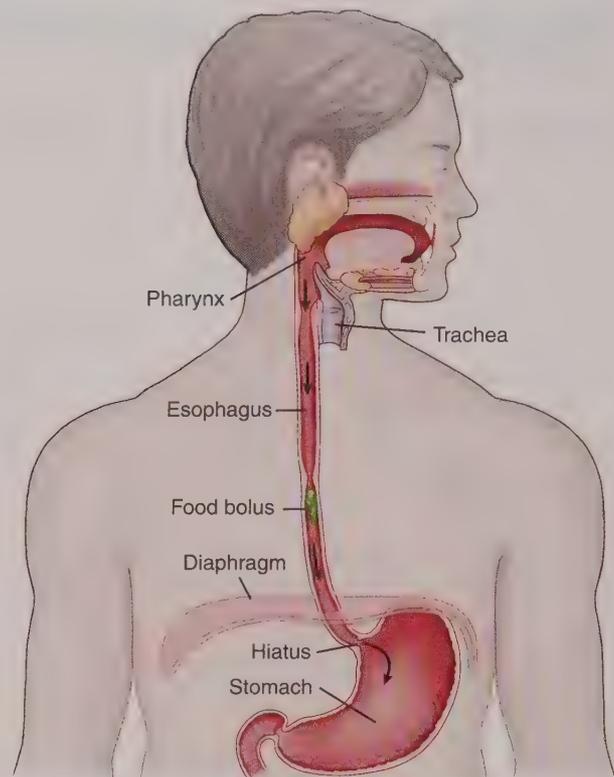

**FIGURE 55.1** Gastrointestinal system.

**FIGURE 55.2** The mouth and salivary glands. The parotid, sublingual, and submandibular glands, located in the mouth, produce saliva and begin digestion in the mouth.

- to active forms. The parietal cells also secrete **intrinsic factor**, a chemical needed for the absorption of vitamin B<sub>12</sub>, an important component of hemoglobin synthesis.
- **Chief cells:** Secrete the enzymes gastric lipase, which digests approximately 15% of dietary fat, and pepsinogen, which is responsible for protein digestion
  - **Enteroendocrine cells:** Secrete hormones needed for digestion:
    - **Gastrin:** Stimulates secretion of hydrochloric acid and enzymes, and intestinal motility
    - **Serotonin:** Stimulates gastric motility
    - **Histamine:** Stimulates secretion of hydrochloric acid
    - **Somatostatin:** Inhibitory hormone that delays emptying of the stomach, reduces absorption in the small intestine, and inhibits secretions from the gallbladder and pancreas

Gastric motility is influenced by smooth muscle regulated by the sympathetic and parasympathetic nervous systems.

**FIGURE 55.3** Esophagus. The esophagus extends through the diaphragm and connects to the stomach. In normal digestion, the lower esophageal sphincter protects the esophageal mucosa from the regurgitation of partially digested food and the acid produced in the stomach.

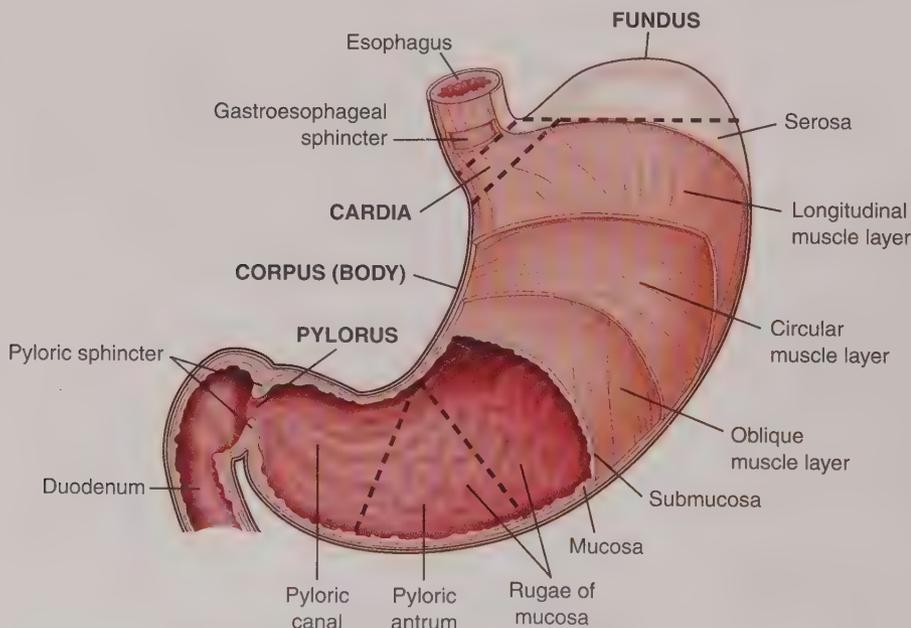

Swallowing stimulates the swallowing center in the medulla oblongata to signal the stomach to stretch to receive food. Before meals, the stomach has a volume of 50 mL but can hold up to 4 L at its fullest. Peristaltic contractions controlled by the pacemaker cells of the smooth muscle churn

the food and mix it with gastric secretions. The stomach has four landmark areas (Fig. 55.4):

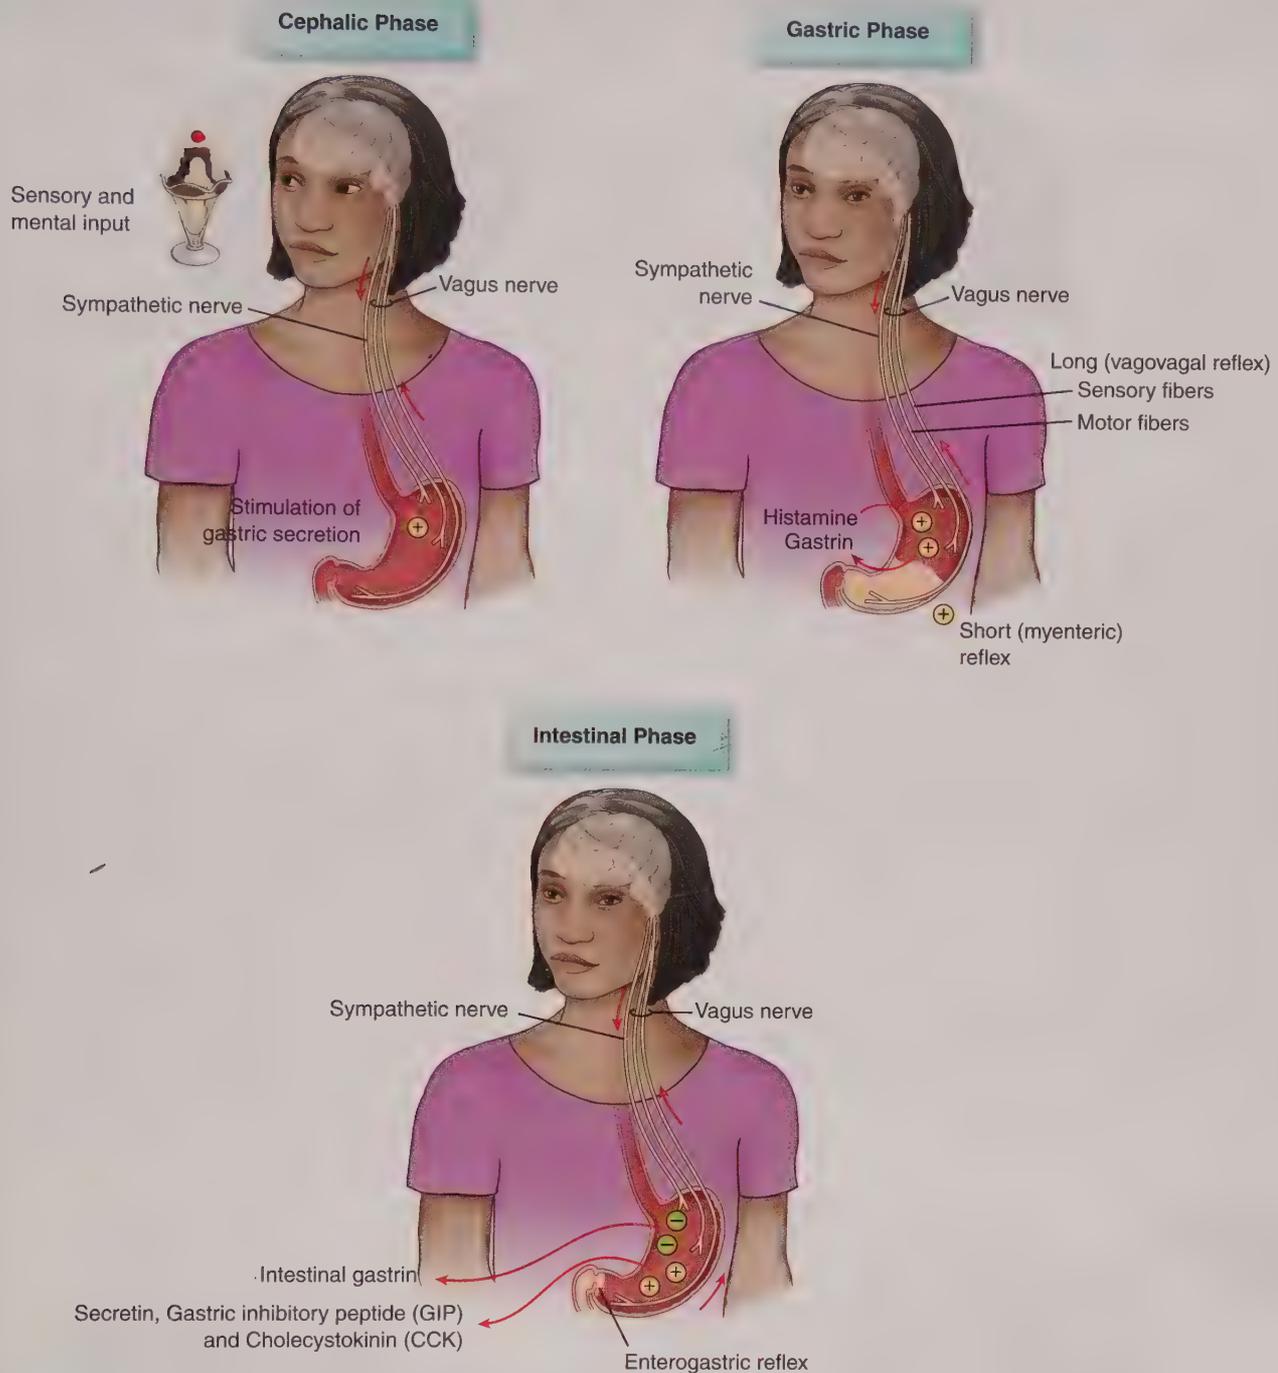

1. The *cardiac area* is a small segment that is 3 cm below the gastroesophageal sphincter.
2. The *fundic area* is the dome-shaped uppermost segment of the stomach.
3. The *corpus*, or body, is the largest segment of the stomach.
4. The *pyloric area* is the lowermost segment of the stomach that consists of the antrum, a narrow funnel that leads to the pyloric canal.

The small area right beyond the canal is the pylorus, and it connects to the duodenum. The passage of chyme into the duodenum is controlled by the pyloric sphincter, which is a ring of smooth muscle surrounding the pylorus. The lining of the stomach has folds known as *rugae* that allow for stretching of the lining in order to facilitate absorption.

Through the hormonal and neurological feedback systems, gastric secretion activity occurs in three phases (Fig. 55.5). In the cephalic phase, mental and sensory stimuli activate the vagus nerve (CN X) to stimulate gastric secretion. In the gastric phase, the presence of carbohydrates, fat, and partially digested protein stimulates the release of acetylcholine, histamine, and the hormone gastrin. These chemicals stimulate the parietal cells to secrete hydrochloric acid and intrinsic factor, whereas the stimulation of the chief cells results in the secretion of pepsinogen. Hydrochloric acid converts pepsinogen to pepsin, the enzyme responsible for the digestion of proteins. Lastly, in the intestinal phase, the presence of chyme stretches the duodenum. Initially, the duodenal stretch leads to the release of intestinal gastrin and stimulation of the vagus nerve, which stimulates the stomach. However, the presence of the acid and semidigested food in the duodenum also begins the inhibitory

**FIGURE 55.4** Anatomy of the stomach. Note the four major landmarks of the stomach: the cardia, fundus, corpus (body), and pylorus.

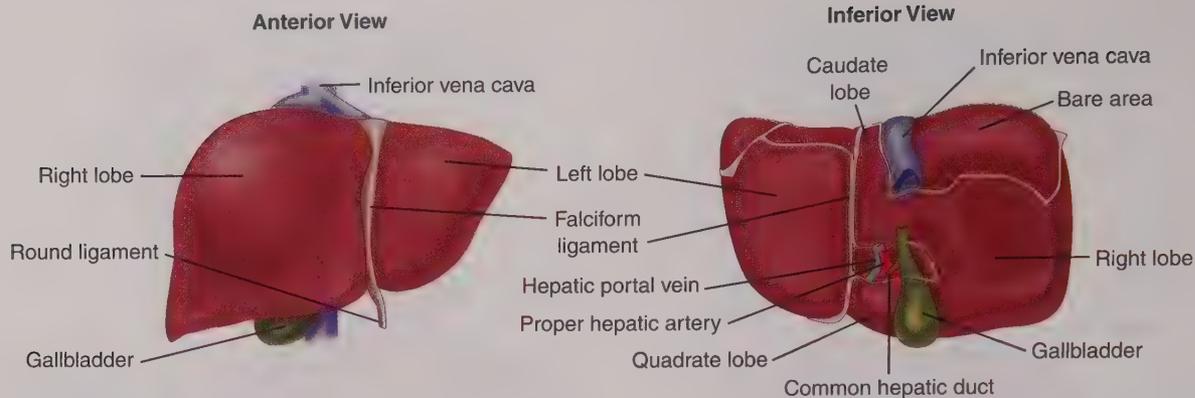

**FIGURE 55.5** Phases of gastric secretion. In the cephalic phase, mental and sensory stimuli activate the vagus nerve (CN X) to stimulate gastric secretion. In the gastric phase, the presence of carbohydrates, fat, and partially digested protein stimulates the release of acetylcholine, histamine, and the hormone gastrin. In the intestinal phase, the presence of chyme stretches the duodenum.

phase. Signals from the medulla stimulate the sympathetic and parasympathetic nervous systems, which inhibit gastric activity. The secretion of secretin and cholecystikin also inhibits gastric motility and enzyme secretion.

## The Liver

After the skin (integumentary system), the liver is the second largest organ of the body and typically weighs 1 to 1.5 kg.

Attached beneath the diaphragm, the liver is positioned largely across the right upper quadrant and extends into the left upper quadrant. It is segmented into four lobes separated by ligaments that suspend the liver under the rib cage and diaphragm in the abdominal cavity (Fig. 55.6). The inferior view of the liver has two grooved areas where the inferior vena cava, hepatic vein and artery, common hepatic duct, and gallbladder are positioned. Twenty-five percent of the cardiac output flows through the dual blood supply

**FIGURE 55.6** Liver. Anatomical features of the liver.

system, an oxygen-rich supply from the hepatic artery and a nutrient-rich supply from the portal vein. Twenty percent of the body's total oxygen consumption is utilized by the liver. The blood supply from the portal vein receives nutrients from the stomach, intestines, spleen, and pancreas.

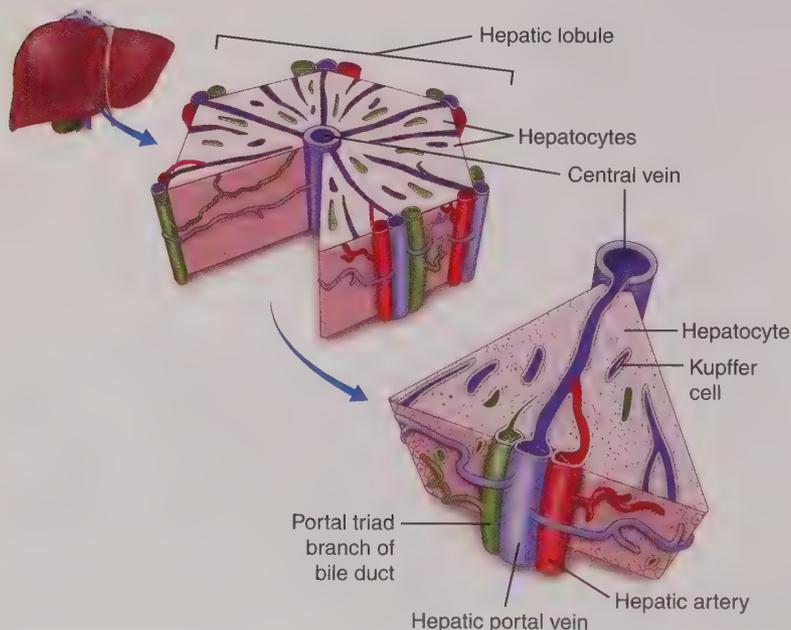

A closer look at the microanatomy of the liver (Fig. 55.7) reveals an intricate network of specialized cells and blood vessels known as hepatic lobules. Hepatocytes constitute the majority of the hepatic cells and are responsible for many of the functions of the liver. Major functions of the liver include (1) absorption and metabolism of nutrients; (2) degradation of toxins, hormones, and medications; and (3) synthesis of proteins (clotting factors, albumin, several clotting factors, fibrinogen, and prothrombin). Other cells known as **Kupffer cells** are responsible for detoxifying the blood of bacteria. The branches of the hepatic artery and portal veins supply a mixture of oxygen- and nutrient-rich

blood to the hepatocytes. In terms of the digestive process, the liver aids in the digestion of fat by producing bile acids and lecithin. The other functions of the liver are listed in Table 55.1.

### The Gallbladder

Located in the right upper quadrant, the gallbladder, a pear-shaped sac, is attached to the inferior portion of the liver and is responsible for bile storage and concentration. Bile is needed for the emulsification of fat. Bile contains phospholipids (lecithin), bile pigments (bilirubin), and bile salts; approximately 500 to 1,000 mL of bile is excreted from the liver and stored in the gallbladder. Bile leaves the liver and passes through a ductal system (Fig. 55.8):

Hepatic ducts → Common hepatic duct →  
Cystic duct and into the gallbladder

**FIGURE 55.7** Liver microanatomy includes an intricate network of specialized cells and blood vessels known as hepatic lobules.

**Table 55.1** Functions of the Liver

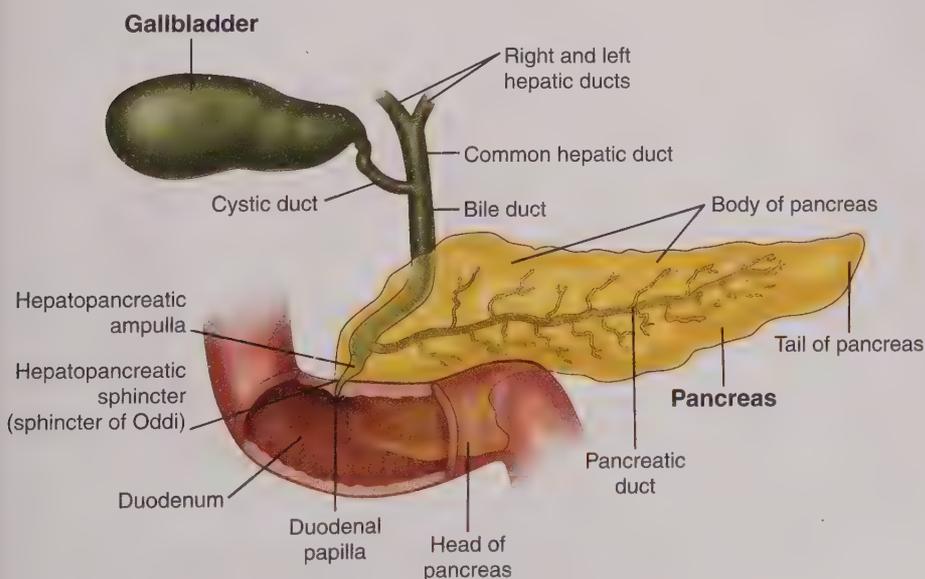

Gastrointestinal Process	Liver Function
<b>Digestion</b>	Emulsification of fat Absorption of dietary fat
<b>Vitamin and mineral metabolism</b>	Storage of vitamins A, B <sub>12</sub> , D, ferritin Excretes excess calcium
<b>Protein metabolism</b>	Deamination and transamination of amino acids Converts ammonia to urea
<b>Carbohydrate metabolism</b>	Conversion of dietary fructose and galactose to glucose Conversion of lactic acid to pyruvic acid or glucose-6-phosphate Storage and release of glycogen Synthesizes glucose from fat and amino acids when glycogen stores are low
<b>Lipid metabolism</b>	Synthesis of fat, cholesterol, and phospholipids Produces ketone bodies, VLDL, and HDL
<b>Plasma protein synthesis</b>	Synthesizes blood plasma proteins: albumin, fibrinogen, prothrombin
<b>Detoxification</b>	Detoxifies alcohol and medications that are metabolized in the liver; deactivates thyroxine and metabolizes bilirubin and excretes it as bile pigment
<b>Phagocytosis</b>	Aids in the elimination of bacteria in the blood

HDL, High-density lipoprotein; VLDL, very low-density lipoprotein.

After the ingestion of a meal, bile exits the gallbladder via the cystic duct that communicates with the bile duct. The terminal end of the bile duct connects with the terminal end of the pancreatic duct to form the hepatopancreatic ampulla in the pancreas. This ampulla connects with the duodenal papilla, which contains the hepatopancreatic sphincter (sphincter of Oddi) that opens during digestion and releases bile to the small intestine to emulsify the dietary fat.

## The Pancreas

The pancreas is a gland that is 12 to 15 cm in length and is positioned inferior to the stomach in the right upper quadrant (see Fig. 55.8). It has three landmark areas: the head, which is surrounded by the duodenum; the body; and the tail. The pancreatic duct is in the middle of the pancreas and extends from the tail to the head, where it joins the bile

**FIGURE 55.8** The gallbladder and pancreas. The gallbladder is a pear-shaped organ located in the right upper quadrant. The pancreas is a gland that is positioned inferior to the stomach in the right upper quadrant. The terminal end of the bile duct connects with the terminal end of the pancreatic duct to form the hepatopancreatic ampulla in the pancreas.

duct. The pancreas has both endocrine and exocrine functions. As an endocrine gland, it produces insulin and glucagon. As an exocrine gland, the pancreas secretes 1,200 to 1,500 mL daily of a liquid known as pancreatic juice that contains water; sodium bicarbonate; proenzymes needed for protein digestion; and the pancreatic enzymes needed for carbohydrate (amylase), fat (lipase, phospholipase A, and cholesterol esterase), and DNA and RNA (deoxyribonucleases, ribonucleases) digestion. The digestion of these nutrients is essential to cellular metabolism. The release of these enzymes is secreted through the acinar cells of the pancreas and is regulated by neural and hormonal feedback systems. Acetylcholine stimulates the release of pancreatic enzymes during the cephalic phase. These pancreatic enzymes are stored in the duodenum and released as the chyme arrives. **Cholecystokinin** is released from the jejunum and duodenum when gastric acid, long fatty chains, and certain amino acids are present. The release of cholecystokinin stimulates the release of pancreatic enzymes that contract the gallbladder and relax the hepatopancreatic sphincter for the release of bile into the duodenum. Lastly, **secretin** is released from the small intestine in response to the presence of the acidic chyme in the small intestine. The release of secretin stimulates the liver and pancreas to release sodium bicarbonate, which neutralizes the acidic chyme and protects the intestinal lining.

### The Small Intestine

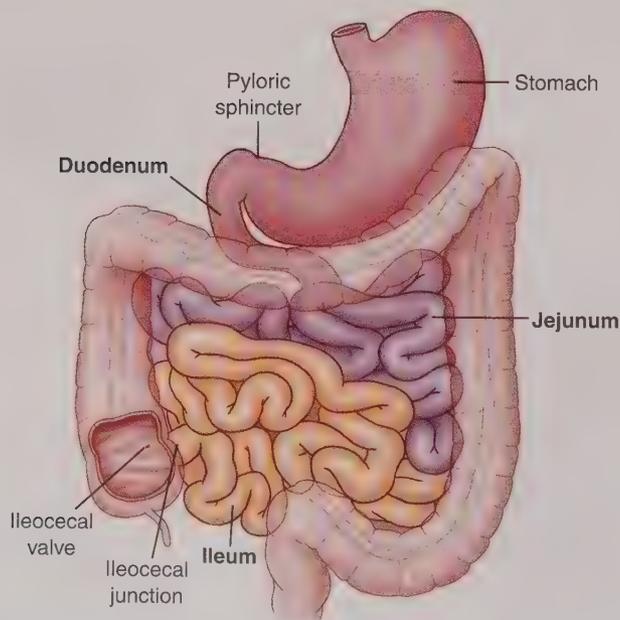

Protein, carbohydrate, and fat digestion and absorption occur in the small intestine (Fig. 55.9). The small intestine has a diameter measuring 2.5 cm, beginning at the end of the pyloric sphincter and ending at the ileocecal junction and filling most of the abdominal cavity. The small intestine is

divided into three components: the duodenum, jejunum, and ileum. Chyme leaves the stomach via the pyloric canal and connects with the duodenum, the first and shortest (10 in.) segment of the small intestine. Measuring 8 ft in length, the rich blood supply and muscular intestinal wall of the jejunum make it the thickest portion of the small intestine, where digestion and absorption occur. As the longest portion of the small intestine, the 12-ft ileum occupies the lower portion of the abdominal cavity and connects to the large intestine at the ileocecal valve. Pancreatic enzymes and bile pass through the bile duct and the pancreatic accessory duct and are released into the duodenum. Pancreatic amylase and intestinal enzymes break down carbohydrates into monosaccharides. The lining of the small intestine has **villi**, fingerlike projections that increase the absorption of nutrients. Each villus has **goblet cells** that secrete mucus and enterocytes, which aid in absorption. This process results in only indigestible fibers entering the large intestine.

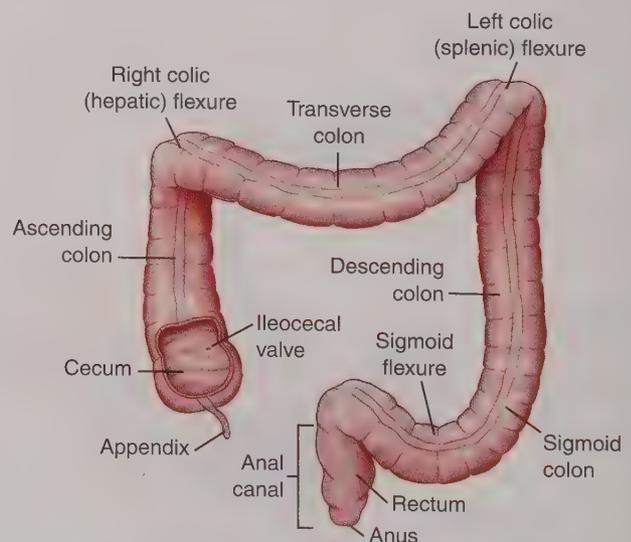

### The Large Intestine

Semiliquid chyme leaves the small intestine through the ileocecal valve and enters the last segment of the digestive tract, the large intestine (Fig. 55.10). Because most nutrients are absorbed in the small intestine, the function of the large intestine is fluid and electrolyte reabsorption and elimination. Measuring 6 ft in length, the large intestine includes the cecum, colon, and anal canal. The cecum is pouchlike and receives the semiliquid chyme from the small intestine. Here, vitamins A, D, E, and K; sodium; and water are reabsorbed, creating semiformed stool. The appendix, a 2- to 7-cm narrow-ended tube, is attached to the end of the cecum. The exact role of the appendix is unknown, but the tube is filled with lymphocytes.

The transformation of waste from a semiliquid state to formed stool occurs in the colon. The colon is divided

**FIGURE 55.9** The small intestine. The small intestine is divided into three components: the duodenum, jejunum, and ileum.

**FIGURE 55.10** Large intestine. The large intestine includes the cecum, colon (ascending, transverse, descending and sigmoid sections), and the anal canal terminating in the anus.

into four sections: ascending, transverse, descending, and sigmoid. The ascending colon begins in the right lower quadrant at the ileocecal valve and extends to the hepatic flexure in the right upper quadrant. Here, the stool is in a semiliquid state. Following the ascending colon is the transverse colon, which extends from the right hepatic flexure in the right upper quadrant to the left splenic flexure in the left upper quadrant. The descending colon then extends from the left splenic flexure in the left upper quadrant to the sigmoid colon in the left lower quadrant. The last portion of the colon, the sigmoid, connects the descending colon and rectum. The rectum is 15 cm long and sits in the pelvic cavity. Finally, the anal canal is the last 3 cm of the digestive tract. It includes internal and external anal sphincters to regulate the passage of stool, which consists of bacteria, bilirubin, and indigestible fiber. The presence of bacteria is the cause for flatus and represents 30% of fecal content.

### Connection Check 55.1

The nurse recognizes that an impairment of which CN makes a patient at risk for aspiration due to ineffective swallowing?

- A. Trochlear
- B. Trigeminal
- C. Vagus
- D. Accessory

### Connection Check 55.2

Patients experiencing diarrhea are at risk for which alteration in absorption?

- A. Decreased chyme absorption
- B. Increased chyme absorption
- C. Decreased potassium absorption
- D. Increased potassium absorption

## ASSESSMENT

### History

The gastrointestinal assessment is included in either the routine physical or a problem-focused examination. The comprehensive assessment of any patient begins with a thorough history. It is important for the nurse to assess the patient's level of understanding and ability to communicate to ensure a reliable health history account. Additionally, the nurse must conduct a culturally sensitive and relevant interview while avoiding stereotyping. Asking questions about cultural practices may provide insight into eating habits as well as general healthcare practices (Table 55.2).

In the routine assessment, patients are initially asked broad, general questions regarding their health history and practices followed by specific questions in response to the patient's response. However, in problem-focused examinations, a history of the present illness is developed by initially asking patients very specific questions based on

**Table 55.2 Health History of the Gastrointestinal System**

Data	Questions
<b>Dietary practices</b>	Who prepares the food in your home? Do you fast for cultural or religious reasons? Do you have any dietary restrictions due to religious or cultural practices? How often do you eat? What do you consider to be healthy or unhealthy foods? Do you use food to treat illnesses? Any food intolerances? Any food allergies?
<b>Nutrition</b>	Do you take vitamins? Any history of vitamin deficiencies? Completion of a food frequency questionnaire. Completion of nutritional screening tool. (MUST, Figure 55-11)
<b>Oral health</b>	Do you see a dentist? How often per year? Do you have a history of dental caries or cavities? Do you wear dentures? Do you have gum disease? Have you been treated for oral candidiasis or oral cancer? Do you have difficulty swallowing or suffer with chronic hoarseness?
<b>Preventive health</b>	What are your exercise habits? Have you had Hepatitis vaccines? Have you had a colonoscopy or sigmoidoscopy? What were the results?
<b>Weight changes</b>	Have you had any unexplained weight loss or weight gain? Do you diet frequently? Any bingeing or purging? Do you ever make yourself vomit?  Any <b>hematemesis</b> (blood in emesis)/ <b>hemoptysis</b> (blood in sputum)? Calculate body mass index (BMI)?
<b>Appetite changes</b>	Have you had increased hunger or thirst? Any early feeling of fullness?
<b>Stool changes</b>	How often do you have a bowel movement? When was your last bowel movement? Have you noticed any changes in color, consistency, or odor? Have you noticed any bright red blood? Have you noticed undigested food? Any laxative use? Frequent flatus?
<b>Pain</b>	Where is the pain? How often do you have pain? When do you have pain? What have you done to relieve the pain? What are the characteristics of your pain? Do you experience pain before or after eating meals? Do you experience pain with defecation?

their reported symptoms and then moving to broader general questions about health. It is also essential to collect a thorough medical, surgical, family, and social history. This information can aid in determining the overall gastrointestinal health of the patient (Table 55.3). For example, cardiac, psychiatric, neurological, and endocrine disorders can impact the function of the gastrointestinal system. Further, it is important to obtain a thorough family history to assess genetic risk factors for cancer screening. Lastly, determining the patient's medication regimen is necessary to ascertain the effects, as well as side effects, of medications on the gastrointestinal system.

A nutritional assessment aids in understanding the patient's behaviors and practices specific to food intake and impact on the gastrointestinal system and includes a thorough nutritional history, physical assessment, and serum studies. Questions focus on weight or appetite changes, loss of appetite (**anorexia**), or bingeing or purging practices. Ascertaining perceptions on what is considered healthy eating and a healthy weight provides information on assessing risk factors for malnutrition. The Malnutrition Universal Screening Tool (MUST), from the British Association of Parenteral and Enteral Nutrition, may be used for a complete nutritional assessment (Fig. 55.11). A referral to a nutritionist for a complete nutritional assessment is indicated for a MUST score of two or higher. Other key questions focus on amounts and types of foods eaten, accessibility to healthy foods, known nutritional deficiencies, and changes in bowel patterns. The patient is also asked about the characteristics of stool: color, frequency, consistency. Presence of blood in the stool can be described as bright blood in the stool (**hematochezia**) or black, tarry stool (**melena**).

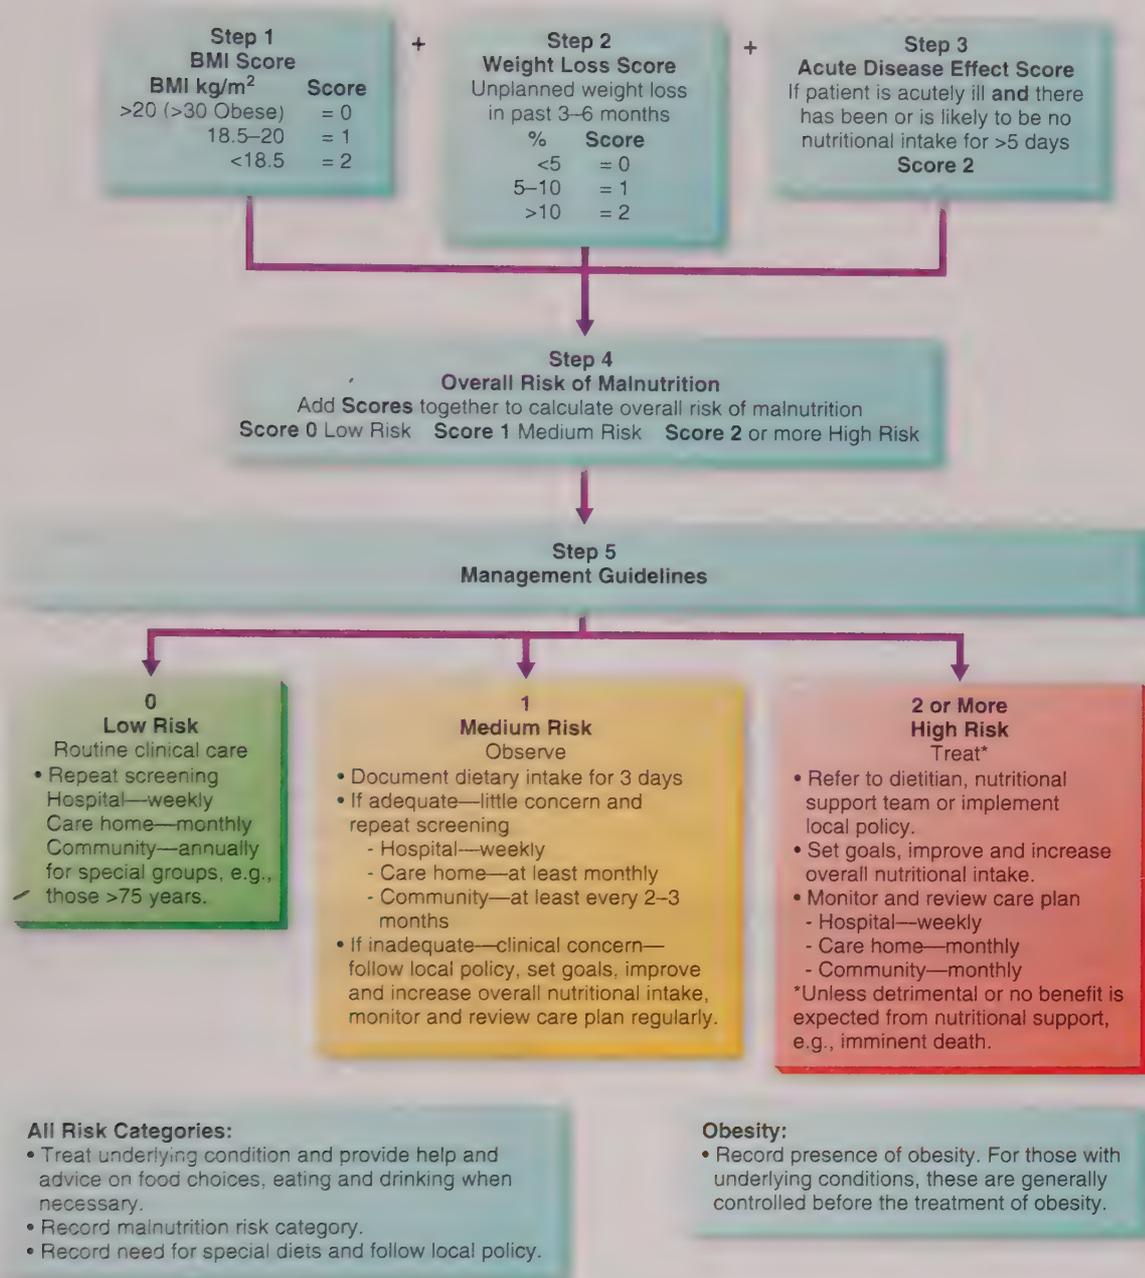

The physical assessment includes both a head-to-toe assessment and anthropometric measurements, including height, weight, body mass index (BMI), waist circumference, body composition, skinfold measurements, and circumference

measurements. If possible, it is recommended that actual height and weight measurements be taken, as opposed to using stated values by the patient, because the calculation of BMI is based on height and weight measurements. Waist circumference is an important nutritional measurement because excess adipose fat along the waist increases the risk for type 2 diabetes mellitus, elevated blood lipids, hypertension, and cardiovascular disease. Body composition measurements, completed through a variety of techniques with varying reliability, provide data about fat mass, muscle mass, and body fat percentage. Skin calipers, biometrical impedance, and dual-energy x-ray absorptiometry (DEXA) scans are examples of techniques to measure body composition, and due to the variability in measurements, body composition is usually trended over time. Skinfold measurements are used to estimate subcutaneous body fat, and circumference measurements of the calf and midarm may be used as another approach to body composition analysis. Based on the patient's current health status, all of these anthropometric measurements may not be available. In these situations, it is important to collect as much data as possible and use the findings, in conjunction with the nutritional assessment and laboratory findings, to determine the patient's nutritional assessment.

Specific diagnostic studies that are helpful in determining nutritional status include serum albumin, prealbumin, and transferrin. Normal serum albumin is 3.4 to 5.1 g/dL, and levels less than 3.5 g/dL are indicative of altered nutritional status and are associated with increased morbidity and mortality in older adults. Prealbumin (normal range 12–42 mg/dL) is considered a more accurate indicator of plasma proteins when compared with albumin, and decreased levels are also associated with increased morbidity and mortality in older adults. Due to transferrin's role in iron binding and transport, transferrin levels are also important to nutritional assessment, and levels range from 215 to 365 mg/dL in males to 250 to 350 mg/dL in females.

**Table 55.3** Questions to Assess the Gastrointestinal System

Pertinent History	Questions
<b>Social history</b>	Do you smoke? Do you use street drugs? Do you use prescription or over-the-counter (OTC) medications? Do you use herbals? Do you drink alcohol? Recent antibiotic use? Any recent international travel?
<b>Medical history</b>	Do you have a history of previous heart attacks, chest pain? Parkinson's disease, sickle cell disease? Sjögren's syndrome? Do you have a history of diabetes, multiple sclerosis? Crohn's disease? Irritable bowel disorder? Gastroesophageal reflux disease (GERD)? Do you have a history of anorexia nervosa? Bulimia? Depression? Familial adenomatous polyposis? Celiac disease?
<b>Surgical history</b>	Any history of previous abdominal surgeries?

**FIGURE 55.11** Malnutrition Universal Screening Tool (MUST).

Decreased levels of transferrin are associated with infection, kidney disease, and hepatic damage, as well as indicative of insufficient protein in the diet in patients with malnourishment.

## Physical Examination

Focused on the collection of objective data, the physical examination includes a direct assessment of the oral cavity; direct assessment of the skin; and an indirect assessment of the underlying structures: the intestinal tract, liver, kidney, spleen, and abdominal arteries. A review of diagnostic testing findings may provide additional information about physical assessment findings. For example, in the patient

with **hepatomegaly** (enlarged liver), the laboratory results may reveal elevated liver function tests (LFTs). Before proceeding with the actual examination, it is important to consider information collected during the health history. Individual preferences, along with religious, cultural, or geriatric considerations, may require the nurse to alter the approach to the examination. Some people, based on cultural or religious reasons, are uncomfortable with exposing the abdominal area or are sensitive to touch, which can lead to contraction of the underlying musculature in the abdomen, giving the false appearance of abdominal rigidity. Additionally, in assessing the older adult, it is important that the nurse recognize age-related changes to the gastrointestinal system. For example, with changes in the esophagus, the

patient often complains of **eructation** (belching), heartburn, and early satiety (Table 55.4). For these reasons, it is important to clearly explain all aspects of the examination and provide the patient a private and comfortable environment.

For the best results in completing a physical assessment of the abdomen, the patient is ideally positioned supine with the arms relaxed at the sides and the knees bent in order to promote relaxation of the abdomen. The abdominal assessment follows the order of inspection, auscultation, percussion, and palpation. The nurse notes normal and abnormal findings during this systematic assessment process.

### Inspection

Inspection of the oral cavity offers insight into gastrointestinal and oral health. With a bright light, assess the oral mucosa, gums, tongue, general repair of dentition, jaw strength, and the ability to swallow. Inspection of the skin over the abdomen can provide valuable information about the underlying structure. Using indirect lighting and tangential views, the nurse inspects the skin for color, striae, lesions, presence of superficial vessels, and scarring. Additionally, the contour and shape of the abdomen are noted; the abdomen should be slightly concave to round. It is important to assess for fullness at the sides. A rounded abdomen from obesity can be confused with abdominal distention

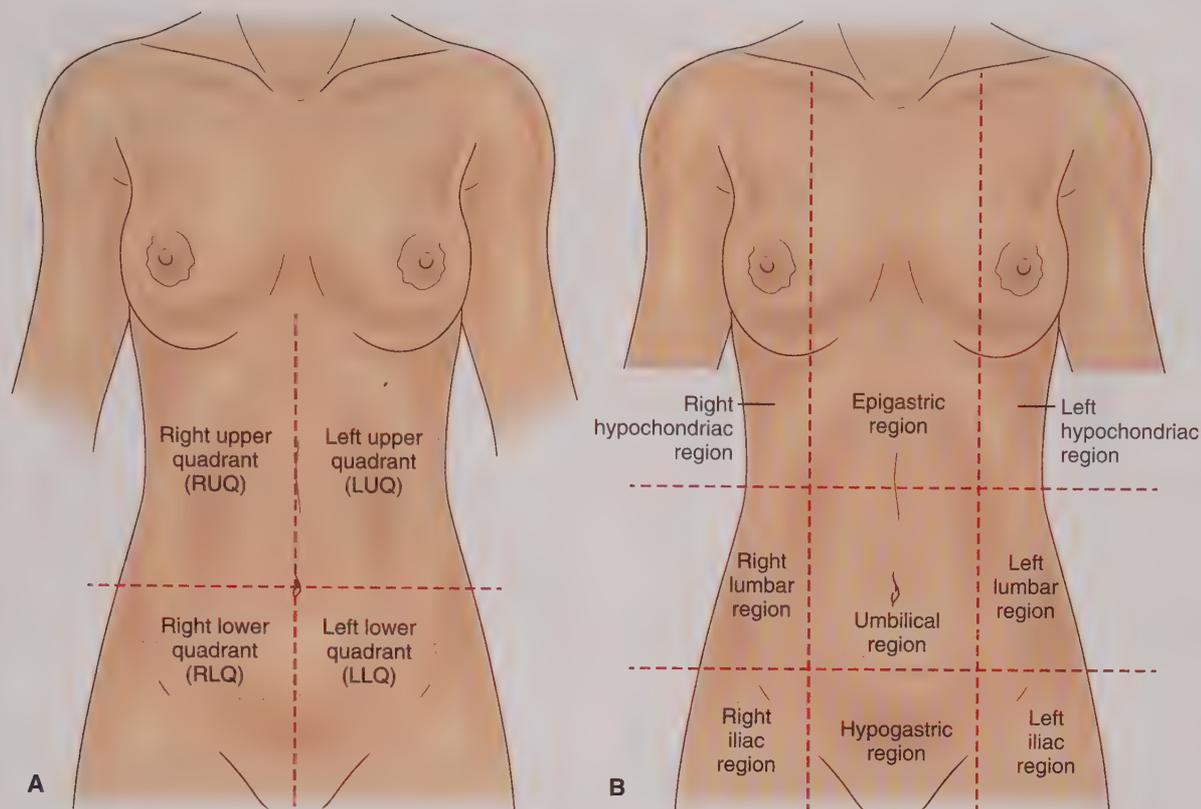

and requires further assessment through percussion and palpation. In very thin patients, it is normal to note a midline pulse. Moving to the exterior portion of the anus, note the color, which should be darker than the surrounding skin. Documentation should include a full description of the findings, and the position should be recorded according to the anatomical locations (Fig. 55.12).

### Abnormal Findings

Bleeding or lesions on the underside of the mouth may indicate oral cancer. Lesions on the tongue can impair taste and appetite or impair the ability to swallow and may contribute to decreased nutritional status. Missing teeth or dental pain can lead to malnutrition. Bulging masses on the abdomen may indicate tumors or **hernias** (displacement or protrusion of a part of the intestine). Pulsatile masses may indicate **aneurysms** (enlargement or bulging of an artery usually associated with weakening of the vascular wall). Striae, commonly known as stretch marks, may be seen with a rapid change in weight. They may also indicate endocrine disorders. Yellow coloring (**jaundice**) of the skin, and perhaps of the sclera of the eyes, or superficial vessels indicate the presence of liver disease. Blue or purple coloring (**Cullen's sign**) around the periumbilical area is often associated with intra-abdominal bleeding. The presence of stomas (Box 55.1) should be noted, including their color

**Table 55.4 Normal Biological Changes of the Gastrointestinal System in the Geriatric Population**

Age-Related Changes	Assessment Focus
<ul style="list-style-type: none"> <li>● Esophageal stiffening</li> <li>● Decreased peristaltic movement of the esophagus</li> <li>● Decreased gastric emptying</li> </ul>	<p><b>Subjective data:</b> Ask about chest pain, eructation, heartburn, indigestion, early satiety, over-the-counter GERD treatment, weight loss</p> <p><b>Objective data:</b> Weight</p>

**FIGURE 55.12** Abdominal assessment according to anatomical locations. A, The four quadrants of the abdomen. B, The nine regions of the abdomen.

## Box 55.1 Assessment of a Stoma

### Inspection of an Ostomy: The Three “Ss”

In a patient with an ostomy, several key areas should be assessed and documented:

- Skin:** The surrounding skin color of the stoma should be consistent with the rest of the abdomen. Any lesions or excoriations should be described and documented.
- Stoma:** Assess the stoma for color and consistency. The stoma should be pink and moist.
- Stool:** Consistency of stool is dependent on the location of the stoma. For instance, an ostomy located in the ileum will pass semiliquid stool, whereas the stool from the sigmoid colostomy will be formed.

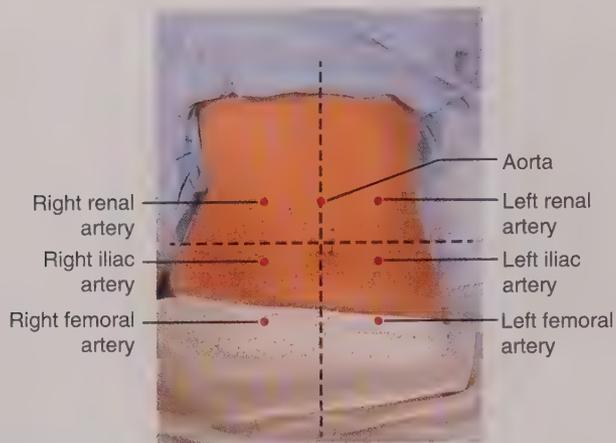

and size. Visible swollen, protruding veins underlying the skin of the anus are indicative of **hemorrhoids**.

### Auscultation

The purpose of auscultation is to indirectly assess bowel sounds and the vascular integrity of the arteries. Typically in the assessment process, percussion and palpation occur prior to auscultation. However, manipulation of the abdomen can result in an inaccurate interpretation of bowel sounds as being hyperactive, so auscultation is completed after inspection. The diaphragm of the stethoscope is

considered best for high-pitched sounds such as bowel sounds. The stethoscope should be placed lightly on the abdomen. Bowel sounds are normally present in the right lower quadrant at the ileocecal valve and are the starting point for auscultation. Moving in a counterclockwise position, the nurse listens in each quadrant, paying close attention to the quality of pitch and sound made by the intestines. Normal bowel sounds can range from low- to high-pitched gurgling, and the frequency of bowel sounds occurs at a rate of 5 to 30 times per minute. A commonly held practice in determining the absence of bowel sounds is to auscultate each quadrant for a minimum of 5 minutes. More recent studies suggest that this practice yields low specificity and sensitivity in determining the absence of bowel sounds. It is important to take into consideration all the assessment findings before determining absence. The frequency of intestinal movement and quality of sound can be influenced by several factors, including the timing of food intake, mobility, medications, neurological disorders, and electrolyte imbalance. Hypoactive bowel sounds can be caused by anesthetics, opioids, and anticholinergic medications, as well as conditions such as **constipation** or **ileus** (absence of normal gastrointestinal motility). Conversely, hyperactive bowel sounds can be secondary to the actions of cholinergic medications or infectious and inflammatory bowel disorders.

The abdominal arteries, including the abdominal aorta, renal, iliac, and femoral arteries (Fig. 55.13), can

**FIGURE 55.13** Auscultation sites for assessing abdominal vascular sounds.

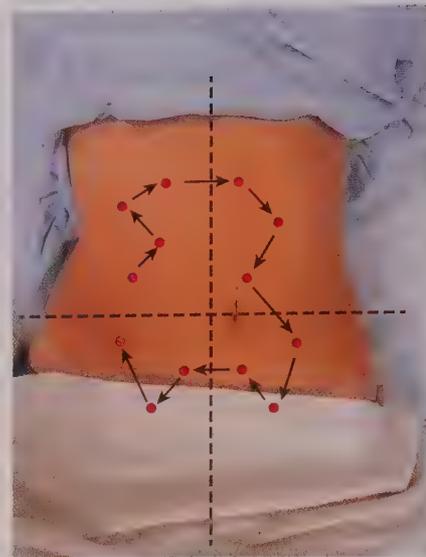

be indirectly assessed in the abdomen by using the bell of the stethoscope, which is best for hearing low-pitched sounds like **bruits** (abnormal sounds heard upon auscultation of blood vessels). The whooshing sound of a bruit may indicate partial obstruction of the vessel, and it is never considered a normal variant to hear a bruit in the abdomen. The nurse should avoid palpation if a bruit is auscultated and report the finding to the healthcare provider.

### Abnormal Findings

Hypoactive bowel sounds can be a later indicator of obstruction, whereas hyperactive bowel sounds can be an early indication of obstruction, diarrhea, or inflammatory bowel disorders. Absent bowel sounds may indicate paralytic ileus caused by mechanical or neurological dysfunction. Bruits can indicate an arterial obstruction.

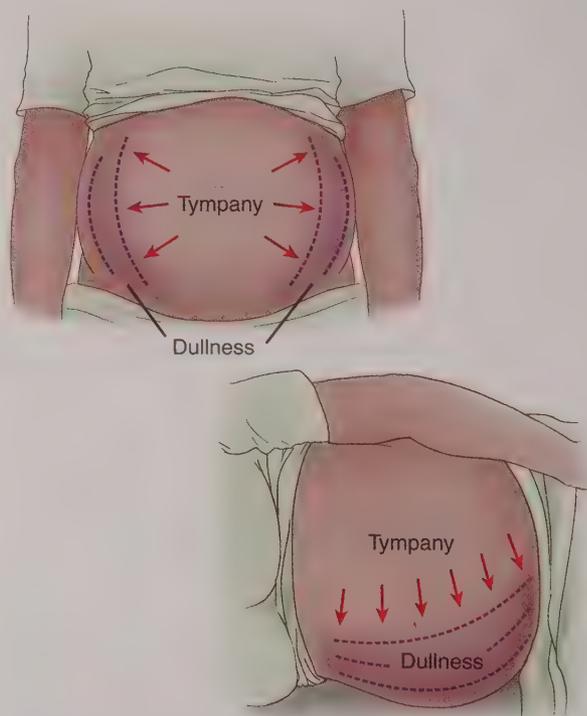

### Percussion

The size of the organs is ascertained through percussion and palpation. Accurate percussion and interpretation require a quiet environment and a skilled practitioner. Nursing students and novice registered nurses often find this skill difficult because of the inability to distinguish between tympany and dullness and the need for proper placement of the fingers on the abdomen. Fingernail length should be short to avoid pinching or scratching the patient. The patient should be supine with the legs partially bent, allowing for the abdominal muscles to be in a relaxed position. To perform this assessment, the nurse places the nondominant hand parallel to the abdomen and firmly places an outstretched finger on the abdomen. Striking the outstretched finger with a finger from the dominant hand, the nurse continues this motion, moving in a clockwise fashion (Fig. 55.14). Percussion over the intestinal area should elicit a drumlike sound known as **tympany**. This sound is similar to the sound heard when percussing a balloon filled with air and should be the predominant sound of the abdomen because air rises in the intestines when patients are in a supine position. Percussion over the liver

**FIGURE 55.14** Percussion sites. Percussion of the abdomen is performed by moving in a clockwise fashion starting in the right upper quadrant.

or stomach should elicit dullness, a flat sound. This sound is similar to the sound produced when tapping a balloon filled with water. Dullness can also be heard in an obese abdomen, over the intestinal tract when filled with fecal matter, over a full bladder, or in the presence of fluid accumulation in the abdomen, or **ascites** (Fig. 55.15).

**FIGURE 55.15** Abdominal distention from ascites. Percussion over the intestinal area should result in a sound known as tympany. Dullness can be heard in the presence of ascites.

## Abnormal Findings

Tympany can be the predominant sound when abdominal gas is present. The presence of fluid can displace air, and dullness can be the dominant sound. This can also indicate constipation.

## Palpation

As stated previously, the purpose of palpation is to evaluate the underlying structures (Fig. 55.16) as well as to assess for abdominal tenderness and abdominal tone. The starting point for palpation is away from any areas of discomfort stated by the patient. *Light palpation* (Fig. 55.17) begins by slightly pressing the pads of the fingers into the abdomen and gliding them over the abdomen in small, incremental, circular movements clockwise around the abdomen. During palpation, it is important to note the abdominal tone and any areas of tenderness. Palpating large abdomens in obese patients can be difficult because of the increased pressure met against the palpating hand. Using the bimanual technique can improve the assessment. Again, it is important to note that pulsating masses should never be palpated.

*Deep palpation* (Fig. 55.18) is a technique that allows the practitioner to assess the size and consistency of the liver, kidney, and spleen. However, it is a skill typically performed by advanced practice nurses or providers.

The *hooking technique* (Fig. 55.19) is also an advanced practice skill used to assess the edge of the liver. Standing to the left of the patient and placing the fingers under the 12th rib as shown in the figure, when the patient inhales, the liver's edge may come below the rib and be palpated by the pads of the provider's fingers. A normal liver span is 6 to 12 cm. *Hepatomegaly* is the term used to describe an enlarged liver.

The spleen is not normally palpated, but in *splenomegaly*, the spleen moves beneath the costal margin and is felt on

palpation (Fig. 55.20). **Organomegaly** is the term used to describe generalized enlargement of organs.

## Abnormal Findings

A rigid abdomen can indicate pain, guarding, or **peritonitis**, which is inflammation of the peritoneal cavity. A mass may indicate a tumor, aneurysm, or hernia.

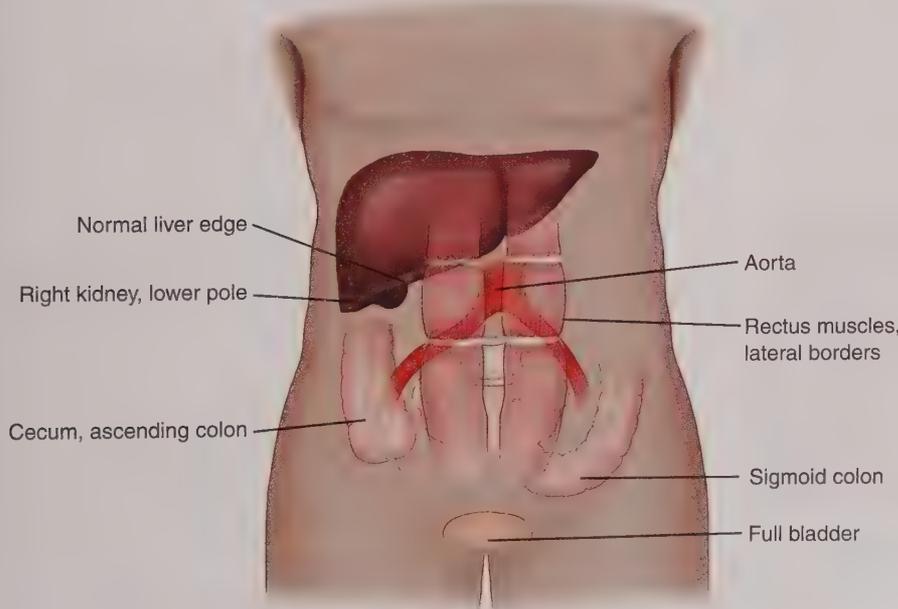

## CASE STUDY: EPISODE 2

The physical examination reveals the following: vital signs: T 97.8°F (36.5°C), pulse 115 bpm, respirations 18, supine BP 130/80 mm Hg, standing 100/60 mm Hg. Abdomen soft, round, slightly distended, and tender. Hypoactive bowel sounds present in all four quadrants. No superficial vessels or lesions present. Generalized tympany with dullness noted in left lower quadrant on percussion. Skin warm, dry, flaky, and intact. No palpable masses present. Fecal occult blood testing results are pending...

## Connection Check 55.3

The nurse places the patient in which position for a gastrointestinal assessment to promote relaxation of the abdominal muscles?

- Sitting upright with arms relaxed in the lap and feet on the floor
- Semirecumbent with knees extended and arms at the sides
- Side lying with arms above the head and knees flexed
- Supine with arms at the side and knees flexed

**FIGURE 55.16** Normal palpable structures. The purpose of palpation is to evaluate the underlying structures of the abdominal cavity.

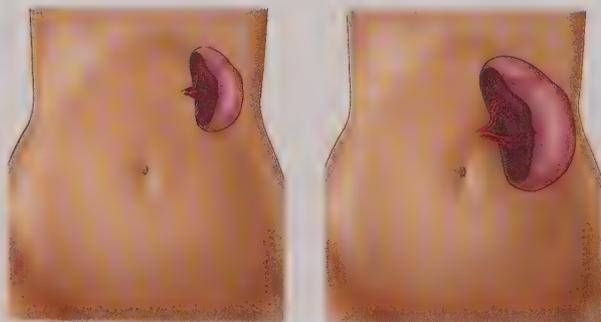

**FIGURE 55.17** Light palpation. Light palpation begins by slightly pressing the pads of the fingers into the abdomen and gliding them in small, incremental, circular movements clockwise around the abdomen.

**FIGURE 55.18** Deep palpation. This is a technique that allows the assessment of the size and consistency of the liver, kidney, and spleen.

**FIGURE 55.19** Hooking technique. This technique is used to assess the edge of the liver. The practitioner stands to the left of the patient and places the fingers under the 12th rib, as shown in the figure. When the patient inhales, the liver's edge may come below the rib and be palpated by the pads of the fingers.

Normal spleen

Splenomegaly

**FIGURE 55.20** Splenomegaly. The spleen is not normally palpated, but in splenomegaly, the spleen is felt on palpation.

## DIAGNOSTIC STUDIES

Diagnostic testing is essential to the comprehensive assessment of gastrointestinal function. The results of diagnostic tests are correlated with the patient's clinical presentation and the healthcare practitioner's physical assessment findings to develop an accurate diagnosis. Laboratory results are also vital in establishing a baseline, as well as in determining the patient's response to treatment.

### Laboratory Studies

Assessment of gastrointestinal function includes various types of serum, urine, and stool analyses (Table 55.5). A complete blood count (CBC) provides important information about potential blood loss through assessment of the red blood cell count, hemoglobin, and hematocrit, and the white blood cell count is indicated for evaluation of inflammatory or infectious processes. A serum chemistry panel is obtained to assess for electrolyte imbalances associated with impaired absorption or excretion. As described previously, serum albumin, prealbumin, and transferrin levels provide data regarding nutritional status. With suspected liver disease, a prothrombin time is important to assess clotting because this test measures the time required for prothrombin to be converted to thrombin and may be prolonged because of impaired synthesis of clotting factors in the liver. Additionally, liver function tests (LFTs) are evaluated with suspected hepatic dysfunction. Urine analysis is indicated in patients with suspected pancreatitis because urine amylase is elevated in this disorder. In patients with complaints of changes in bowel pattern, stool samples are collected for occult blood.

Patients may be apprehensive while awaiting test results. To avoid delays in treatment or inaccurate results, nurses must be knowledgeable and aware of all aspects of the diagnostic study, including patient education and preparation. Patients should understand the purpose of the test, possible side effects, and what is expected during and after the procedure.

### Connection Check 55.4

The nurse correlates an increase in which laboratory value with the diagnosis of acute pancreatitis?

- Serum sodium
- Serum amylase
- Serum potassium
- Serum creatinine

### Imaging Studies

Patients presenting with complaints of abdominal pain typically undergo a routine plain x-ray of the abdomen. This diagnostic study may reveal abnormal masses, obstruction, or strictures. The presence of air in the abdomen is consistent with an obstruction and requires further assessment because perforation can occur with increasing pressure behind the obstruction. Routine plain x-rays require no

**Table 55.5 Diagnostic Testing for Gastrointestinal Function—cont'd**

Gastric Analysis	Teaching	Pre-/Intra-/Posttest	Results
Albumin Normal: 3.4–5.1 g/dL	Patient education on rationale for test and specimen collection methods	Collected in gold-, gray-, or red-top tube	↑ levels Dehydration ↓ levels Malnutrition Thyroid disorders Liver disorders Hypervolemia Genetic hypoalbuminemia
Aspartate aminotransferase (AST) Normal value: Male: 20–40 units/L Female: 15–35 units/L	Patient education on rationale for test and specimen collection methods		↑ levels Hepatitis Cirrhosis Liver cancer Skeletal muscle trauma/diseases Severe burns Acute pancreatitis Acute hemolytic anemia ↓ levels Acute renal disease Beriberi Chronic renal dialysis Diabetic ketoacidosis
Bilirubin Normal: Total bilirubin: 0.3–1 mg/dL Indirect bilirubin: 0.2–0.8 mg/dL Direct bilirubin: 0.1–0.3 mg/dL	Patient education on rationale for test and specimen collection methods		↑ levels (conjugated) Gallstones Extrahepatic duct obstruction Dubin–Johnson syndrome ↑ levels (unconjugated) Hemolytic jaundice Large-volume blood transfusion Sepsis Hemolytic anemia Pernicious anemia Sickle cell anemia Transfusion reaction

preparation except an explanation. In the patient with severe, acute abdominal pain, positioning may be difficult because the patient may experience increased pain secondary to peritoneal irritation when placed in a supine position.

## Ultrasonography

Using a Doppler, sound waves are transmitted to a particular organ. The sound waves are converted to an electronic image to provide a real-time depiction of the soft tissue structure. As a diagnostic procedure, ultrasonography can detect any size and structural abnormalities of the underlying abdominal cavity organs and vessels. The abdominal cavity is also evaluated for the presence of ascites. The liver and pancreas can be visualized to detect cysts, tumors, or masses. The gallbladder and kidneys can be further visualized for stones. As a therapeutic intervention, ultrasonography can be utilized to place stents in obstructed areas. Ultrasonography is the preferred method of visualization of abdominal structures in patients who cannot tolerate contrast dye (Table 55.6).

## Barium Studies

Barium studies consist of a series of x-rays and are ordered to examine the integrity and patency of the gastrointestinal tract; these studies can be diagnostic or therapeutic. Preparation for barium studies typically requires the patient to follow a special diet the day before the test (clear liquids) and then nothing by mouth after midnight. A laxative or enema may also be prescribed for the night before the study. Patients are typically given barium, a radiographic opaque liquid, to drink. However, if there is a concern about possible perforations anywhere along the gastrointestinal tract, a water-soluble liquid, gastrografin, is administered. With the use of fluoroscopy, patients are then taken through a series of time-sensitive x-rays. There are several studies that can be performed: an upper gastrointestinal series,

**Table 55.6 Abdominal Ultrasonography**

Types of Ultrasonography	Abnormal Findings
<b>Gallbladder</b>	Polyps Tumor Gallstones
<b>Liver</b>	Tumor Abscess Intrahepatic dilated bile ducts
<b>Pancreas</b>	Tumor Cysts Pseudocysts Abscess Inflammation
<b>Bile ducts</b>	Gallstone Dilation Stricture Tumor
<b>Abdominal aorta</b>	Aneurysm
<b>Abdominal cavity</b>	Ascites Abscess

which visualizes the esophagus, stomach, and duodenum; a small bowel series, which visualizes the small intestine; and lastly, the barium enema, which visualizes the colon. Regardless of the type of barium study performed, the nursing interventions are similar (Table 55.7).

**Table 55.7 Types of Barium Studies**

Barium Study	Description	Rationale	Special Considerations	NPO	Significance of Findings
<b>Swallow</b>	More thorough view of the esophagus	Dysphagia	Barium related Fecal impaction Administer ↑ fluid intake Laxative	8–12 hours prior to study	Strictures Stenosis Varices Muscular weakness Tumors
<b>Upper GI</b>	Visual of lower esophagus, stomach, duodenum	Dyspepsia Dysphagia Epigastric pain	Barium related Fecal impaction Administer ↑ fluid intake Laxative	8–12 hours prior to study	Ulcers Gastric Duodenal Cancers/tumors Esophageal

Continued

Table 55.7 Types of Barium Studies—cont'd

Barium Study	Description	Rationale	Special Considerations	NPO	Significance of Findings
					Gastric Duodenal Diverticulum Duodenal Esophageal Hiatal hernia
<b>Small bowel follow-through (SBFT)</b>	Visual of small intestine Patient drinks barium	Nausea, vomiting	Barium related Fecal impaction Administer ↑ fluid intake Laxative	8–12 hours prior to study	Small bowel obstruction, malabsorption disorders
<b>Small bowel enema (SBE)</b>	Visual of small intestine Patient given an enema	Provides better visualization than SBFT	Barium related Fecal impaction Administer ↑ fluid intake Laxative	8–12 hours prior to study	Small bowel obstruction, malabsorption disorders
<b>Barium enema</b>	Visual of colon	Persistent diarrhea Bloody stools Fistulas	Barium related Fecal impaction Administer ↑ fluid intake Laxative	8–12 hours prior to study	Polyps Tumors Inflammatory bowel diseases Intussusception

### Safety Postprocedural Care Alert

Increased fluid intake and/or enemas are necessary to prevent constipation and impaction in patients who undergo barium studies.

### Connection Check 55.5

The nurse monitors for which complication in the patient who has undergone a barium enema?

- Fluid overload
- Dehydration
- Diarrhea
- Constipation

### Endoscopy

*Endoscopy* is the general term used to describe the procedure in which a fiberoptic scope is used to visualize the gastrointestinal tract. Endoscopic studies can serve three purposes: diagnostic, curative, or palliative. Patients are sedated with a narcotic and a sedative. The pre- and postprocedural nursing interventions are similar and are outlined in Table 55.8.

### Safety Endoscopy Procedural Care Alert

After an upper endoscopy, the nurse monitors for the return of swallow before providing oral intake to decrease the risk of aspiration. After a lower endoscopy, anticoagulants and aspirin (acetylsalicylic acid, or ASA) are usually held temporarily due to the risk of bleeding.

## Evidence-Based Practice

### Preferred Colorectal Cancer Screening Recommendations

#### Patient Population

Male or female age 50 at average risk

#### Test

Colonoscopy every 10 yrs.

Fecal immunoassay test (FIT) annually

OR

Alternative colorectal cancer screening:

- Flexible sigmoidoscopy every 5 to 10 years
- Computed tomography (CT) colonography every 5 years
- FIT-fecal DNA every 3 years

African Americans beginning at age 45

Colonoscopy every 10 years or FIT annually

OR

Alternative colorectal cancer screening:

- Flexible sigmoidoscopy every 5 to 10 years
- CT colonography every 5 years
- FIT-fecal DNA every 3 years

Persons who have had consistent screening and remain negative can consider stopping screening at age 75 or life expectancy of less than 10 years.

Colonoscopy every 10 years or FIT annually

OR

Alternative colorectal cancer screening:

- Flexible sigmoidoscopy every 5 to 10 years
- CT colonography every 5 years
- FIT-fecal DNA every 3 years

Persons who have not had a colonoscopy may consider screening up to age 85. Consider comorbidities.

Colonoscopy every 10 years

OR

Alternative colorectal cancer screening:

- Flexible sigmoidoscopy every 5 to 10 years
- CT colonography every 5 years
- FIT-Fecal DNA every 3 years

#### Family History of Colorectal Cancer (CRC) or Advanced Adenomas

Patient or family history of CRC or advanced adenoma in first-degree relative < age 60 or 2 first-degree relatives

Colonoscopy every 5 years beginning at age 40 years

OR

10 years younger than age at diagnosis of youngest affected relative

Patients with adenomas without known history of hereditary nonpolyposis colorectal cancer (HPNCC)

- Advise genetic testing or counseling for patients with more than 100 adenomas
- Annual flexible sigmoidoscopy or colonoscopy until colectomy is deemed best treatment
- Patients with retained rectum after subtotal colectomy
- Flexible sigmoidoscopy every 6 to 12 months

*Continued*

## Evidence-Based Practice—cont'd

Those affected or a known first-degree relative with HNPCC

Colonoscopy every 1–2 years beginning at age 20–25 years until age 40 years, then consider annually 2–5 years before the youngest age of diagnosis of CRC in the family if diagnosed before age 25 years.

- Women should consider screening for endometrial cancer beginning at age 30–35.
- Consider screening for gastric cancer beginning at age 30–35.
- Consider screening for urinary cancer beginning at age 30–35.

U.S. Preventive Services Task Force, Bibbins-Domingo, K., Grossman, D. C., Curry, S. J., Davidson, K. W., Epling, J. W., ... Siu, A. L. (2016). Screening for colorectal cancer: US Preventive Services Task Force recommendation statement. *JAMA*, 315(23), 2564–2575.

Study	Description	Rationale	Special Considerations	NPO Status	Significance of Findings
<b>Small bowel endoscopy</b>	Visualization of the jejunum and ileum	Gastrointestinal bleeding Abdominal pain		12 hours	Upper gastrointestinal bleeding
<b>Esophagogastro-duodenoscopy</b>	Visualization of the esophagus, stomach, and duodenum	Suspected upper gastrointestinal bleeding, dysphagia Epigastric pain	Monitor return of gag reflex Vital signs	8–10 hours prior to study	Peptic ulcers <i>Helicobacter pylori</i> infection Gastritis Hiatal hernia Esophageal ● Varices ● Strictures ● Tumors
<b>Endoscopic retrograde cholangiopancreatography</b>	Visualization of pancreatic and biliary ducts	Jaundice Right upper quadrant pain Elevated ● Amylase ● Lipase ● Serum alkaline phosphatase	Should not be performed during acute illness phase of pancreatitis	8–12 hours prior to study	<b>Common bile duct</b> ● Gallstones ● Tumor ● Strictures ● Cysts <b>Pancreatic duct</b> ● Chronic pancreatitis ● Pseudocysts
<b>Colonoscopy (see Evidence-Based Practice)</b>	Visualization of colon from anus to cecum	Colon cancer screening +Fecal occult blood testing Abnormal sigmoidoscopy	Bowel prep 24 hours prior to colonoscopy	6–8 hours prior to study	Colon cancer Benign polyps Crohn's disease Diverticular disease arteriovenous malformations

**Table 55.8** Types of Endoscopic Studies—cont'd

Study	Description	Rationale	Special Considerations	NPO Status	Significance of Findings
		Lower gastrointestinal bleeding Family history of familial nucleus polyposis			
<b>Sigmoidoscopy</b>	Visualization of the sigmoid colon, rectum, and anus	Lower gastrointestinal bleeding Colon cancer Tumors Screening family history of polyps Abdominal pain Persistent or chronic intermittent diarrhea Constipation	The following medications may need to be stopped temporarily ● Aspirin ● Clopidogrel ● Warfarin	Clear liquid meal	Colitis ● Ulcerative ● Pseudomembranous Crohn's Polyps Intestinal ischemia

## AGE-RELATED CHANGES

The gastrointestinal system has a large functional reserve capacity, and aging generally has minimal effects on gastrointestinal function (see Table 55.4). Digestion and absorption of nutrients are usually normal in older adults, and changes in function are primarily secondary to changes associated with the rate of new cell growth, as in other body systems. As smooth muscle tone decreases in the gastrointestinal system, contractions responsible for propelling food along weaken, and the movement of food through the digestive system is slower. This usually presents as constipation and may be accompanied by hemorrhoids if the constipation is chronic and requires straining when having bowel movements. If there is weakening of the cardiac sphincter related to aging, esophageal reflux may develop, and the patient may present with “heartburn.” Cancer rates, particularly stomach and colon, increase with age. Loss of bone mass and changes in calcium regulation may also be associated with tooth loss in older adults that impacts nutritional intake and digestion.

### Connection Check 55.6

The nurse recognizes which clinical manifestation as a normal age-related variant in an older adult?

- Diarrhea
- Melena
- Constipation
- Anorexia

## Making Connections

### CASE STUDY: WRAP-UP

The healthcare provider orders the following diagnostic tests for Mr. Jhanes:

- CBC with differential
- Electrolyte panel
- Fecal occult blood test
- Abdominal flat x-ray
- Esophagogastroduodenoscopy (EGD)

The results of Mr. Jhanes's diagnostic tests are as follows:

Hgb 7 g/dL

HCT 21%

BUN 30 mg/dL

Creatinine 2.0 mg/dL

The EGD reveals a gastric ulcer, and a biopsy is sent to the laboratory for *Helicobacter pylori*.

On the basis of these results, Mr. Jhanes is referred back to his primary healthcare provider for treatment of the gastric ulcer.

### Case Study Questions

- On the basis of the assessment findings of the case study, which requires immediate follow-up by the registered nurse?
  - Reported bowel movement several days ago
  - Missed dose of lisinopril
  - Hypoactive bowel sounds present in all quadrants
  - BP 130/80 mm Hg, standing 100/60 mm Hg
- Which subjective and objective data support the order for fecal occult blood testing? (*Select all that apply.*)
  - Reports of stool darker than usual
  - Reports of feeling tired and complaints of light-headedness when moving from a sitting to a standing position
  - Clopidogrel (Plavix) 75 mg PO daily
  - Skin warm, dry, flaky, and intact
  - Heart rate 115 bpm, respirations (R) 18, supine BP 130/80 mm Hg, standing 100/60 mm Hg
- Which statement by Mr. Jhanes regarding the endoscopic procedure indicates that further teaching is required?
  - "I can eat solid foods 3 hours prior to the procedure."
  - "I can eat solid foods 12 hours prior to the procedure."
  - "I cannot eat or drink 1 hour prior to the procedure."
  - "I can return to my normal diet after the procedure."
- Mr. Jhanes returns to the unit after an endoscopic gastro-duodenoscopic procedure. The nurse will prioritize the interventions in which order?
  - Vital signs, focused physical assessment, start diet, and discontinue IV fluids
  - Focused physical assessment, vital signs, discontinue IV fluids, and start diet
  - Discontinue IV fluids, vital signs, focused physical assessment, and start diet
  - Start diet, discontinue IV fluids, focused physical assessment, and vital signs
- The biopsy results are positive for *H. pylori*. Which statement by the patient indicates understanding of these results?
  - "There is no cure for this disease, and I will have it for the rest of my life."
  - "I hope that I don't pass this on to my wife."
  - "I think I contracted this infection from eating shellfish."
  - "I will need to take antibiotics to get rid of the infection."

### CHAPTER SUMMARY

The gastrointestinal system includes the mouth, pharynx, esophagus, stomach, and small and large intestines, as well as the salivary glands, liver, gallbladder, and pancreas. Primary functions of the gastrointestinal system include the intake, digestion, metabolism, and elimination of food and fluid. Additionally, certain hormonal homeostatic actions are dependent on the normal function of the gastrointestinal system.

The process of digestion begins in the mouth, where the mechanical and chemical breakdown of food occurs. Deglutition involves the pharynx, esophageal muscles, and cranial nerves (CNs) V, VII, IX, and XII. This is a two-phase process: the buccal phase involves the tongue, and the pharyngeal-esophageal phase involves the palate and esophageal muscles. Peristaltic movement of the esophagus moves the bolus of food into the stomach.

The esophagus is a hollow muscular tube that extends from approximately the vertebral levels of C6 to T7. The peristaltic movements push the food bolus downward as the esophagus constricts above the bolus and dilates below the bolus. The esophagus extends through the diaphragm and connects to the stomach. In normal digestion, the lower esophageal sphincter protects the esophageal mucosa from the regurgitation of partially digested food and the acid produced in the stomach. Specialized cells in the stomach secrete hydrochloric acid, enzymes, and hormones. Gastric motility is controlled by smooth muscle, pacemaker cells, and the autonomic nervous system.

Protein, carbohydrate, and fat digestion and absorption occur in the small intestine. Bile and pancreatic enzymes are released into the duodenum to break down the chyme for digestion. The thickest part of the intestine, the jejunum, digests and absorbs the nutrients. The small intestine is lined with villi, which aid in the absorption of the nutrients.

Indigestible fiber in the form of semiliquid chyme passes through the ileocecal valve into the large intestine, where fluid and electrolyte reabsorption and elimination occur. Entering into the cecum, vitamins (A, D, E, and K), sodium, and water are absorbed, and the stool becomes semiformed. As the stool passes through the colon, it becomes formed and passes through the rectum to the anal canal.

The liver, gallbladder, and pancreas are considered accessory organs of the gastrointestinal tract. Attached beneath the diaphragm, the liver is positioned largely across the right upper quadrant and extends into the left upper quadrant. The liver is responsible for detoxification of blood; metabolism of medications, as well as carbohydrate, protein, and fat; vitamin storage; production of bile acids and lecithin; and synthesis of fibrinogen and prothrombin.

The gallbladder is attached to the inferior portion of the liver and is responsible for bile storage and concentration. Lecithin, bilirubin, and bile salts are excreted from the liver

through a ductal system and stored in the gallbladder. The terminal ends of the bile and pancreatic ducts form the hepatopancreatic ampulla in the pancreas. The pancreas is inferior to the stomach in the right upper quadrant. As an endocrine gland, the pancreas produces insulin and glucagon, and as an exocrine gland, it secretes sodium bicarbonate; proenzymes; and pancreatic enzymes needed for carbohydrate, fat, and DNA and RNA digestion.

Diagnostic tests are essential to a comprehensive gastrointestinal assessment. Diagnostic studies relevant to the gastrointestinal system include serum studies, radiographical examinations, and endoscopic evaluations. Because nurses are often directly involved in the pre- and postprocedure care of these patients, knowledge of the anticipated

complications and providing support to patients while awaiting results are important.

Assessment of oral health, nutritional status, and gastrointestinal function is important because there are structural and functional problems that can impair nutrition, digestion, and elimination and lead to systemic dysfunction. A comprehensive history, physical examination, and review of diagnostic study results provide essential data for the diagnosis, treatment, and management of gastrointestinal disorders. Additionally, age-related changes should be taken into consideration during the history and physical. In order to obtain an accurate assessment, it is important to remember the order in which an abdominal assessment is conducted: inspection, auscultation, percussion, and palpation.

# Chapter 56

## Coordinating Care for Patients With Oral and Esophageal Disorders

*Cindy Fox*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of disorders of the oral cavity and esophagus
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Stomatitis
  - b. Hiatal hernia
  - c. Gastroesophageal reflux disease
  - d. Oral cancer
  - e. Oral trauma
  - f. Esophageal cancer
  - g. Esophageal trauma
3. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the oral cavity and esophagus
4. Discussing the medical management of:
  - a. Stomatitis
  - b. Hiatal hernia
  - c. Gastroesophageal reflux disease
  - d. Oral cancer
  - e. Oral trauma
  - f. Esophageal cancer
  - g. Esophageal trauma
5. Describing complications associated with selected disorders of the oral cavity and esophagus
6. Developing a comprehensive plan of nursing care for patients with oral and esophageal disorders
7. Developing a teaching plan for a patient with oral or esophageal disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Comfort
- Digestion
- Inflammation
- Nutrition
- Safety

### ESSENTIAL TERMS

Barrett's esophagus  
Candidiasis  
Dysarthria  
Dysphagia  
Erythroplakia  
Gastroesophageal junction (GEJ)  
Gastroesophageal reflux disease (GERD)  
Gastropexy  
Herniorrhaphy  
Herniotomy  
Leukoplakia  
Lower esophageal sphincter (LES)  
Mallory-Weiss syndrome  
Odynophagia  
Squamous cell carcinoma (SCCA)  
Stomatitis  
Stricture  
Supradiaphragmatic volvulus  
Trismus  
Xerostomia

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Juan Rodriguez is a 50-year-old man presenting to his health-care provider for a clinic appointment. Mr. Rodriguez has what appears to be a small ulcer on the side of his tongue. It has been there for 2 weeks, and it is painful and not healing. Mr. Rodriguez has been smoking two packs of cigarettes per day since he was 20 years old, and he admits to drinking bourbon before he goes to bed at night. Mr. Rodriguez has not been to a dentist for 5 years, and he has a notable oral fetor (foul breath). His medical history includes hypertension, gastroesophageal reflux disease (GERD), and depression. Medications prescribed to him include nortriptyline, triamterene, and omeprazole (Prilosec). Mr. Rodriguez has been divorced for the last 15 years and lives with his girlfriend. Mr. Rodriguez works as a mechanic and supplements his income by working temporary jobs when he can find work...

## INTRODUCTION

The oral cavity (mouth) and the esophagus are part of the upper gastrointestinal (GI) tract. The oral cavity extends from the lips to the anterior tonsils and is responsible for mastication, chewing, taste, breathing, and articulation of speech. The esophagus is a muscular hollow canal 25 cm long and 2 cm in diameter extending from the pharynx to the stomach, and it transports food from the pharynx to the stomach.

The structures of the oral cavity and the esophagus are vulnerable to injury, infection, trauma, and cancer. According to *Healthy People 2020*, many cancers are preventable by eliminating risk factors such as tobacco products, physical inactivity, obesity, and exposure to ultraviolet light. Diseases of the oral cavity and esophagus are particularly vulnerable to lifestyle choices. Screening and prevention are key elements in the elimination of diseases of the oral cavity. Unfortunately, screening for disorders of the esophagus in most cases occurs after clinical manifestations occur and the disease has progressed.

Health disparities contribute to the risk of developing cancer. The most prevalent factor influencing inequity in healthcare is socioeconomic status (SES). Because SES is primarily based on income, education level, occupation, social status within the community, and place of residence, it has a greater influence than race or ethnicity on an individual acquiring education, health insurance, and a safe/healthy work environment. Based on *Healthy People 2020*, socioeconomic status also influences behavioral risk factors such as smoking, level of physical activity, obesity, and the likelihood of participating in cancer screenings.

## ORAL AND ESOPHAGEAL DISEASES

### Stomatitis

#### Epidemiology

Oral stomatitis is an inflammatory condition affecting the oral mucosa, dentition, and periosteum. Known risk factors for stomatitis are:

- Viral infections
- Bacterial infections
- Fungal (*Candida albicans*) infections
- Irritants (alcohol, tobacco, mouthwash)
- Radiation therapy (7–14 days after starting treatment)
- Chemotherapy (peaks 6–12 days after last dose)
- Allergic (metal, medications, dental material, cosmetics, gum, foods)
- Vitamin deficiency (vitamin B complex, folate, zinc, iron)
- Systemic disease (chronic kidney disease, inflammatory bowel disease)

Stomatitis occurs in about 40% of patients receiving chemotherapy. The rate and severity of occurrence are higher in females than in males. When chemotherapy and radiation therapy are given in combination (chemoradiation), the risk of developing stomatitis is compounded, and up to 90% of these patients develop stomatitis. Measures to decrease the severity of stomatitis and to promote healing include frequent mouth care, hydration, using artificial saliva, and avoiding food that is very hot or that has rough edges. Factors that affect the rate and severity of stomatitis include:

- Age
- Nutrition
- Type of cancer
- Chemoradiation
- Oral hygiene

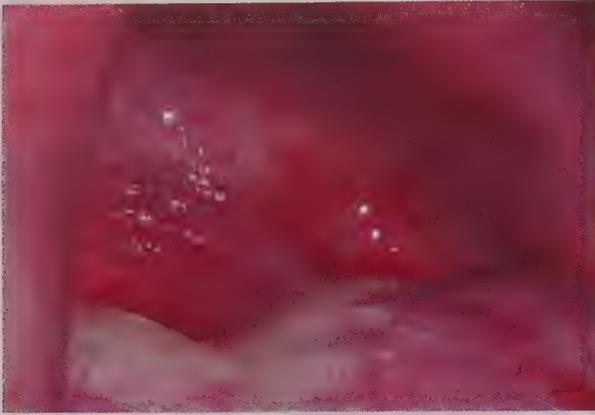

### Connection Check 56.1

The nurse recognizes which risk factors for the development of stomatitis? (Select all that apply.)

- A. High-fiber diet
- B. Radiation therapy
- C. Past history of skin cancer
- D. Poor dental hygiene
- E. Smoking

#### Pathophysiology and Clinical Manifestations

Stomatitis (also known as oral mucositis) presents as a painful inflammation and ulceration of the lining of the mouth that may also include the lips, pharynx, tongue, gingiva, esophagus, roof and floor of the mouth, buccal mucosa, and other mucous membranes anywhere along the GI tract. The most commonly affected locations are the tongue and buccal area (Fig. 56.1).

**FIGURE 56.1** Oral mucositis. Stomatitis presents as a painful inflammation and ulceration in the mouth.

These sores are painful and increase the risk of bleeding, as well as local and systemic infections. Stomatitis is classified as primary or secondary and is determined by the cause of the inflammation. For the purposes of this chapter, the information presented is limited to stomatitis occurring in the oral cavity.

- Primary stomatitis occurs most often, and the most common types are aphthous stomatitis or canker sores that present as painful, small oral ulcers, herpes simplex stomatitis, and traumatic ulcers.
- Secondary stomatitis usually occurs as the result of viral, bacterial, or fungal infections in patients with suppressed immune systems, often secondary to radiotherapy and/or chemotherapy.

Depending on the severity, stomatitis can alter the quality of life. Swallowing and speaking can become painful, and tissue damage resulting from stomatitis can lead to local or systemic infections.

Recurrent aphthous ulcers (RAUs) are the most common lesion affecting the oral cavity, with up to 66% of the population affected. These lesions occur as single or multiple rounded, flat, painful ulcers and are usually white or yellow and surrounded by inflamed tissue. Eating, drinking, and oral hygiene may be interrupted. Recurrent aphthous ulcers are classified as minor, major, or herpetiform. Minor RAUs occur in 70% to 85% of the cases, are less than 1 cm, occur as one to five ulcers at a time, and last up to 14 days. Major RAUs represent 10% of all cases and are the most severe of the cases. Major RAUs are over 1 cm; are found on the lips, tongue, soft palate, and pharynx; can last about 6 weeks; and may produce scarring. The herpetiform type accounts for up to 10% of the cases and presents as recurrent outbreaks of small, deep, painful ulcers. Several ulcers can appear simultaneously, measuring 2 to 3 cm, and can merge together to form larger ulcerations.

The etiology of RAUs is not known, but a number of factors are known to predispose an individual to this disease. These factors include genetic factors; streptococcal infections; decreased immunity; stress; trauma; food allergies;

endocrine imbalances; and deficiencies of iron, vitamin B<sub>12</sub>, and folic acid.

Another common cause of stomatitis is related to an oral fungal infection known as **candidiasis**, moniliasis, thrush, or yeast infection (Fig. 56.2). *Candida albicans* is normally present in the mouth. Infrequently, oral candidiasis is caused by *Candida glabrata* or *Candida tropicalis* yeasts, which are also present in the oral cavity. Common factors contributing to candidiasis include:

- Radiation therapy
- Chemotherapy
- Long-term use of antibiotics
- Steroids
- Certain antidepressant medications
- Diabetes
- Malnutrition
- Dementia
- Denture colonization
- Poor oral hygiene
- Dry mouth
- Decreased immune function
- Anxiety and stress

Oral candidiasis often presents with redness and cracking at the corners of the mouth, or there may be a red, smooth area near the middle of the tongue. A white coating of the tongue is usually called thrush and is also secondary to oral candidiasis (see Fig. 56.2).

Older adults in long-term care and residential facilities with self-care and cognitive deficits often have poor oral hygiene, contributing to an increased risk for oral infections. In addition, older adults are more prone to developing candidiasis because of their decreased immune function and other risk changes related to the aging process. Early identification and assessment of patients at risk for stomatitis facilitate appropriate treatment and prevention of complications.

Patients undergoing chemotherapy and radiation therapy are at risk for developing stomatitis. In severe cases, patients who are receiving chemotherapy may need to have a dose reduction or a delay in treatment if clinical manifestations of stomatitis become severe. Normally, the cells that line the GI tract undergo rapid division, and old cells undergo rapid replacement by new cells. Chemotherapy destroys mucous membrane cells faster than new ones can develop. The result is the formation of painful sores in the

**FIGURE 56.2** Oral candidiasis. The white coating of the tongue is called thrush and is secondary to oral candidiasis.

mouth. When chemotherapy and radiation therapy are given in combination (chemoradiation), stomatitis is more severe. A number of scales used to rate stomatitis exist. These scales are used to grade symptoms in order to manage patient care and can also be used to quantify data for research. An example of an oral stomatitis grading scale is listed in Table 56.1.

**Xerostomia** (dry mouth) can increase the risk of contracting candidiasis and developing stomatitis, and it is a clinical manifestation of several diseases, as well as a side effect of many different medications. Patients receiving radiation to the oral cavity are prone to develop oral complications. Xerostomia is also a side effect of radiotherapy, occurring up to 78% of the time in patients receiving significant radiation exposure to the salivary glands. Patients with xerostomia have decreased, thickened, or no saliva, causing them to experience difficulty with eating, swallowing, talking, and tasting. Xerostomia can be temporary or permanent, and up to 57% of patients remain symptomatic 1 year or more after completing radiotherapy.

Saliva keeps the oral cavity moist, and it helps with taste, swallowing, and speech. Saliva also helps prevent dental caries (tooth decay) by washing away bacteria, plaque, and food debris, and it also decreases the acidity in the oral cavity that can lead to the erosion of enamel on the surface of the teeth. Patients with xerostomia are at risk for developing dental caries and require a thorough dental prophylaxis at least twice per year.

Other causes of xerostomia include removal of the salivary glands, dehydration, diabetes, Sjögren's syndrome (autoimmune disorder affecting the salivary and lacrimal glands), cystic fibrosis, HIV, and rheumatoid arthritis. Common types of medications that can cause xerostomia include cold and allergy medications, psychiatric medications, and pain relievers. Interventions to relieve the effects of xerostomia include frequent mouth care, use of medications to promote saliva production (pilocarpine), lubricants, moistening agents, and sipping water throughout the day. Patients with xerostomia should avoid foods with excessive amounts of sugar, alcohol, tobacco, and caffeine to prevent further irritation or dryness of the oral cavity. Prevention,

patient education, and early treatment are important in order to decrease the risk of complications in these patients.

## Management

### Medical Management

Management of stomatitis includes prompt diagnosis through frequent assessment of the oral cavity before, during, and after chemotherapy and radiation therapy. Preventive measures include oral mouth rinses every 4 hours or more frequently and at bedtime using a solution of 1 teaspoon of salt or sodium bicarbonate (baking soda) per pint of water, or a saline and sodium bicarbonate mixture. Benefits of oral rinses include removal of loose particles and hydration of oral tissue. In particular, sodium bicarbonate thins oral mucus and decreases acidity and yeast growth. Topical analgesics and anesthetics may be prescribed to relieve lip or mouth pain, and moisturizers should be applied to the lips and oral membranes as needed to prevent dryness and cracking. Patients are encouraged to see the dentist for a thorough oral cleaning and examination at least 1 month prior to chemotherapy or radiotherapy in order to prevent oral cavity complications.

### Complications

Patients with stomatitis are at an increased risk for pain because of inflammation and ulcerations of the oral mucosa. Due to the painful ulcerations in the mouth, they may demonstrate **dysphagia** (difficult swallowing) or **odynophagia** (painful swallowing). Patients who are unable to eat require parenteral or enteral feedings to maintain nutritional requirements. In severe cases of stomatitis, open lesions and edema may result in airway obstruction as well as oral and systemic infections with the spread of bacteria, viruses, and other infectious agents.

Stomatitis interrupts the function and the integrity of the oral cavity, which affects quality of life. Patients may experience interruptions in treatments and dose adjustments related to the mucotoxic side effects of the therapies, thus affecting therapeutic outcomes in patients receiving radiation and chemotherapy.

**Table 56.1 Oral Stomatitis Grading Scale**

	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
<b>Functional/ symptomatic</b>	Able to eat a normal diet with minimal symptoms	Symptomatic but can eat a modified diet	Symptomatic and unable to eat or drink by mouth	Symptoms are life threatening	Death
<b>Clinical examination</b>	Redness of mucosa	Patchy oral ulcerations	Confluent oral ulcerations that bleed with minor trauma	Tissue necrosis with significant bleeding; life-threatening consequences	Death

## Nursing Management

### Assessment and Analysis

Diagnosis of stomatitis is based on physical examination, patient history, and clinical presentation. Chemotherapeutic agents, radiotherapy, steroids, and decreased immune function are associated with this disorder. Patients with stomatitis have a higher risk of contracting opportunistic infections from viruses, bacteria, and other organisms because of impaired immune function and inadequate nutrition. Determination of the offending irritant is important so that it can be avoided in the future and treatment plans are not interrupted. Common assessment findings include:

- Dry, red, swollen, and cracked oral mucosa
- Mouth ulcers
- Recurrent aphthous ulcers (canker sores)
- Open, bleeding mouth sores
- Pain
- Presence in inflammation or irritations in other mucosal areas (vagina, rectum, esophagus)

### Nursing Diagnoses

- **Acute pain** related to swollen, cracked, ulcerated oral mucosa
- **Risk for infection** related to impaired nutritional status and impaired integrity of oral mucosa
- **Imbalanced nutrition, less than body requirements** secondary to decreased oral intake related to dysphagia or odynophagia
- **Impaired oral mucous membranes** related to effects of chemotherapy/radiation therapy or deficiencies in providing routine oral care
- **Knowledge deficit** related to postprocedural understanding or inability to follow treatment plan
- **Impaired swallowing** related to abscess/infection and immunosuppressive therapies

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Temperature may be elevated if there is infection associated with the stomatitis. Fluid volume deficit may lead to increased pulse rate and decreased blood pressure.*
- Oral mucosa  
*Bleeding or ulcerated oral mucosa occurs from a number of causes, including nutritional deficiencies, exposure to radiation, chemotherapy, irritants, allergic responses, and pathogenic organisms. Assessing the cause and the severity of the oral mucosa impairment determines the treatment plan.*
- Nutritional intake  
*Patients with painful oral lesions avoid eating and drinking and experience dysphagia and weight loss.*
- Weight  
*Due to pain in the mouth and difficulty swallowing, the patient may have insufficient caloric intake to maintain an ideal weight.*

- Intake and Output  
*Fluid intake may be compromised due to oral ulcerations as well as difficulty swallowing.*

#### ■ Actions

- Implement aspiration precautions.  
*Viscous lidocaine can decrease the gag reflex for a short period of time. Suction equipment should be in place, and the head of the bed (HOB) should be elevated at least 45 degrees.*
- Administer prescribed medications.  
*Antimicrobials (antibiotics, antifungals, topical and immune modulators) are used to treat stomatitis-related infections.*
  - **Antimicrobials:** tetracycline syrup and minocycline swish and swallow  
*Topical and oral antimicrobial medications provide systemic and topical therapy for relief of infection-related symptoms.*
  - **Antiviral medications:** acyclovir (Zovirax) IV and acyclovir PO/topical  
*For herpes simplex stomatitis, IV acyclovir (Zovirax) is given to patients who have impaired immune function. Patients with intact immune function may receive acyclovir in topical or oral form.*
  - **Antifungal medications:** nystatin ice pop or troche (lozenge)  
*Nystatin (Mycostatin) swish-and-swallow suspension provides both local and topical applications.*
  - **Viscous lidocaine,** Campho-Phenique mouthwash, triamcinolone in benzocaine (Kenalog in Orabase) topically, and with dexamethasone elixir: swish and expectorate.  
*For relief of local discomfort, viscous lidocaine, topical triamcinolone in benzocaine (Kenalog in Orabase), and dexamethasone elixir are used to swish and expectorate and are often used for RAUs. Other medications used for the treatment of RAUs include antibiotics, multivitamins, low-level laser therapy (LLLT), and a variety of combined therapies.*
- Administer water-soluble lubricants for the lips and mouth.  
*Lanolin-based creams and ointments are most effective for moisturizing and softening dry, chapped lips.*
- **Teaching**
  - Mouth care after each meal and as needed, using a soft-bristled toothbrush  
*Frequent gentle mouth care cleanses the mouth of pathogens and prevents further infection. Frequent mouth rinsing with warm saline or sodium bicarbonate (baking soda) solution promotes comfort and gentle cleansing and rinses pathogens from the oral cavity.*
  - Discourage the use of alcohol-containing mouthwash and lemon-glycerin swabs.  
*Mouthwashes containing alcohol can further dry and irritate the oral mucosa, and lemon-glycerin swabs can irritate sore, inflamed oral tissue.*

- Dentures and other oral appliances should be removed if patient experiences severe stomatitis or oral pain.

*Dental appliances can cause irritation and ulcerations of oral tissues and increase the risk of infection. Dentures should not be worn if oral injury exists. Daily cleaning with a commercial denture cleaner, brushing, and rinsing after each meal to prevent colonization of pathogenic organisms and infection.*

- Encourage regular dental checkups

*Dental examinations provide thorough cleaning and expert assessment of the oral cavity to screen for complications and pathology.*

- Encourage saline mouth rinses every 4 hours and as needed.

*A dry mouth puts patients at risk for oral complications.*

- Dietary choices influence pain and healing.

*Foods and fluids that are high in protein or vitamin C promote healing. Foods that cause irritation are those that are spicy, salty, hot, hard, and acidic and have sharp edges.*

### Evaluating Care Outcomes

Stomatitis is a preventable disease process except when related to radiation and chemotherapy. In the latter instance, symptoms may be unavoidable but lessened with prompt recognition of clinical manifestations and early therapeutic interventions. Oral hygiene, including cleaning of dental appliances and feeding utensils, and the maintenance of an adequate nutritional status are paramount in the prevention or management of stomatitis. With appropriate treatment, the patient should have stable vital signs, fluid volume status, and weight.

### Hiatal Hernia

The esophagus carries food from the oropharynx to the stomach, and its function is essential in maintaining adequate nutrition and nourishment to the body. The esophagus is a hollow muscular tube that carries food from the oral cavity to the stomach. The esophagus has three types of layers, the mucosa, the submucosa, and the muscularis propria, each with different functions and tissue types. The esophageal mucosa has an inner and an outer layer. The outer layer is the epithelial layer, and it is made of squamous cells. The inner layer, the lamina propria, is the mucosal layer under the epithelium, and it is made of connective tissue. The next layer is called the *submucosa*, and it is found in some parts of the esophagus. The submucosa contains glands that secrete mucus. The innermost layer, located under the submucosa, is a thick muscular band called the *muscularis propria*. This muscular layer rhythmically contracts as it pushes food through the esophagus to the stomach.

The upper esophageal sphincter is located at the upper portion of the esophagus. This muscle relaxes to allow food and fluids to pass into the esophagus. The lower portion of the esophagus that connects to the stomach is called the **gastroesophageal junction (GEJ)**. Below the

GEJ is a muscular area called the **lower esophageal sphincter (LES)**. The purpose of this sphincter is to allow food from the esophagus to enter the stomach and to prevent contents from the stomach from entering the esophagus.

The diaphragm normally has an opening (esophageal hiatus) that allows the distal end of the lower esophagus to pass through it. The thoracic cavity is above the diaphragm, and the abdominal cavity is below the diaphragm. The lower esophageal sphincter (LES) is located at the gastroesophageal junction (GEJ) near the lower end of the esophagus. The pressure in the LES is considerably higher than the pressure in the thoracic cavity. The ability of the LES to maintain higher pressures is due in part to its anatomical placement in the abdomen and the acute angle formed as the esophagus enters the stomach (angle of His).

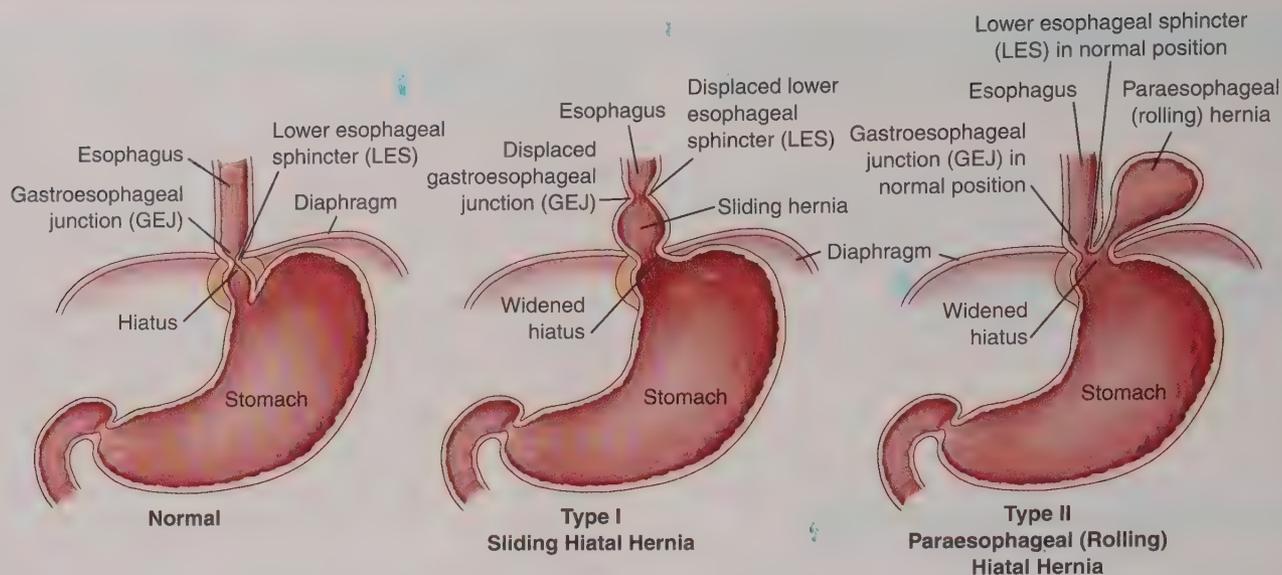

### Epidemiology

The incidence of hiatal hernia increases with age as supportive structures weaken over time. Approximately 60% of those affected are 50 or older, and of those affected, 9% are symptomatic. There are two main types of hiatal hernia; 95% are the “sliding” type, and 5% are the “rolling” type. Ninety-six percent of patients who have Barrett’s esophagitis (complication of GERD) have a hiatal hernia that is 2 cm or more in size.

The prevalence of hiatal hernia is more common in Western countries as opposed to rural African countries because of the lack of dietary fiber and the “unnatural” sitting position (causes straining) used for defecation. These factors can cause increased intra-abdominal pressures that push the stomach through the esophageal hiatus. Other risk factors include obesity, pregnancy, and smoking.

### Pathophysiology and Clinical Manifestations

A hiatal hernia occurs when a portion of the stomach protrudes upward through the esophageal hiatus (opening in the diaphragm that the esophagus passes through) and into the thoracic cavity. The two major types are type 1 and type 2 hernias (Fig. 56.3). A type 1 hiatal hernia (sliding type) is usually acquired through an ongoing process of disruption to the GEJ. The consequences of years of wear and tear typically occur after age 50 from the repetitive stresses of deep inspiration, Valsalva maneuvers, positional changes, acid reflux, and vomiting compounded by pregnancy and obesity, eventually compromising the integrity of the hiatus. As the competence of the GEJ becomes impaired, reflux occurs, and the ability of the esophagus to clear the acid becomes compromised. **Strictures** (esophageal narrowing) and lower esophageal mucosal rings (Schatzki’s rings) may develop secondary to this esophageal mucosal damage from GERD and lead to dysphagia. Another manifestation of a type 1 hiatal hernia is the development of Cameron lesions. These lesions are described as single or multiple gastric erosions and/or ulcerations typically visualized at the level of the diaphragmatic hiatus on upper endoscopic examination.

**FIGURE 56.3** Type 1 and type 2 hiatal hernias. Type 1 (sliding) hernias involve a widening of the hiatal tunnel that allows part of the cardiac portion of the stomach to herniate upward, which allows stomach acids and enzymes to come into contact with esophageal tissue. Type II (rolling) hernias involve the fundus and sometimes part of the greater curvature of the stomach rolling through the esophageal hiatus.

Cameron lesions are usually found incidentally and represent a source of obscure gastrointestinal bleeding in patients with type 1 hiatal hernias. Mechanical trauma at the level of the diaphragmatic hiatus in combination with mucosal injury from gastric acid and/or NSAID use may cause Cameron lesions. With type 1 hernias, there is a widening of the hiatal tunnel that allows part of the cardiac portion of the stomach to herniate upward, which allows stomach acids and enzymes to come into contact with esophageal tissue, putting the patient at risk for the development of a premalignant condition known as **Barrett's esophagus**. The hernia slides in and out through the esophageal hiatus into the chest as a result of a weakened diaphragm. Most of these hernias are asymptomatic, and the size of the hernia influences the likelihood of developing reflux disease. A type 1 hiatal hernia is mainly an acquired condition and can be caused by trauma, hereditary weakness in the surrounding muscles, or a congenitally large hiatus. Clinical manifestations typically include:

- Heartburn
- Regurgitation
- Chest pain
- Dysphagia
- Belching

Type 2 (rolling type), or paraesophageal, hernias are thought to occur because of an anatomical defect that causes improper anchoring of the stomach below the diaphragm. The GEJ remains in its normal anatomical position, but the fundus and sometimes part of the greater curvature of the stomach roll through the esophageal hiatus. Variable degrees of herniation can occur, with some type 2 hernias being quite small. In rare cases, the whole stomach can

herniate above the diaphragm and into the chest. Reflux is not usually present because the LES remains secured below the diaphragm. Clinical manifestations of type 2 hernias usually include:

- Feeling full after eating
- Feeling breathless after eating
- Feeling of suffocation
- Chest pain that feels like angina
- Increased symptoms when lying flat

### Connection Check 56.2

The nurse correlates which clinical manifestation with a type 1 hiatal hernia?

- Heartburn
- GERD
- Chest pain
- Anorexia

### Management

#### Medical Management

The following commonly performed tests are used to determine the cause of upper abdominal pain and to diagnose hiatal hernia:

- Upper abdominal x-ray
- Endoscopy
- Barium swallow with fluoroscopy (most specific diagnostic test)
- Esophagogastroduodenoscopy, or EGD (views the esophagus and stomach lining)

Medications are used for the symptoms of heartburn and acid reflux. Most people who have a hiatal hernia do not experience these symptoms, but if they do, they may require medication management or surgery.

- Antacids are used to neutralize stomach acid and are usually obtained over the counter. Common antacids are Mylanta, Maalox, Gelusil, Roloids, and Tums. Common side effects include diarrhea and constipation.
- Proton pump inhibitors and H<sub>2</sub>-receptor antagonists are prescribed to treat GERD (Table 56.2).

Some complementary medicine practitioners report that a hiatal hernia can be reduced or corrected by using massage to push the stomach back into its normal position below the diaphragm. Currently, there is no evidence or clinical trials to prove the efficacy of these claims, and further research is needed to investigate the efficacy of this practice.

### Surgical Management

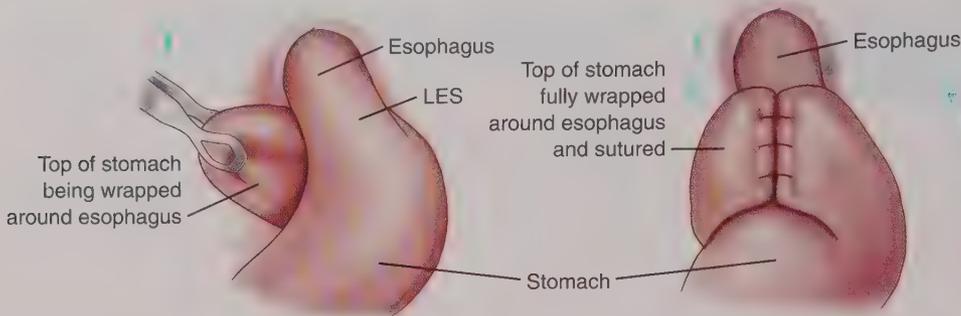

Surgery for hiatal hernia is the treatment of choice when the benefits outweigh the risks for the patient. Hiatal hernias tend to progressively become larger over time. Usually, asymptomatic type 1 hiatal hernias are treated medically, but larger symptomatic type 1 hernias may be treated surgically. If left untreated, type 2 hernias have the potential to enlarge to the stage of becoming a giant intrathoracic stomach, in which at least one-third of the

stomach is herniated into the chest cavity. At this stage, clinical manifestations of substernal pain, pressure, and gastric ulcers may develop as a result of displacement of the stomach into the thoracic cavity. Patients may present acutely with strangulation of the stomach from acute gastric volvulus. Gastric volvulus is a surgical emergency. The pathology of gastric volvulus is demonstrated as an abnormal rotation of all or part of the stomach around one of its axes. The most common cause of gastric volvulus is paraesophageal hiatal hernia. Clinical manifestations may include abdominal or chest pain, early satiety, dysphagia, GI bleed, gastric outlet obstruction, and retching without vomiting. It may be difficult or impossible to place a nasogastric tube. The significance of this pathologic change is that hemorrhage, ischemia, necrosis, and perforation may occur. Prompt surgical intervention is necessary to prevent irreversible damage and mortality. Surgery is the treatment of choice for type 2 (paraesophageal) hernias even in the absence of symptoms because of the potential risk of incarceration and strangulation if left untreated. There is a higher recurrence rate for type 2 hernias than for type 1 hernias because the tissues of the hiatus encounter more impairment with type 2 hernias.

Nissen fundoplication and laparoscopic antireflux surgeries are frequently used to treat type 2 hernias. The open Nissen fundoplication is a surgical procedure whereby the surgeon wraps part of the stomach around the distal esophagus to stabilize it and to reinforce the LES (Fig. 56.4).

**Table 56.2 Comparison of H<sub>2</sub>-Receptor Antigen Antagonists and Proton Pump Inhibitors**

H <sub>2</sub> -Receptor Antigen Antagonists (H <sub>2</sub> RAs)	Proton Pump Inhibitors (PPIs)
H <sub>2</sub> -receptor blockers reduce acid production longer than antacids but are slower to take effect.	PPIs block production of acid and allow the esophagus to heal.
H <sub>2</sub> RAs decrease acid production of parietal cells in the stomach lining by blocking histamine-2 at one of the first steps of acid production.	PPIs block the last step in gastric acid secretion and stop the acid pumps in the stomach. PPIs are more effective in suppressing gastric acid secretion than H <sub>2</sub> RAs.
Used to treat <i>Helicobacter pylori</i> in combination with antibiotic therapy; also used to treat gastroesophageal reflux symptoms	Used to treat gastroesophageal reflux symptoms
Common H <sub>2</sub> -blockers include cimetidine (Tagamet HB), famotidine (Pepcid AC), nizatidine (Axid AR), or ranitidine (Zantac 75). Stronger prescription-strength H <sub>2</sub> -blockers are available.	Over-the-counter (OTC) PPIs include lansoprazole (Prevacid 24HR) and omeprazole (Prilosec OTC). Prescription-strength PPIs are available.
Patients may develop a tolerance.	Tolerance is unlikely.
Cimetidine can interact with warfarin, phenytoin, and theophylline with long-term use.	PPIs can interfere with the absorption of ketoconazole, ampicillin, iron, and digoxin.
H <sub>2</sub> RAs have an onset of action of 1 hour and a duration of about 12 hours.	PPIs have a delayed onset of action and a duration of action lasting up to 24 hours.
H <sub>2</sub> RAs are frequently used as a step-down treatment for patients with uncomplicated GERD symptoms after PPI-induced symptom relief. H <sub>2</sub> RAs have few side effects and are well tolerated.	Long term use is linked to a reduction of micronutrient absorption, gastrointestinal and pulmonary infections, osteoporosis and bone fractures, heart and kidney disease, and dementia.

**FIGURE 56.4** Nissen fundoplication. Laparoscopic Nissen fundoplication is the gold standard for the treatment of a hiatal hernia and is performed through several small incisions in the abdomen.

**Gastropexy** (attachment of the stomach below the diaphragm to prevent reherniation) is used after reduction if the stomach is unusually movable after reduction is performed. Other surgical procedures for type 2 hernias include:

- **Herniotomy** (surgical removal of the herniated sac)
- **Herniorrhaphy** (repair of the hiatal defect)
- Antireflux procedure
- Reduction (attachment of the stomach below the diaphragm to prevent reherniation)

Laparoscopic Nissen fundoplication (LNF) is the gold standard and is performed most often for hiatal hernia repair. The surgeon performs the surgery through several small incisions in the abdomen. Advantages vary with these types of surgeries. Patients with advancing age and significant comorbidities are often better candidates for the minimally invasive laparoscopic surgery rather than open surgery. There are fewer complications and shorter hospital stays with minimally invasive laparoscopic surgery. The disadvantage of laparoscopic repair is that the recurrence rates are higher than with open surgical procedures. Postoperative complications include infection, bleeding, atelectasis, pneumonia, obstructed nasogastric tube, gas bloat syndrome, and temporary dysphagia.

### Complications

The most common complication of type 1 (sliding) hernias is gastroesophageal reflux, or GERD. Reflux occurs when there is chronic exposure of the LES to the low pressure of the thorax. Reflux symptoms increase with coughing, obesity, ascites, and positional changes such as bending and lying supine.

Supradiaphragmatic volvulus (abnormal 180-degree twisting of the stomach above the diaphragm) and obstruction are rare complications of a type 2 (rolling) hiatal hernia. Iron-deficiency anemia is a later symptom seen in some adults with type 2 hernias that present as slow bleeding from gastric mucosal folds caused by gastric ulcers and erosions.

### Nursing Management

#### Assessment and Analysis

A hiatal hernia is often asymptomatic and is usually found incidentally when a patient is being evaluated for another problem. Large hiatal hernias can cause gastroesophageal

reflux with clinical manifestations of heartburn and non-cardiac chest pain. Typically, the clinical manifestations of hiatal hernia are worse after meals because of the displacement of stomach contents into the thoracic cavity. Lifestyle changes such as weight reduction, sleeping with the HOB elevated, avoiding the use of tobacco or alcohol, and stress control can help reduce clinical manifestations. Medications are prescribed to relieve GERD symptoms, but surgical intervention may be necessary. Clinical manifestations of hiatal hernia include:

- Heartburn
- Regurgitation
- Dysphagia
- Eructation (belching)
- Breathlessness
- Feeling of suffocation
- Chest pain
- GERD
- Iron-deficiency anemia (related to volvulus)

**Safety Alert** Gastrointestinal and cardiac symptoms are similar, and it is important to assess the patient, notify the healthcare provider, and perform an electrocardiogram if the patient complains of chest pain or shortness of breath.

### Nursing Diagnoses

- **Impaired swallowing** related to esophageal narrowing
- **Anxiety** related to impaired breathing
- **Pain** related to damage secondary to exposure of esophageal tissue to gastric acid
- **Knowledge deficit** related to the therapeutic regimen

### Nursing Interventions

#### Assessments

- Breathlessness, feelings of suffocation, chest pain, palpitations  
*Respiratory symptoms and asthma-like symptoms are a result of aspirating stomach contents and occur mostly while sleeping. After eating a large meal, patients may experience a feeling of breathlessness or chest pain if the hernia interferes*

with lung expansion. Palpitations develop secondary to irritation of the vagal nerve.

- **Dysphagia**  
Strictures and lower esophageal mucosal rings are common causes of dysphagia, related to esophageal mucosal damage from GERD. Schatzki's rings are narrow areas, less than 1.3 cm, and can also occur congenitally. These rings are located at or near the GEJ where normal mucosal epithelium transitions from columnar cells to squamous cells. Incarcerated or strangulated paraesophageal or mixed paraesophageal hernias are causes of dysphagia.
- **Clinical manifestations of GERD, heartburn**  
A hiatal hernia can cause the LES to weaken. This causes reflux of gastric contents into the esophagus, resulting in irritation, inflammation, and pain.
- **Nausea and vomiting**  
Persistent nausea and vomiting in patients with a hiatal hernia who are unresponsive to antiemetic medications may indicate gastric volvulus. This strangulation can lead to GI tract or esophageal obstruction.
- **Eructation**  
Air escapes from the stomach and into the esophagus, and occasionally, reflux material is brought up into the mouth.
- **Iron-deficiency anemia**  
Herniated gastric pouches and folds from paraesophageal hernias (with erosions and ulcerations) are a cause of chronic blood loss that may lead to anemia.

## ■ Actions

- **Medication management:**
  - Antacids  
*Neutralize or buffer stomach acid*
  - Histamine receptor agonists  
*Acid production is decreased (see Table 56.2).*
  - Proton pump inhibitors  
*Acid production is blocked (see Table 56.2).*
  - Prokinetic medications  
*Gastric emptying is increased with prokinetic medications such as Reglan. Long-term use is not recommended because of the possibility of psychotropic or neurological side effects such as tardive dyskinesia.*
- **Position the patient supine on the right side, and elevate the HOB at least 30 degrees after meals.**  
*Lying on the right side promotes gastric emptying, and the elevated HOB position promotes peristalsis and uses gravity to return gastric refluxate from the esophagus to the stomach.*

## ■ Teaching

- Educate the patient to limit the following foods and substances: spicy/fatty foods, caffeine, chocolate, carbonated beverages, acidic foods, peppermint, alcohol, caffeinated beverages, and certain medications (if possible), such as calcium channel blockers, anticholinergic medications, and smooth muscle relaxers. *These foods, substances, and medications are associated with decreasing LES pressure, which allows gastric reflux from the stomach into the esophagus.*

- Encourage the patient to eat meals 2 hours before lying supine.  
*Eating large meals causes delayed gastric emptying and leads to gastric reflux.*
- Educate the patient to wear nonrestrictive clothing.  
*Tight clothing causes an increase in intra-abdominal pressure, which weakens the LES and contributes to GERD.*
- Educate the patient and family about maintaining a normal weight.  
*Obesity increases intra-abdominal pressure, increasing the hiatal hernia and GERD.*
- Educate the patient on proper positioning after eating.  
*Compliance increases with sound understanding of instructions as well as the rationale.*
- Conduct postoperative education for patients after laparoscopic Nissen fundoplication (LNF) (see Box 56.1).  
*Large paraesophageal hernias are surgically repaired to prevent obstruction or strangulation. Postoperative care after LNF begins preoperatively. Complications are less frequent with LNF procedures than with an open surgical approach.*

## Evaluating Care Outcomes

Lifestyle changes and medication management often effectively relieve the clinical manifestations of hiatal hernia. Surgical intervention is recommended for large or symptomatic hernias. Patients need to receive education aimed at reinforcing dietary and lifestyle choices and reduction of risk factors that exacerbate the symptoms of hiatal hernia. Nursing education postoperatively focuses on pain management, airway management, respiratory management, and nutritional support.

## Gastroesophageal Reflux Disease

**Gastroesophageal reflux disease (GERD)** is a chronic disorder that describes a variety of clinical manifestations, with or without tissue damage, caused by acid reflux from the stomach (or duodenum) into the esophagus. Reflux occurs when the LES is weak or relaxes inappropriately, causing the pressure gradient between the LES and the stomach to be lost. Gastroesophageal reflux disease usually occurs in association with hiatal hernia, but herniation of the gastric mucosa does not occur with GERD. Gastroesophageal reflux disease can be caused by a temporary or sustained decrease in LES competence. Certain foods and substances can also affect LES tone. Gastroesophageal reflux disease is one of the most common diseases of Western civilization, with many factors contributing to the development of GERD. Lifestyle choices are the primary determinants related to acquiring GERD, and a variety of treatments and surgeries are available for the management of GERD.

All people at some point will experience “physiological” gastroesophageal reflux. Esophageal motility and gravity facilitate esophageal clearance, and adequate emptying of gastric contents acts as a physiological means to prevent gastroesophageal reflux. Saliva is rich in bicarbonate, and it

## Box 56.1 Postoperative Patient Education After Laparoscopic Nissen Fundoplication

- Follow a soft diet for about 1 week until swallowing improves. Avoid foods that are not easy to swallow. Take small bites and eat slowly.
- Avoid activities that cause air to be swallowed. Examples are drinking carbonated beverages, lemonade, and punch; sucking on sweets; chewing gum; and using a straw.
- Notify the healthcare provider for chest pain or difficulty breathing that gets worse with time.
- Continue antireflux medication regimen unless notified otherwise by a healthcare provider.
- Driving is allowed after 1 week and after narcotic pain medications have been discontinued.
- Walking is encouraged.
- No heavy lifting.
- After surgery, the doctor usually changes the original surgical dressing after 2 days. Steri-Strips are left intact and usually fall off in about 10 days. Keep them clean and dry and do not peel them off.
- Wash incisions with soap and water and pat them dry with a clean towel.
- Observe incisions for redness or drainage, and report any of these symptoms to the healthcare provider.
- Notify the healthcare provider for a fever greater than 101°F, or 38.3°C. Patients older than 65 years: report temperature above 100°F, or 37°C. Report nausea, vomiting, and severe bloating or unusual pain.
- Bring a list of questions to the first postoperative appointment, usually within 4 weeks after surgery.

### Seek medical care emergently for:

- Feeling very full, with inability to vomit or burp
- Thick drainage that has a foul odor coming from incisions
- Difficulty swallowing
- Abdomen that feels hard and painful
- Gauze that becomes soaked with blood
- Stools that are black, bloody, or tarry
- Vomiting up blood or “coffee grounds” emesis
- Difficulty breathing and feeling light-headed
- Coughing up blood, new chest pain when breathing in
- An arm or leg that is painful, swollen, warm, and red

coats the esophageal epithelium. Production of mucus, prostaglandins, and epithelial growth factors helps to protect the esophageal mucosa. Anatomically, the structures that form the high-pressure zone at the lower esophagus include the intra-abdominal esophagus, the phrenoesophageal ligaments, the gastric mucosal “rosette,” and the esophageal hiatus. This high-pressure zone forms a physiological sphincter called the LES. Pressures are higher at the gastroesophageal junction (GEJ), and gastric luminal pressures are lower. This prevents the reflux of gastric contents from the stomach. The angle of His (cardioesophageal junction)

and physiological factors work together to control the amount and frequency of gastric reflux into the esophagus.

### Epidemiology

Gastroesophageal reflux disease results from the backward flow of gastroduodenal contents (refluxate) into the esophagus and/or adjacent organs, producing a variety of clinical manifestations that may or may not cause tissue damage. Chronic in nature, GERD is a highly prevalent disorder in Western countries, with about 10% to 20% affected, whereas the prevalence in Asian countries is 5%. Sanitation practices and chlorination of the water supply have influenced the low prevalence of *Helicobacter pylori* (HP) in Western countries. The lower prevalence of GERD in undeveloped countries is thought to be related to lifestyle, dietary habits, and the presence of HP, a gram-negative bacterium commonly associated with gastric ulcers and stomach cancer. *Helicobacter pylori* has been found to decrease gastric acid secretion, but because it is a class 1 carcinogen, steps have been taken to eradicate this organism.

There are many factors that are associated with a decrease in LES pressures that influence transient or chronic gastroesophageal reflux; common examples include:

- Hiatal hernia
- LES hypotension
- Loss of esophageal motility
- Increased compliance of the hiatal canal
- Increased states of gastric secretion
- Eating large meals
- Delayed emptying of gastric contents
- Obesity
- Pregnancy
- Ascites
- Tight belts or girdles
- Presence of a nasogastric tube

### Pathophysiology and Clinical Manifestations

Gastroesophageal reflux disease results when there is a retrograde flow of GI contents into the esophagus, resulting in inflammation. Gastroesophageal reflux disease is the result of many different factors; some of these factors are the result of esophageal motility dysfunction, anatomical or diaphragmatic defects, or increased intra-abdominal pressure. The most common cause of GERD is from the relaxation of the LES, allowing gastric reflux into the esophagus.

Refluxed material in the esophagus normally returns to the stomach with the help of gravity, peristalsis, and saliva. When the esophagus is inflamed or injured, the ability of the esophagus to clear refluxed material becomes slower, resulting in an extended period of exposure of the esophagus to refluxed material from the stomach. Each episode of acid reflux results in hyperemia (increased blood flow), erosion (ulceration), and possible minor bleeding to the esophagus. During reflux, other gastric substances such as pepsin and bile may be present. These substances, like acid, are caustic to the esophageal epithelium.

## Management

### Medical Management

#### Diagnostic Tests

Twenty-four-hour ambulatory esophageal pH monitoring involves continuous measurement of gastric pH by monitoring and recording the pH of the stomach through a catheter that is placed in the nose and terminates at the distal esophagus. The patient keeps a diary of symptoms and activities. pH monitoring is a useful diagnostic tool used in patients with atypical symptoms.

The esophagogastroduodenoscopy (EGD) test evaluates esophagitis and monitors Barrett's esophagitis. During this test, biopsy samples can be taken and strictures can be dilated. Strictures occur as a result of fibrosis and scarring related to injury from acid exposure. Over time, strictures can lead to dysphagia.

Esophageal manometry or motility testing is the gold standard for the assessment and measurement of esophageal motor activity. During this test, catheters filled with water are inserted into the nose or mouth and withdrawn slowly while readings of LES pressure and peristalsis are taken. Esophageal manometry is used infrequently to diagnose GERD, and when used for this purpose, it is inconclusive except when used in conjunction with patient history, barium radiology, or endoscopy.

### Connection Check 56.3

In preparing a patient for esophageal manometry, which content does the nurse include in preprocedure teaching?

- This test measures the acid content in your stomach.
- This test measures the pressure and action of the esophagus.
- This test allows a sample of the esophagus to be obtained.
- This test is used only in patients with diagnosed hiatal hernia.

#### Medications

Medication management for the treatment of GERD focuses on any or all of the following:

- Inhibiting gastric acid secretion
- Increasing gastric emptying
- Protecting the lining of the stomach

Because gastroesophageal reflux disease is a chronic disease, it requires long-term management and maintenance in most cases. About 80% of patients who discontinue treatment relapse within 1 year. Side effects of some of these medications require additional attention. For example, the long-term use of proton pump inhibitors (PPIs) is associated with hip fractures, and metoclopramide (Reglan) is associated

with tardive dyskinesia. The categories of medications used to treat GERD include:

- Antacids (increase gastric pH)
- Histamine receptor antagonists (decrease gastric acid production; short acting)
- Prokinetic medications (increase gastric emptying)
- Proton pump inhibitors (decrease gastric acid production; long acting)

#### Endoscopic Treatments

The Stretta procedure involves the use of radiofrequency energy through an endoscope by using needles positioned near the GEJ. This procedure reduces pain by decreasing vagus nerve activity. The endoluminal gastroplication is an endoscopic procedure whereby the LES is tightened with sutures.

#### Surgical Management

A small number of patients with GERD will require surgery. Patients who have not responded favorably to medical treatment or who have developed complications are surgical candidates. When indicated, the gold standard for surgery is laparoscopic Nissen fundoplication.

#### Complications

When damaged esophageal tissue heals, the body sometimes substitutes columnar epithelium (Barrett's epithelium) for the normal squamous cell epithelium of the lower esophagus. Barrett's epithelium is more resistant to acid than squamous cell epithelium, but it has a high propensity for malignancy. After exposure to gastric acid, fibrosis and scarring may occur in response to the healing process. Strictures may develop and lead to progressive dysphagia.

#### Nursing Management

##### Assessment and Analysis

The clinical presentation of GERD is related to the effect of gastric reflux material on the esophagus. The effects of GERD range from mild irritation to cancer-causing cellular changes. Common clinical manifestations of GERD include:

- Heartburn (dyspepsia)
- Severe atypical chest pain
- Odynophagia (painful swallowing)
- Hemorrhage
- Dental caries
- Aspiration pneumonia
- Chronic cough
- Morning hoarseness
- Adult-onset asthma
- Laryngitis
- Pharyngitis
- Bronchitis
- Regurgitation

##### Nursing Diagnoses

- **Acute/chronic pain** related to physical injury as evidenced by esophageal irritation

- **Risk for aspiration** related to inadequate LES function
- **Impaired swallowing** related to stricture or inflammation
- **Imbalanced nutrition, less than body requirements** related to decreased intake secondary to dysphagia and pain

### Nursing Interventions

#### ■ Assessments

- Respiratory symptoms: aspiration pneumonia, chronic cough, morning hoarseness, night-time wheezing, adult-onset asthma, laryngitis, pharyngitis, bronchitis with long-term regurgitation

*Respiratory symptoms occur with aspiration of acid reflux into the tracheobronchial tree, larynx, pharynx, nose, and mouth (especially when supine). Gastroesophageal reflux disease is a causative factor in the development of adult-onset asthma.*

- Regurgitation  
*Occurs when acid reflux reaches the level of the pharynx, leaving a sour taste in the mouth. If the patient is supine, regurgitation can lead to aspiration.*
- Severe atypical chest pain  
*Caused by esophageal spasms or stimulation of esophageal pain receptors. Pain may be so severe that it lasts for 2 hours, and it can radiate to the neck. Pain increases when supine, bending, or performing a Valsalva. The etiology of chest pain needs to be determined to rule out cardiac causes.*
- Hemorrhage  
*Associated with erosion and necrosis of the esophagus from chronic acid reflux*
- CBC  
*Chronic erosion of the esophageal tissue may lead to bleeding that results in decreased hematocrit and hemoglobin.*
- Dyspepsia  
*Reflux of gastric contents into the esophagus occurs most often as a result of excessive relaxation of the LES, leading to inflammation and ulceration of the esophagus. Minor bleeding from capillaries may occur with erosion.*
- Dysphagia and odynophagia  
*The damage from the refluxate causes inflammation and ulcerations in the esophagus. When healing occurs, scarring occurs with the development of strictures or rings, causing esophageal stenosis and difficulty swallowing.*
- Signs of Barrett's esophagus  
*Metaplasia of columnar epithelium from squamous cells in the lower third of the esophagus results from chronic acid reflux into the esophagus. Columnar cells, like the cells found in the stomach, are resistant to the damaging effects of stomach acid; however, these cells, not normally seen in the esophagus, have a propensity for dysplasia, thus becoming adenocarcinomas.*
- Dental caries  
*Eruption of acid reflux into the oral cavity leads to the destruction of tooth enamel and decay.*
- Water brash  
*A production of excessive saliva in response to reflux, leading to the sense of fluid in the throat, is termed water brash.*

*There is no sour taste, and acid is not present. Patients who exhibit water brash may or may not have esophageal injury.*

- Eructation, flatulence, or bloating  
*Occurs when eating a large meal and with abdominal distention, causing increased intra-abdominal pressure. The LES pressure decreases and allows gastric refluxate to enter the esophagus.*
- Nausea  
*Nausea occurs as a result of stomach acid and bile that reflux into the esophagus from the stomach, usually after eating.*
- Globus (sensation that there is a lump in the throat)  
*Gastric refluxate into the larynx and pharynx resulting from GERD*
- pH of gastric aspirate  
*Acid refluxate from the stomach has a pH of 1.5 to 2.0, whereas the normal pH of the esophagus is 6.0 to 7.0.*

#### ■ Actions

- Medication management:
  - Antacids  
*Neutralize or buffer stomach acid*
  - Histamine receptor agonists  
*Acid production is decreased (see Table 56.2).*
  - Proton pump inhibitors  
*Acid production is blocked (see Table 56.2).*
  - Prokinetic medications  
*Gastric emptying is increased with prokinetic medications such as Reglan. Long-term use is not recommended because of the possibility of psychotropic or neurological side effects such as tardive dyskinesia.*
- Position the patient on the right side with the HOB elevated 6 to 12 inches.  
*Lying on the right side promotes gastric emptying, and elevating the HOB promotes peristalsis and uses gravity to return gastric refluxate from the esophagus to the stomach. Sleeping in this position also decreases reflux at night.*
- Provide 4–6 meals per day.  
*Eating three larger meals per day increases pressure in the stomach and delays gastric emptying. Eating four to six smaller meals decreases pressure.*

#### ■ Teaching

- Educate the patient to limit the following foods and substances: spicy/fatty foods, caffeine, chocolate, carbonated beverages, acidic foods, peppermint, alcohol, and certain medications (if possible), such as calcium channel blockers, anticholinergic medications, and smooth muscle relaxers.  
*These foods, substances, and medications are associated with decreasing LES pressure, which allows gastric reflux from the stomach into the esophagus.*
- Avoid smoking and alcohol.  
*Both smoking and alcohol may lead to a decrease in LES pressure, increasing the risk of reflux.*
- Avoid NSAIDs and aspirin.  
*Both NSAIDs and aspirin can irritate the lining of the esophagus.*

- Encourage the patient to eat meals 2 hours before lying supine.  
*Eating large meals causes delayed gastric emptying and leads to gastric reflux.*
- Educate the patient to wear nonrestrictive clothing  
*Tight clothing causes an increase in intra-abdominal pressure, which weakens the LES and contributes to GERD.*
- Educate the patient and family about maintaining ideal body weight.  
*Obesity increases intra-abdominal pressure, increasing the hiatal hernia and GERD.*

### Evaluating Care Outcomes

Positive healthcare outcomes in patients with GERD are primarily a result of lifestyle choices. Individuals with GERD are frequently asymptomatic, and the disease remains undetected. Many patients ignore minor symptoms and choose to self-medicate, seeking medical attention when symptoms become advanced. It is essential that patients seek medical attention if they develop clinical manifestations of GERD in order to obtain relief and to prevent complications. Patients with GERD require education about lifestyle changes involving diet modification and adherence to medication regimens in order to maintain an optimal quality of life and to avoid complications. Surgical candidates today usually undergo minimally invasive laparoscopic surgery or endoscopic procedures in order to treat GERD.

## ORAL CANCER

### Epidemiology

In the United States, 3% of all new cancers are oral cancers. In 2018, the estimated number of new cases in the United States was 51,540, and the estimated number of deaths was 10,030 (see Evidence-Based Practice: Rising Incidence of Oropharyngeal Cancer). Men are affected two to four times more than women are, and the risk of developing oral cancer increases with age. The average age of diagnosis is 62. African American and Caucasian individuals are about equally affected. Oral cancer accounts for 25% of all head and neck cancers. Patients who survive 5 to 10 years have a 20-times higher risk of developing a second cancer.

### Evidence-Based Practice

#### Rising Incidence of Oropharyngeal Cancer

- The incidence of oral cancer, including cancers of the tonsils and base of the tongue, continue to increase in North America and Western Europe, with up to 70% of new cases being related to HPV.
- The suspected cause of the rising incidence of oropharyngeal cancer is related to increasing numbers of sexual partners and oral sexual practices with exposure to human papillomavirus (HPV).

- Human papillomavirus 16 accounts for most of the oropharyngeal squamous cell carcinomas (OSCCs) in the United States and Europe.
- By the year 2020, it is expected that the incidence of HPV-related OSCC will surpass the incidence of HPV-related cervical cancer.
- Patients with HPV-positive oropharyngeal cancer are not necessarily heavy cigarette smokers and alcohol users.
- Patients who have OSCC and who are HPV positive have an overall survival rate of 95%, whereas an HPV-negative patient can expect a 62% survival rate at 2 years.
- Preliminary evidence shows that the HPV vaccine is effective in preventing cervical HPV infections, but data showing effectiveness in preventing oral HPV infections are lacking.

Gooi, Z., Chan, J. Y., & Fakhry, C. (2016). The epidemiology of the human papillomavirus related to oropharyngeal head and neck cancer. *The Laryngoscope*, 126(4), 894–900.

Malignancies of the lip are most commonly seen because of intense exposure to the sun, excessive alcohol consumption, and pipe or cigarette smoking (Fig. 56.5). Of the lip carcinomas, about 95% are squamous cell carcinomas (SCCAs). Of these, 85% occur on the lower lip, 5% occur on the upper lip, and 5% affect both lips. Basal cell carcinomas occur most often on the lower lip and are usually slow growing initially, with metastasis occurring in later stages. Outcomes regarding carcinoma of the upper lip are less favorable because 95% of these tumors are squamous cell carcinomas that tend to grow rapidly and metastasize. Basal cell carcinomas tend to grow slowly and become invasive over time. These lesions usually appear as ulcerations or lesions on the outer border of the lip. The average age for carcinoma of the lip is 60 to 65, the male–female ratio is 30:1, and Caucasians are more commonly affected than African Americans.

**FIGURE 56.5** Squamous cell cancer of the lip. Ninety-five percent of lesions on the lip are squamous cell carcinomas.

Cancer of the oral cavity is primarily SCCA and is staged in relation to the following locations of the mouth:

- Lip
- Anterior two-thirds of the tongue
- Buccal mucosa
- Floor of the mouth
- Hard palate
- Upper and lower gingiva

Risk factors for oral cancer include:

- Habitual tobacco use
- Habitual alcohol use
- Poor oral hygiene
- Mechanical irritation from dental appliances
- Use of mouthwash with high alcohol content
- Chewing betel nut
- Herpes simplex virus (HSV-1)
- Human papillomavirus (HPV-2, 11, and 16)
- Mutations (related to the *p53* gene, *EGFR* gene, or TGF- $\alpha$ )
- Abnormalities such as nonhealing ulcers, **leukoplakia** (white patches), or **erythroplakia** (red patches)

The majority of malignant tumors of the oral cavity are SCCAs because the oral cavity is lined with squamous epithelium. About 90% of SCCAs are related to nicotine and alcohol abuse, and almost 75% of these malignant tumors develop between the base of the ridge that forms the borders of the lower jaws containing the sockets of the teeth (alveolar ridge) and the border of the tongue (Fig. 56.6). This location is the drainage area of the oral cavity. The significance of this location, also known as the “gutter area” of the mouth, is that the oral mucosa in this area is more likely to come into contact with carcinogenic and irritating substances, and tumors in this area have a propensity for metastasis.

Basal cell carcinoma is the second-most-frequent oral cancer but is considerably less common than SCCA. It primarily occurs on the lips. Initially, basal cell cancer causes very few clinical manifestations, and it appears as a raised

**FIGURE 56.6** Cancer of the floor of the mouth. Malignant tumors develop between the base of the ridge that forms the borders of the lower jaws containing the sockets of the teeth and the border of the tongue.

scab that later looks like an ulcer with a raised, pearly border. Basal cell carcinomas do not metastasize but can aggressively invade the skin of the face. The Oral Cancer Foundation presents information about oral cancer, including video and audio clips and a pictorial gallery, as well as links that provide current information about oral cancer.

## Pathophysiology

Most malignancies of the oral cavity are SCCAs (Fig. 56.7) arising from squamous epithelium lining the oral cavity. Other types of oral cancers include verrucous carcinoma (Fig. 56.8), which is a low-grade SCCA that rarely metastasizes. Minor salivary glands are potential sites of adenocarcinoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, and polymorphous low-grade carcinoma.

## Premalignant Lesions

### Leukoplakia

Leukoplakia is the most prevalent premalignant lesion occurring on the lips and in the oral cavity, often found incidentally. These lesions occur from long-term irritation to oral mucous membranes, causing a thickening of the keratin layer of the dermis (Fig. 56.9).

**FIGURE 56.7** Squamous cell carcinoma of the tongue. Malignancies of the oral cavity are squamous cell cancers arising from squamous epithelium lining the oral cavity.

**FIGURE 56.8** Verrucous carcinoma. Verrucous carcinoma is a low-grade squamous cell cancer that rarely metastasizes.

**FIGURE 56.9** Leukoplakia. Leukoplakia manifests as slightly raised, sharply rounded white plaques.

Leukoplakia presents as nonremovable (by rubbing), slightly raised, sharply rounded white plaques. Irritants such as pressure from dental prostheses, cheek chewing, and tobacco and alcohol abuse are risk factors for the development of leukoplakia. These irritants also increase the risk for development of cancerous changes to existing plaques. Other abnormalities include infection of these plaques and development of cancerous changes. Leukoplakia can be present anywhere on the oral mucosa and occurs most often in adults over 40. Men are two times more likely than women to develop leukoplakia, primarily because of smoking. Upon visual examination, it is not possible to determine if these lesions are carcinoma in situ or invasive carcinoma because of similar morphological appearances. Owing to the potential for malignant degeneration, leukoplakia lesions require examination through biopsy and surgical removal. Leukoplakia lesions of the tongue or lips are most likely to develop into cancer and should always be examined and biopsied. Leukoplakia has the potential of malignant degeneration and the morphological likeness to carcinoma in situ and invasive carcinoma.

### Erythroplakia

Erythroplakia is less common than leukoplakia, and it can occur in combination with leukoplakia. Located on the mucosal surface of the floor of the mouth, tongue, palate, or mandibular mucosa, these macular lesions are red because of increased vascularity and are velvety in appearance. Erythroplakia is often asymptomatic but may cause complaints of a sore, burning sensation. Erythroplakia lesions are highly suspicious for malignancy and require biopsy. Disruption from the basement membrane to the surface of the epithelium occurs, with mild to moderate dysplasia resulting from the erythroplakia. Dysplasia that fills the entire epithelium is termed carcinoma in situ. Further dysplasia to the basement membrane becomes invasive carcinoma.

### Clinical Manifestations

The clinical presentation of cancer of the oral cavity usually affects the floor of the mouth or the tongue. Patients are

often asymptomatic in the early stages, but later clinical manifestations of oral cancer include:

- Oral bleeding
- Raised area on the lip or in the mouth
- Oral ulcer with poorly defined margins, mucosal lesion, or nodule
- White and/or red patches in the oral cavity
- Increasing pain that radiates to the ear and neck
- **Dysarthria** (difficulty speaking)
- Dysphagia
- Difficulty chewing
- Oral fetor (odor)
- Regional lymph node involvement
- Weight loss
- Poor-fitting dentures

### Management

The management of oral cancer depends on the size, location, and stage of the cancer and the patient's current and potential level of function related to the side effects of treatment. After an interprofessional work-up, patients review their treatment options and make decisions on the basis of individualized counseling and informed consent.

The prognosis among oral carcinomas is variable. Factors influencing the prognosis and treatment options include tumor site, extent of involvement, and histological differentiation of the lesions. In order to determine prognosis and an appropriate treatment regimen, the tumor, nodes, metastasis (TNM) classification is a tool used for consistent documentation purposes. HPV-positive patients have a much better prognosis than HPV-negative patients even when classified with stage 4 head and neck cancer. Even patients with multiple positive lymph nodes who are HPV positive have a favorable prognosis for cure. The *Cancer Staging Manual* (8th ed.) of the American Joint Committee on Cancer (AJCC) gives a more accurate prediction of survival for patients newly diagnosed with head and neck cancer using separate scales for patients based on HPV status.

### Diagnostic Tests

Laboratory tests include:

- Complete blood count (to monitor for anemia, infection and bleeding risk)
- Chemistry profile (to monitor fluid, electrolytes, renal and nutritional status)
- Liver function tests (to rule out metastasis to the liver)

Imaging studies include:

- Computed tomography (CT) scan to evaluate bone involvement
- Magnetic resonance imaging (MRI) to evaluate soft tissue involvement
- Chest x-ray to rule out metastasis

### Rationale for Tests

In order to determine correct diagnosis and staging, special tests and examinations are performed. These tests include:

- Examination of the oral cavity and oropharynx under anesthesia
- Direct laryngoscopy
- Tumor mapping
- Positron emission tomography (PET) to check for metastasis
- Panorex films (an x-ray that provides a full view of the upper and lower jaws, teeth, temporomandibular joints) of the mandible to rule out invasion of the mandible

### Medical Management

Oral cavity tumors and the treatment modalities for these tumors can potentially affect the integrity of the oral mucosa and the patient's ability to eat, speak, and breathe. Medical management includes:

- Airway management
- Removal of the source of irritation
- Radiotherapy
- Chemotherapy
- Chemoradiation
- Surgical removal (treatment of choice) using scalpel, laser, or cryoprobe
- Retinoids (vitamin A derivative)
- Beta-carotene (antioxidant that converts to vitamin A)

### Radiation Therapy

Radiation therapy (radiotherapy) can be the primary treatment for oral cancer or can be used after surgery to destroy areas of cancer that were not possible to remove surgically. Radiotherapy delivery is by external beam radiation or interstitial implantation (brachytherapy). *External beam radiation* reaches the tumor site by passing through the mucous membrane outside of the tumor. The regimen for radiotherapy is usually 5 days per week for 6 to 9 weeks. Monitoring of radiation doses allows for careful dose monitoring in order to limit the amount of radiation to the brain and spinal cord. *Interstitial implantation* (used for small non-infiltrating lesions) involves the placement of radioactive seeds close to the tumor bed. These seeds emit low levels of radiation and are permanently implanted. In early-stage lesions involving the floor of the mouth or anterior tongue, implanted radiation seeds can be curative. Interstitial implantation increases the dosage of radiation because of its close proximity to the tumor; in addition, after external beam radiation, interstitial implantation further boosts the radiation dose with less exposure of radiation to surrounding structures. Methods of radiation delivery include seeds, needles or wires, and radiation catheters or through a mold of radioactive material placed over a lesion for a prescribed amount of time. Patients receiving interstitial radiation, with the exception of seeds, require hospitalization during

treatment with radiation precautions in place. The reason that patients receiving radioactive seeds do not require hospitalization is that the seeds emit low levels of radiation and pose no risk to others, with the exception of pregnant women and small children who require specific precautions and are more sensitive to the effects of radiation.

### Medications

Oral cancer is treated with medications alone or in combination with surgery or radiotherapy. The benefit of medications alone or as an adjunct to surgery or radiation continues to be under investigation. Types of medications include chemotherapeutic agents and agents that target and block growth factors (GFs). Epidermal growth factor (EGF) is one of the GFs associated with oral cancers. Growth factors are hormone-like substances normally found in the cells of the human body. Oral cancer cells grow more quickly because they have more GF receptors than normal, healthy tissue. More than a dozen medications recently received U.S. Food and Drug Administration (FDA) approval, including cetuximab (Erbix) and erlotinib (Tarceva); these medications target and block EGF receptors.

Intensity-modulated radiation therapy (IMRT) is a three-dimensional conformal radiotherapy that involves a highly precise type of external beam radiation therapy that uses software/hardware to deliver radiation to a specific location while sparing surrounding structures unaffected by the cancer. The use of IMRT results in improved quality of life as seen by decreased rates of xerostomia (dry mouth).

Chemotherapy may be given prior to or in combination with radiation therapy. Deep, infiltrating lesions of the anterior tongue may be treated with surgery, radiotherapy, and chemotherapy or a combination of therapies (concomitant therapy). Surgery, radiation, and chemotherapy are standard treatments for infiltrating lesions of the upper gingiva and hard palate. Other types of oral cancers require radiation and/or surgical interventions.

Patients undergoing radiation therapy may experience the following side effects:

- Skin irritation to the treated area
- Fatigue
- Nausea
- Weight loss
- Stomatitis (mucositis)
- Xerostomia from damage to the salivary glands
- Loss of taste
- Erythema and moist desquamation of the skin
- Laryngeal edema
- Bone pain

With the use of IMRT, a type of external radiation therapy that delivers radiation doses more effectively and with less damage to healthy cells than external beam radiation, fewer side effects occur (see Evidence-Based Practice: Proton Therapy).

## Evidence-Based Practice

### Proton Therapy

Proton therapy is a newer form of external beam radiation that is specifically shaped to the dimensions of the tumor site. Proton therapy uses a precise beam of radiation to kill cancer cells. The beam is aimed at various levels, and it is specifically shaped to the dimensions of the tumor. The procedure is painless, is noninvasive, and produces very little side effects.

Frank, S. J., Blanchard, P., Lee, J. J., Sturgis, E. M., Kies, M. S., Machtay, M., ... Fuller, C. D. (2018, April). Comparing intensity-modulated proton therapy with intensity-modulated photon therapy for oropharyngeal cancer: The journey from clinical trial concept to activation. *Seminars in Radiation Oncology*, 28(2), 108–113.

Chemotherapy for oral cancer may be given as a neoadjuvant therapy (the first treatment before surgery and/or radiation therapy) or as an adjuvant therapy (the first treatment after surgery and/or radiation therapy). Chemoradiation treatments may be given during clinical trials for oral cancer. Common side effects of chemotherapy include:

- Xerostomia
- Taste disturbance
- Anorexia
- Nausea and vomiting
- Stomatitis
- Fatigue
- Hair loss
- Hearing loss
- Diarrhea and/or constipation
- Low red and white cell counts

### Connection Check 56.4

Which statement by the patient undergoing external beam radiation indicates the need for further teaching?

- A. "My grandchildren will not be able to visit because I will be radioactive."
- B. "This therapy will hopefully decrease the size of the tumor."
- C. "I will have daily radiation treatments for several weeks."
- D. "At least this procedure is not painful."

### Surgical Management

Surgical management of small, noninvasive lesions requires treatment under local or general anesthesia in an ambulatory clinic setting. Other options for the management of smaller lesions include carbon dioxide laser, cryotherapy (extreme application of cold), and photodynamic therapy. Factors that influence surgical intervention of oral cancers include tumor

size, location, invasion into bone, and lymph node metastasis. Large tumors require external surgical removal, and the most advanced tumors may require composite resections. Extensive oral surgeries include single or combinations of glossectomy (partial or total), partial mandibulectomy, or neck dissection (removal of lymph nodes in the neck and possible removal of muscle, veins, and nerves).

### Complications

Complications of oral cancer include infiltration to muscles and underlying tissue, resulting in difficulty eating or talking. Lymphatic spread varies with tumor site. Common sites for metastasis are the lungs, liver, and bone. Surgery and radiation therapy are the primary treatment modalities for oral cancer. After surgery for oral cancer, the following complications may occur:

- Infection
- Facial edema
- Weight loss
- Difficulty/inability talking
- Dysphagia

Rare but severe complications of radiotherapy include:

- Hearing loss
- Osteoradionecrosis (bone death from radiation)
- **Trismus** (difficulty opening the mouth)
- Carotid artery rupture

### Nursing Management

#### Assessment and Analysis

Oral cancer has an effect on many daily functions, including swallowing, chewing, and talking. Tumors may become invasive, rapidly growing into underlying muscles and interfering with the ability to speak, eat, and talk. The goals of pain management are to optimize quality of life and to increase the ability to perform the activities of daily living. Treatments for oral cancer, such as surgery and medication management, chemotherapy, and radiotherapy, also can have debilitating and sometimes disfiguring side effects as well. Common manifestations related to the presentation and management of oral cancer include:

- Dysphagia
- Oral bleeding
- Impaired nutritional status
- Weight loss
- Anorexia
- Dysarthria
- Oral or lip lesions that do not heal in 2 weeks
- Leukoplakia
- Oral fetor
- Poor-fitting dentures
- Xerostomia

#### Nursing Diagnoses

- **Risk for ineffective airway clearance** related to ineffective cough and swallow secondary to postoperative edema

- **Imbalanced nutrition, less than body requirements**, related to difficult or painful swallowing or inability to swallow
- **Impaired verbal communication** related to surgeries affecting quality of speech
- **Acute or chronic pain** related to surgery, malignancy, or treatment
- **Anxiety** related to impaired breathing, cancer diagnosis, or treatment course

## Nursing Interventions

### ■ Assessments

- Ability to swallow

*Impaired swallowing due to pain or edema interferes with adequate oral fluid and nutritional intake. This provides important data needed to determine the best diet according to the patient's ability to chew and swallow.*

- Fluid intake

*Fluid intake is also compromised based on mouth pain and dysphagia.*

- Nutritional intake

*Data collection related to overall caloric intake, as well as intake of carbohydrates, proteins, and fats, enables the nurse to make appropriate nutritional recommendations in collaboration with the nutritionist.*

- Weight

*Weight loss trends are an indicator of metastasis. Other causes of weight loss are related to edema from oral lesions causing difficulty swallowing and chewing.*

- Albumin and total protein levels

*Decreased nutritional status is indicated with decreased serum levels of albumin and total protein.*

- Clinical manifestations of oral mucosal irritation or infection, irritation from dental appliances, oral lesions, bleeding, difficulty swallowing or chewing, lesions, and nodules

*The purpose of an oral cavity assessment is to inspect the condition of the oral mucosa and identify the presence of infection, the level of hygiene practices, and the presence of lesions and to determine the potential for or presence of malignant processes.*

- Lymph nodes

*Enlarged cervical lymph nodes indicate metastasis.*

- Psychosocial adjustment

*Adjustments to the disease process, treatments, and side effects may require consultation with the palliative care team, social worker, or chaplain.*

### ■ Actions

- Airway management

*Airway management promotes adequate air exchange by removing secretions either by encouraging coughing and deep breathing or by suctioning. Ineffective airway clearance may result in some patients with an enlarged tumor or who have undergone surgical procedures to the oral cavity. Other associated oral cavity findings include edema, inflammation, and thick and tenacious secretions.*

- Aspiration precautions

*Aspiration precautions help identify those patients who are at risk and to identify specific preventive measures to prevent aspiration. Specific actions taken to prevent aspiration include assessment of the patient's ability to swallow; providing thickened liquids; performing respiratory assessment; pulmonary toilet; elevating the patient's HOB as high as possible, at least 30 degrees; and providing elixir forms of medications when possible.*

- Maintain emergency bedside equipment at all times. Maintain suction setup, oxygen setup, pulse oximetry (nearby), and an oral airway at the HOB for ineffective airway clearance.

- Provide oral care.

*Due to xerostomia, as well as soreness of the mouth, frequent oral care is needed to decrease chances of further irritation from food particles and to provide comfort.*

- Administer steroids as prescribed.

*Decrease oral edema and improve airway and breathing.*

- Provide cool mist via oxygen tent as needed.

*Cool mist provides humidification and lessens the complications of xerostomia.*

- Nutritional consult

*All patients with oral cancer should have a nutritional consult upon admission in order to ensure optimal caloric intake and to identify disease-specific nutritional risks and individual dietary preferences.*

### ■ Teaching

- Aspiration Precautions

*Encouraging the patient to eat small amounts of food and not to talk while eating decreases the risk of aspiration.*

- Avoid tobacco products and alcohol intake.

*Use of tobacco products and excessive alcohol intake increase the risk of oral cancer.*

- Provide nutritional education to the patient.

*As a result of chemotherapy, changes in taste may occur, such as a metallic taste, and aversions to certain foods may occur, especially meats. Encourage high-protein foods and the use of gravies, sauces, herbs, and seasonings to make foods more palatable.*

*Collaborate with the nutritionist to teach patients and families about patients' nutritional needs and how to assess whether patients are getting adequate nutrition. Liquid nutritional supplements are ordered for nutritionally depleted patients.*

- Oral hygiene and assessment education

*The patient/family needs to inspect the oral cavity daily to identify any redness, irritation, or signs of infection. Additionally, frequent mouth rinsing, particularly after eating, can ease discomfort and decrease food retained in the oral cavity.*

- Management of xerostomia

*Patients receiving chemoradiation are at increased risk for oral complications such as stomatitis, oral infections, and xerostomia. These patients must be diligent in performing their regimen of oral hygiene, including frequent mouth rinses to rinse away oral pathogens and to maintain adequate*

hydration. Radiation to the oral cavity affects the production of saliva from the salivary glands, as seen by a decrease in or absence of the secretion of saliva.

- Frequent sips of water or saliva substitutes  
These help to decrease the symptoms of xerostomia. Salivary dysfunction is temporary or permanent as a result of radiotherapy and permanent if the salivary glands are surgically removed.

### Evaluating Care Outcomes

Prevention is the key to reducing the number of patients diagnosed with oral cancer, and it is achieved through decreasing risk factors. The screening provided through regularly scheduled dental examinations provides a mechanism for prevention and early recognition of oral cancer and premalignant lesions so that patients can expect more favorable outcomes related to quality of life and prognosis. Most often, an oral cancer diagnosis occurs when the disease is at an advanced stage. This delayed diagnosis results in patient and family education focusing on treatment modalities such as surgery, radiation, and/or chemotherapy and the side effects or changes that occur as a result of these treatments.

### CASE STUDY: EPISODE 2

Mr. Rodriguez has received his biopsy results. He has squamous cell carcinoma on the right side of his tongue. The PET scan results are negative for distant metastasis, and Mr. Rodriguez is scheduled to go to the dentist for a full mouth extraction due to severe gingivitis and tooth decay. He will have a right hemiglossectomy with a right modified radical neck dissection soon after his tooth extraction, and he will receive IMRT about 4 weeks later...

## ORAL TRAUMA

### Epidemiology

Oral trauma includes injury to specific bones of the face, including nasal, mandibular, and maxillary fractures, as well as soft tissue injuries in and around the mouth. The severity of injuries ranges from minor soft tissue injuries to complicated fractures and is usually the result of blunt or penetrating injuries. The causes of oral trauma include automobile accidents, athletic activities (boxing, basketball, baseball, etc.), and physical altercations. As the population ages, there is an increased incidence of facial trauma in older adults (over 60 years of age), most often secondary to falls.

### Pathophysiology

The pathophysiology of oral trauma is directly related to the location and severity of the injury. Of primary concern is potential direct damage to the oral cavity that can lead to

partial or complete airway occlusion. Because of the rich blood supply to the face, the patient is at risk of significant blood loss, and with oral hemorrhage, this can further compromise the airway. Because of normal flora in the mouth, infection may develop after traumatic injuries to the oral cavity. Injuries to the maxilla may occur and are classified as Le Fort I (horizontal maxillary fracture of the alveolar process with the teeth contained with the detached fragment, passing through the alveolar ridge, lateral nose, and inferior wall of maxillary sinuses), Le Fort II (pyramidal fracture that passes through the posterior alveolar ridge, lateral wall of the maxillary sinuses, inferior orbit rim, and nasal bones), and Le Fort III (fracture that passes through the nasofrontal suture, maxilla-frontal suture, orbital wall, and zygomatic arch; Fig. 56.10).

### Clinical Manifestations

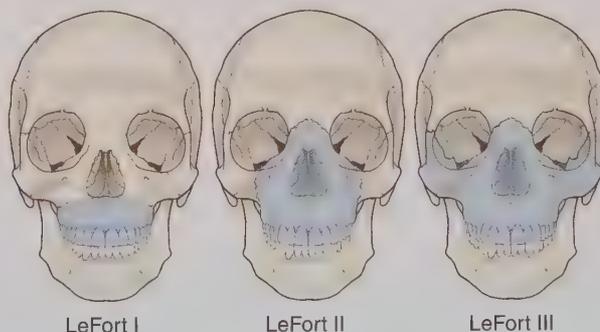

Clinical manifestations of oral trauma include:

- Increased respiratory rate
- Stridor (noisy breathing)
- Shortness of breath
- Decreased oxygen saturation
- Hypercarbia (elevated carbon dioxide levels)
- Elevated heart rate
- Changes in level of consciousness
- Oral bleeding
- Swelling and edema
- Loss of teeth
- Pain

### Management

#### Medical Management

Initial emergency management is directed at establishing and maintaining the airway and controlling bleeding. The patient may require an emergent tracheostomy on the basis

**FIGURE 56.10** Types of Le Fort fractures. Le Fort I fractures are horizontal maxillary fractures of the alveolar process with the teeth contained with the detached fragment, passing through the alveolar ridge, lateral nose, and inferior wall of maxillary sinuses. Le Fort II fractures are pyramidal fractures that pass through the posterior alveolar ridge, lateral wall of the maxillary sinuses, inferior orbit rim, and nasal bones. Le Fort III fractures pass through the nasofrontal suture, maxilla-frontal suture, orbital wall, and zygomatic arch.

of a clinical presentation that reveals that the patient cannot maintain an effective airway. Because most facial injuries are related to some type of trauma, the patient is typically evaluated in an emergency department, where IV access is established. Diagnostic studies include:

- Complete blood cell count
- Serum chemistry analysis
- Arterial blood gas analysis
- Facial x-rays
- Facial CT or MRI

Because of the increased risk for infection, broad-spectrum antibiotics are ordered. Consultations with neurosurgeons, oral surgeons, and dentists are often initiated to determine specific interventions.

### Surgical Management

Surgical stabilization of the facial fracture is typically indicated, and one of the following procedures may be performed:

- Open reduction internal fixation is indicated with extensive facial fractures and includes the placement of plates and screws that provide jaw stability.
- Fixed occlusion of the fracture involves the use of wires to immobilize the jaw in a fixed, mouth-closed position. This procedure is indicated when there is a need to replace and realign damaged teeth. The wires are usually maintained in place for 6 to 12 weeks to allow adequate healing of the bones (see Safety Alert).
- Microplating surgical procedures may be performed that use bone substitutes to foster repair of the facial fractures.
- Inner maxillary fixation is used to stabilize mandibular fractures. This procedure aligns the bites and also uses wires to keep the mouth closed for healing.

**Safety Alert** Patients with wired jaws are at risk for airway compromise, particularly with managing saliva and emesis. Because the patient is unable to open the mouth as a result of the wiring, wire cutters are required to be available with the patient at all times in the event the mouth needs to be opened to clear the airway or perform other lifesaving maneuvers.

### Complications

Based on the location and severity of the oral trauma, the patient is at risk for life-threatening complications, including airway compromise, aspiration of teeth, infection, and the inability to consume adequate nutrition. Even with successful surgical restoration, the patient may continue to have issues with pain, temporomandibular joint (TMJ) function, and disfigurement. With extensive facial trauma, the patient may develop a cerebrospinal leak, with an increased risk of meningitis.

## Connection Check 56.5

In caring for a patient who sustained a Le Fort fracture, the nurse monitors for which complications? (Select all that apply.)

- A. TMJ pain
- B. Esophageal strictures
- C. Airway obstruction
- D. Infection
- E. Dyspepsia

### Nursing Management

#### Assessment and Analysis

Facial trauma is a medical emergency that requires prompt assessment and definitive treatment. The priority assessments focus on ensuring an intact airway and effective breathing pattern. Clinical manifestations of oral trauma include alterations in respiratory rate and rhythm, bleeding and swelling in and around the mouth, difficulty managing oral secretions (potentially related to impaired swallowing), disfigurement, changes in level of consciousness, and visual disturbances.

#### Nursing Diagnoses

- **Risk for ineffective airway clearance** related to bleeding and swelling in and around the mouth
- **Risk for bleeding** related to increased vascularity of the face and mouth
- **Risk for infection** related to normal flora in the mouth, as well as risk of wound contamination with a facial fracture
- **Imbalanced nutrition**, less than body requirements, related to impaired ability to eat/drink secondary to facial trauma

#### Nursing Interventions

##### Assessments

- **Oral airway**  
*Because of the increased risk of soft tissue edema and bleeding, the patient remains at risk for airway compromise, including after surgical interventions. Increased swelling can lead to partial or complete airway obstruction.*
- **Respiratory rate and quality**  
*The patient may hypoventilate because of airway compromise, and this increases the risk of hypercapnia. Respiratory stridor is indicative of airway obstruction.*
- **Oxygen saturation**  
*Because of trauma in and around the mouth, as well as possible breathing impairment, the patient is at risk of decreased oxygenation.*
- **Arterial blood gas values**  
*The patient is at risk for hypoxemia and hypercarbia secondary to hypoventilation associated with facial trauma and edema*
- **Temperature**  
*Because of flora in the mouth and nose along with possible bone disruption, the patient is at increased risk of infection that is manifested by an increase in temperature.*

- Serial complete blood count (CBC)  
*Because of the increased vascularity of the face, the patient may have significant blood loss. Serial assessments of CBC may allow earlier confirmation of hemorrhage. The white blood cell count needs to be monitored due to risk of infection.*
- Serial serum electrolytes  
*Due to decreased nutritional and fluid intake, the patient is at risk for electrolyte disturbances.*
- Daily weights  
*Oral intake may be limited or totally prohibited during the emergent phase, leading to decreased nutritional intake.*

### ■ Actions

- Maintain wire cutters with the patient at all times if jaw is wired.  
*Wire cutters are required in the event the patient experiences respiratory compromise, requiring the mouth to be opened.*
- Provide oral humidification.  
*The patient is at risk for dry mouth and thickened secretions because of the decrease in normal humidification and the filtering actions of the nose and mouth. Even if the patient does not require supplementation oxygen, supplemental humidification may be required.*
- Elevate the head of the bed 30 to 45 degrees.  
*This position decreases the risk of aspiration, facilitates breathing, and promotes gas exchange.*
- Administer antibiotics as ordered.  
*The patient has an increased risk of infection because of oral trauma.*
- Provide diet as ordered.  
*The patient may be on tube feedings or soft oral diet. Even with jaw wiring, patients may be able to have oral intake via a syringe or straw. Adequate nutrition is essential to wound healing.*
- Provide frequent mouth care.  
*Rinsing the mouth after meals is important to decrease the risk of infection and promote wound healing.*

### ■ Teaching

- Have wire cutters with patient at all times.  
*The patient or a family member must be able to cut the wires in the event the patient experiences respiratory distress. If the wires have to be cut, the patient is also instructed to immediately notify the healthcare provider because the wires may need to be replaced.*
- Mouth care after each meal  
*To decrease risks of inflammation and infection*
- Signs and symptoms of infection  
*Because of the increased risk of infection related to oral trauma, it is important that the patient report a temperature elevation, increased oral swelling, pain, or a change in oral secretions.*

### Evaluating Care Outcomes

Patients experiencing oral or facial trauma require emergent stabilization and treatment, usually followed by weeks or months of follow-up care and monitoring. Once the oral

trauma has stabilized, the patient requires close surveillance for infection, impaired wound healing, decreased nutritional intake with associated weight loss, and issues related to change in appearance. Stable weight, lack of infection, and wound healing are indicative of successful outcomes.

## ESOPHAGEAL CANCER

Esophageal cancer develops in the mucosal layer of the esophagus and grows outward into the submucosal and muscular layers, and it occurs in any part of the esophagus. The types of cells that normally line the esophagus are squamous cells. There are two main types of esophageal cancers, SCCAs and adenocarcinomas. Less than 1% of esophageal cancers include small-cell neuroendocrine cancers, lymphomas, and sarcomas. Recent trends in North America and Western Europe show the incidence of esophageal adenocarcinoma taking the lead over SCCAs. This trend lends itself to the prevalence of GERD in developed countries. Patients are usually asymptomatic until the tumor has occluded 50% of the esophageal lumen and metastasis has occurred to the lung, liver, bone, stomach, cervical lymph nodes, or other sites. Overall 5-year survival rates range from 5% to 30%. Palliative care treatment options exist for patients diagnosed in the later stages of the disease.

### Epidemiology

Esophageal cancer accounts for 1% of all new cancer cases in the United States, and the estimated number of new cases in 2018 was 17,290, with 13,480 being males and 3,810 being females. Of these cases, the estimated number of deaths for 2018 was 15,850, with 850 being males and 3,000 being females. The incidence of esophageal cancer in adults is greatest between the ages of 45 and 70. The rate of incidence of esophagus adenocarcinoma (EA) is higher in Caucasians than in Asians and African Americans, whereas the incidence of esophageal squamous cell carcinoma (ESCC) is highest in Asians. The rates are very high in parts of China, Iran, and Southern Africa, suggesting an association between either genetics or environment.

Nonmodifiable risk factors of esophageal cancer include age, sex, and race, whereas modifiable risk factors include the use of alcohol and tobacco. The risk of developing esophageal cancer increases 18 times for those who drink more than 13 oz of alcohol per day, and the amount of alcohol consumed on a consistent basis has a direct effect on the cancer risk. Cigarette smokers are two to six times more likely to develop esophageal cancer than nonsmokers, and the combination of smoking and heavy alcohol use increases the risk for esophageal cancer 44 times. The following factors also influence the risk of developing esophageal cancer:

- Nutritional deficiency (molybdenum, zinc, and vitamin A)
- Barrett's esophagus (columnar cells in the lower esophagus)

- GERD (long term, untreated)
- Obesity
- Lye strictures (esophageal narrowing caused by lye ingestion)
- Esophageal diverticula
- Achalasia (decreased esophageal smooth muscle relaxation)
- Tylosis (esophageal callus formation)
- Obesity (associated with hiatal hernia and GERD)

## Pathophysiology

The majority of tumors occurring in the upper two-thirds of the esophagus are usually SCCAs. The use of alcohol and tobacco products increases the risk of squamous cell esophageal cancer more so than adenocarcinoma, with more than half of the cases of squamous cell esophageal cancer associated with smoking. Esophageal adenocarcinoma is mostly found in the lower one-third of the esophagus, mainly at the GEJ and cardiac (first part of the stomach) portion of the stomach. When reflux of gastric acid occurs over a long period of time, the squamous cells lining the lower one-third of the esophagus are replaced with columnar cells (gland cells that normally line the stomach and small intestine). This metaplastic transformation is known as Barrett's esophagus and is a known cause of esophageal adenocarcinoma. Esophageal cancer grows rapidly, spreading to nearby lymph nodes and into the esophageal lumen, causing thickening and invasion of neighboring tissue. More than 50% of esophageal cancers metastasize, with the most common sites being the liver, lung, bone, and stomach. Patients are usually asymptomatic until the tumor is large and well advanced. By the time patients seek medical attention, these fast-growing tumors have progressed to later stages. Another factor contributing to late diagnosis is that there is no preventive screening for esophageal cancer.

Heavy alcohol consumption and tobacco use are primary risk factors linked to SCCA of the esophagus, especially when used together. The compounds found in tobacco smoke may be responsible for genetic mutations commonly found in esophageal tumors. A mutation of the *Tp53* gene is usually present in patients with advanced adenocarcinoma. Long-standing alcohol and tobacco use increase the ability of these substances to damage suppressor genes and overexpress the oncogenes that cause esophageal disease (see Evidence-Based Practice: Gene Mutation and Carcinogenesis).

## Evidence-Based Practice

### Gene Mutation and Familial Clustering

- Mutations of three genes have been associated with the development of esophageal disease.
- Mutations of the *MSR1*, *ASCC1*, and *CTHRC1* genes have been associated with Barrett's esophagus (BE) and

adenocarcinoma and accounted for 11% of cases in the study population.

- In the past 40 years, there has been a six-fold increase in esophageal cancer in Western countries.
- Individuals having no siblings with BE or esophageal adenocarcinoma (EA) have a 3.2% baseline risk of developing BE or associated cancers.
- The risk of developing BE or EA increases with the number of siblings who are affected:
  - With one sibling affected, the risk goes up to 9.1%.
  - With two siblings affected, the risk goes up to 26.6%.

Contino, G., Vaughan, T. L., Whiteman, D., & Fitzgerald, R. C. (2017). The evolving genomic landscape of Barrett's esophagus and esophageal adenocarcinoma. *Gastroenterology*, 153(3), 657–673.

There is a strong causal relationship with GERD and adenocarcinoma. Patients with adenocarcinoma are seven times more likely to have GERD symptoms than patients who do not have adenocarcinoma. Patients with chronic, severe GERD are at least 43 times more likely to develop esophageal adenocarcinoma. There is no relationship between GERD and SCCA.

## Clinical Manifestations

Progressive dysphagia is the most common symptom of esophageal cancer, indicating a large late-stage cancer in most cases. When patients experience difficulty swallowing, the tumor has narrowed the lumen of the esophagus to about half its diameter. Other clinical manifestations include hemoptysis (coughing up blood), pain or a burning sensation in the middle of the chest, painful swallowing as food or fluids reach the tumor, vomiting, weight loss, anorexia, hoarseness, and melena. Hypercalcemia may develop related to metastasis of the esophageal tumor to the bones, production of hypercalcemic substances by the tumor tissue, or release of a parathyroid hormone-related protein (PTHrP). Esophageal cancers do not usually produce clinical manifestations until the disease has advanced and recovery is unlikely.

## Management

### Medical Management

#### Screening

Currently, screening for esophageal cancer in the general population is nonexistent. Careful screening and follow-up for high-risk patients, such as those with Barrett's esophagus, are monitored closely for malignancy with scheduled endoscopies. These patients are treated medically or surgically according to the degree of esophageal dysplasia.

## Diagnostic Tests

- A *barium swallow* identifies irregularities in the surface of the wall of the esophagus and is one of the first tests done to diagnose esophageal cancer. A barium swallow can also diagnose a tracheoesophageal fistula. These fistulas occur when a tumor invades the tissue between the esophagus and the trachea, creating a hole connecting them, increasing the patient's risk of food or fluid traveling from the esophagus to the trachea.
- *Computed tomography scans* are used to determine how far the cancer has spread in the esophagus and to assess for spread to the lymph nodes and nearby organs. Patients may receive oral or IV contrasts before a CT scan to visualize various structures and to identify tumors. Decisions to perform surgical interventions are determined according to CT scan results. When performing a CT-guided needle biopsy, a radiologist guides a biopsy needle toward a mass to obtain a tissue sample for evaluation.
- *Positron emission tomography scans* detect areas of metastasis and can even detect small collections of cancer cells that are not detectable with other diagnostic studies. Radioactive glucose is administered intravenously and then concentrates in cancers. A scanner is used to detect the radioactive deposits.
- *Endoscopic ultrasonography* is performed by placing a small ultrasound probe in the esophagus. The probe produces sound waves that penetrate into normal tissue and abnormal tissue. These sound waves are converted into a picture that shows how much the tissue and nearby lymph nodes are affected by the cancer.
- *Endoscopy* is used to diagnose esophageal cancer, and there are two different approaches. An *upper endoscopy* is performed by inserting an endoscope through the patient's mouth, the esophagus, and to the stomach. The esophageal wall is observed, and a biopsy can be performed on tissue that appears abnormal. A *bronchoscopy* is performed using an endoscope to view the trachea and the bronchi in order to detect abnormal tissue in these areas. Therapeutic procedures and collection of tissue specimens can be obtained.

- *Thoracoscopy and laparoscopy* are performed by a health-care provider who passes a scope and instruments through a tube and into the chest or the abdomen of the patient. Lymph nodes and other organs located near the esophagus are viewed, and tissue samples for biopsy are taken to determine potential areas of metastasis. *Biopsies* may be performed with several of these diagnostic tests and involve removing tissue samples that appear to be cancerous or abnormal. These tissue samples are observed under a microscope, and if cancer cells are present, the grade and the type are determined.

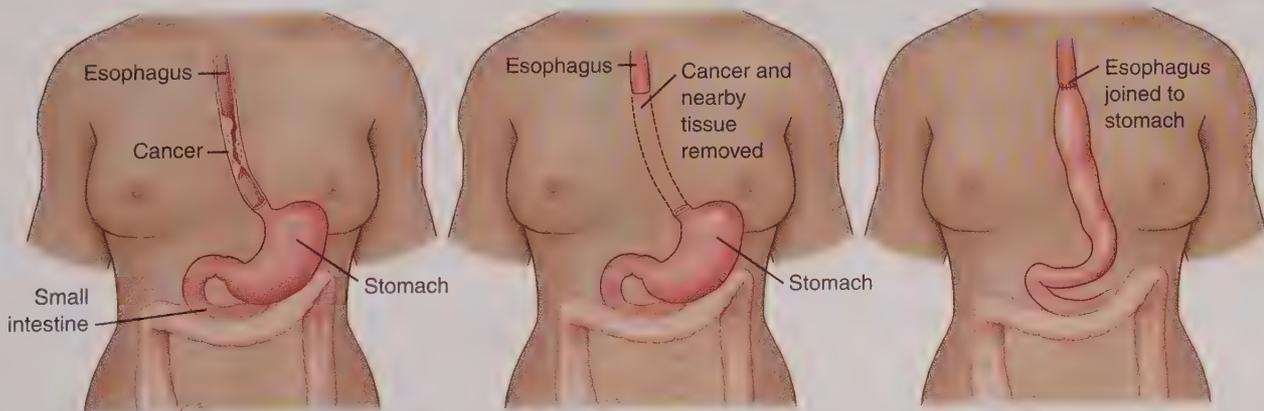

## Complementary and Alternative Medicine

Complementary and alternative therapies can promote relaxation and relieve muscle tension that contributes to the sensation of pain. Yoga, meditation, spirituality, and religion are used to relieve pain in some individuals with esophageal cancer. Massage and vibration are used for muscular relaxation, which decreases the perception of pain by decreasing pain signal transmission. Other complementary and alternative therapies used for chronic pain include imagery, aromatherapy, music, and humor. These therapies have been used as adjuncts or in place of medical or surgical interventions (see Chapter 12).

## Surgical Management

In rare cases, esophageal cancer is discovered when it is localized to the esophagus, and surgery can be curative. Esophageal tumors, lymph nodes, and surrounding tissue are surgically removed depending on the stage of the cancer. Most often, palliative surgical interventions are done to restore patients' ability to swallow and to maintain optimal nutrition.

An open esophagectomy is a surgical procedure that involves the removal of all or part of the esophagus and the neighboring lymph nodes (Fig. 56.11). When a portion of the upper or middle esophagus is removed, most of the esophagus is removed, and the stomach is pulled up and connected to the esophagus in the neck area. If the stomach cannot be used to replace the esophagus in the neck, then a piece of intestine

**FIGURE 56.11** Esophagectomy. A part of the esophagus with the cancer is removed, and then the stomach is connected to the remaining esophagus in the upper chest or the neck.

is used to form a new esophagus. When the cancer is in the distal esophagus or the gastroesophageal juncture, parts of the stomach and esophagus are removed, and the stomach is connected to the remaining esophagus in the upper chest or the neck. Treatment regimens include surgery combined with chemotherapy and/or radiation therapy. In some cases, a minimally invasive esophagectomy is performed laparoscopically for small cancers through several small incisions.

### Endoscopic Treatments

Several endoscopic interventions are also indicated in the management of esophageal cancer. *Endoscopic mucosal resection (EMR)* involves the removal of the esophageal lining with instruments attached to an endoscope. Endoscopic mucosal resection is used to remove precancerous (dysplastic) lesions and small, singular esophageal cancers. Proton pump inhibitors are used after EMR to prevent recurrence. *Photodynamic therapy* is used to treat dysplasia, early esophageal cancer, and recurrence of esophageal cancer. This therapy uses light to activate a chemical that can kill cancer cells. *Laser ablation* is performed using a laser through an endoscope to destroy cancer cells. It is also used to relieve esophageal obstruction and improve swallowing. Liquid nitrogen therapy (cryotherapy ablation) has also been used to destroy abnormal cells with Barrett's esophagus (see Evidence-Based Practice: Cryotherapy Ablation). *Radiofrequency ablation* is used to treat dysplasia in areas of Barrett's esophagus. A balloon is passed into the area of Barrett's esophagus and inflated until the balloon comes in contact with the inner lining of the esophagus. High-powered energy is applied to destroy the cells in the inner lining. Normal cells should replace the Barrett's cells, and afterward, the patient remains on acid-blocking medications. Follow-up with periodic endoscopy and biopsies is done to monitor for further changes to the esophageal lining. *Argon plasma* coagulation is used to clear the esophagus when the patient is having difficulty swallowing, and it is similar to laser ablation. *Electrocoagulation* is used to remove the tumor with electrical current and occasionally is used to clear the esophageal blockage.

### Evidence-Based Practice

#### Cryotherapy Ablation

A pilot study was conducted at the University of Maryland Medical Center (UMMC) using liquid nitrogen (cryotherapy ablation) to remove the abnormal cells seen in Barrett's esophagus. This endoscopic procedure showed regression of the abnormal cells found in Barrett's esophagus. Further research using larger clinical trials at other hospitals is currently in progress.

University of Maryland Medical Center. (2015). *Cryotherapy*. Retrieved from <http://www.umm.edu/gi/cryotherapy.htm>

### Complications

Complications of esophageal cancer include risks related to treatment for the disease in addition to risks associated with advanced disease. Complications associated with surgical interventions include dysphagia caused by strictures at the surgical site of anastomosis, heartburn related to disturbance or loss of the LES pressure allowing reflux of acid and bile into the esophagus, and frequent nausea and vomiting due to decreased stomach emptying from nerve involvement related to the surgical procedure. The patient may also develop *dumping syndrome* due to partially digested food entering the small intestine too quickly and causing distention and diarrhea. Radiation therapy also has the potential for complications, including blistering and ulceration of the skin and fatigue. Gastrointestinal complications include stomatitis, nausea and vomiting, and diarrhea. In addition to complications associated with chemotherapy discussed in the oral cancer section, specific side effects associated with the chemotherapeutic medications commonly given for esophageal cancer include diarrhea associated with the administration of 5-FU, nerve and renal impairment associated with cisplatin administration, and cardiac toxicities seen with the administration of doxorubicin and epirubicin.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with esophageal cancer are related to cellular changes that lead to obstruction of the esophageal lumen. Common findings include:

- Dysphagia (with or without hiccups)
- Pain (throat, back, or chest)
- Hoarseness
- Chronic cough
- Weight loss
- Hypercalcemia
- Gastrointestinal bleeding
- Anemia
- Coughing up blood

#### Nursing Diagnoses

- **Impaired swallowing** related to obstruction by the tumor or the effects of radiotherapy
- **Imbalanced nutrition:** Less than body requirements related to decreased nutritional intake secondary to swallowing impairment
- **Acute/chronic pain** related to the physical injury (pressure of the tumor mass in the esophagus)
- **Ineffective coping and compromised family coping** related to the effects of the disease and prognosis

#### Nursing Interventions

##### ■ Assessments

- Respiratory assessment

*Aspiration related to dysphagia can cause adventitious breath sounds and decreased oxygenation. As the cancer progresses, infiltration of the tracheobronchial tree or development of a*

tracheoesophageal fistula may occur, with eventual lung metastasis. Other respiratory symptoms may be due to aspiration and regurgitation of undigested food particles.

- Nausea and vomiting

Nausea and vomiting occur from the interruption of normal peristalsis by the tumor. Patients with dysphagia who experience vomiting are at risk for aspiration. Postoperative nausea and vomiting can occur because of decreased gastric emptying and vagal nerve involvement.

- Hoarseness or cough

A hoarse cough is related to tumor involvement with the larynx or recurrent laryngeal nerve, aspiration pneumonia, or a tracheoesophageal fistula.

- Painful swallowing (odynophagia)

Dull, substernal pain that may radiate occurs when esophageal cancer is so large that food is blocked from passing into the stomach. Pain occurs a few seconds after swallowing as food reaches the area of blockage where the tumor is located.

- Dysphagia and hiccups together

Difficulty swallowing progressively increases over a few months. Patients will usually eat softer foods as the dysphagia starts; they may avoid meat, bread, and raw vegetables because these foods get stuck in the throat more easily. Eventually, liquids can become difficult to swallow.

- Weight loss

Patients are at risk for nutritional deficiency when food becomes stuck in the esophagus because of the increasing size of the tumor. Dysphasia is a late symptom that indicates a large esophageal cancer. Weight loss occurs because of problems with swallowing and the associated pain. Additionally, the increase in metabolism from the cancer adds to the weight loss.

- Hematocrit and hemoglobin

There is an increased risk of bleeding as tumors invade the esophageal tissues. Bleeding from the tumor can appear in stool or emesis, causing anemia. Stools may appear black (melena).

- Serum calcium levels

Elevated calcium levels are seen in patients with advanced squamous cell esophageal carcinoma. Potential causes of the increased calcium levels are bone metastasis, production of hypercalcemic substances by the tumor tissue, or release of PTHrP.

- Liver enzymes and jaundice

Elevated liver enzymes and jaundice are indicators of liver metastasis or alcohol-related liver disease.

- Psychosocial adjustment

Adjustments to the disease process, treatments, and side effects may require consultation with the palliative care team, social worker, or chaplain.

## ■ Actions

- Maintain the HOB greater than 30 degrees, and provide suction and oxygen equipment.

Esophageal obstruction from tumor growth increases the risk of aspiration. Measures to prevent aspiration help to prevent respiratory complications.

- Collaborate with the nutritionist.

The patient may require calorie counts, soft diet/thickened liquids, nutritional supplements. Food and fluids prevent

weight loss and promote healing. Collaboration with a nutritionist ensures an individualized diet plan to maintain optimal nutrition. Thickened or soft foods are easier to swallow, and nutritional supplements between meals increase caloric intake. Following esophagogastrectomy, provide six small meals low in complex sugars and high in protein and fat to prevent dumping syndrome (diarrhea after eating).

- Provide six small meals per day, low in complex sugars and high in protein and fat, for patients after esophagogastrectomy.

Smaller meals along with a decrease in complex sugars and foods high in protein and fat delay gastric emptying and prevent dumping syndrome (diarrhea after eating).

- Collaborate with speech and language pathologist.

Speech and language pathologists treat problems with swallowing and can teach the patient and family strategies to increase the effectiveness of swallowing and decrease aspiration.

## ■ Teaching

- Lines, tubes, and incisions

Patients will receive information about their surgery preoperatively to psychologically prepare for what they will experience postoperatively. Patients undergoing esophageal surgery can expect to see chest incisions, drains, a jejunostomy tube (for enteral tube feeding), a nasogastric tube for decompression of the stomach, an IV line, and possibly a chest tube.

- Preoperative care for esophageal surgery; smoking cessation 2 to 4 weeks before surgery

Smoking cessation improves respiratory outcomes postoperatively.

- Coughing, deep breathing, incentive spirometry, turning every 2 hours, and early ambulation

This is the highest postoperative priority in patients who have undergone esophagectomy to promote prevention of respiratory complications.

- Pain management: monitoring duration, quality, and intensity

Teach the patient and family the use of alternative pain techniques and to request pain medication when anticipating painful events. Nonpharmacological measures enhance the patient's perception of pain control. Pain management teams use specific patient reports to adjust pain regimens.

- Enteral or parenteral nutrition support may be necessary up to 3 weeks after surgery.

Patients need to remain NPO to prevent postoperative complications and to allow surgical incisions time to heal.

- Dental screening

Preoperative dental examinations and oral care four times per day will help prevent postoperative infection.

- Postoperative nutritional education: The patient is instructed to sit upright and eat six to eight small meals per day with fluids in between meals.

The size of the stomach is considerably smaller. Diarrhea resulting from interruption of vagal nerve fibers can occur 20 minutes to 2 hours after eating. Imodium can be given before meals to manage diarrhea.

### Connection Check 56.6

The nurse implements which interventions to decrease the risk of dumping syndrome in the patient after esophageal resection for cancer?

- Limit diet to clear liquids only.
- Increase protein in the diet.
- Increase simple sugars in the diet.
- Provide 8 to 10 small meals.

### Evaluating Care Outcomes

Esophageal cancer is usually diagnosed in later stages because symptoms occur when the tumor has invaded deep into the layers of the esophagus and distant metastasis has occurred, thus decreasing survival. Currently, the only screening method used is endoscopy, but this is used when patients have suspicious symptoms or precancerous conditions such as Barrett's esophagus. The most important outcome for patients who have esophageal cancer is that the patient maintains a stable weight and receives adequate nutrition. Treatment goals aim to slow the progression of the disease, and overall, there is about a 20% chance of 5-year survival. Surgery, radiation therapy, and chemotherapy are used to treat esophageal cancer. Patient education that focuses on avoiding lifestyle choices such as alcohol and tobacco use and maintaining a healthy weight is important in order to inform patients of how these behaviors impact the disease process. Often, newly diagnosed patients enter into palliative care regimens, with the possibility of a cure being unlikely.

## ESOPHAGEAL TRAUMA

Because of its anatomical position in the thoracic cavity and its close proximity to the oropharynx, the esophagus is the most common site for GI trauma. Direct effects of esophageal trauma may cause impairment of swallowing and nutrition, and indirect trauma may occur to the lungs or the mediastinum. Excessive force applied to the esophageal mucosa may cause it to rupture or perforate. Perforation can cause respiratory impairment, shock, or sepsis (most likely related to GI contents spilling into the thoracic cavity) and gastric acid entering the mediastinal cavity. High mortality rates are associated with esophageal perforation.

### Epidemiology

The most common causes of esophageal trauma are from diagnostic and therapeutic interventions (iatrogenic) performed while passing endoscopic instruments through the esophagus. Diagnostic endoscopy carries a complication rate of 0.1%, and therapeutic endoscopic procedures have a complication rate of 10% to 15%. Other epidemiological facts about esophageal trauma include the importance of early treatment and determining the etiology, severity, and location of the trauma. Factors that contribute to morbidity

and mortality secondary to esophageal trauma are related to the amount of time from diagnosis to intervention. Mortality doubles 24 hours after the injury. Esophageal perforations have a 12% to 36% survival rate if diagnosed and surgically treated within 24 hours, and after 24 hours, the mortality rate increases to 30% to 50%. The location of the injury is also important because the mortality varies by site; cervical injury mortality is 6%, thoracic mortality is 27%, and abdominal mortality is 21%. Spontaneous perforation of the esophagus has a 30% to 40% mortality, iatrogenic injuries have a 15% to 20% mortality, and direct trauma has a 5% to 10% mortality.

There are various and multicausal factors related to esophageal trauma that include:

- Blunt injuries
- Ingestion of caustic agents
- Endoscopic procedures
- Chronic vomiting
- Straining
- Seizures
- Foreign objects
- Instruments/tubes
- Ulcers
- Complications of esophageal surgery
- Open penetrating wounds

There are approximately 25,000 chemicals today known to cause chemical burns when ingested. These substances are classified by how they damage protein. See Table 56.3 for examples.

### Pathophysiology and Clinical Manifestations

The pathophysiology of esophageal trauma is related to the cause of the trauma, and there are many factors that cause esophageal trauma. Common causes of esophageal trauma include ingestion of caustic substances, blunt injuries, open penetrating wounds, foreign-body ingestion, instrumentation

**Table 56.3 Caustic Substances That Cause Chemical Burns When Ingested**

Category of Caustic Agent	Examples of Common Caustic Substances
Oxidizing agents	Bleach, peroxide, etc.
Corrosives	Sulfuric acid, hydrochloric acid, etc.
Reducing agents	Ferrous ion, sulfite compounds, etc.
Desiccants	Calcium sulfate, silica gel, etc.
Vesicants	Sulfur, mustard, nitrogen mustard, etc.
Protoplasmic poisons	Hydrozoa acid, etc.

and tube placement, and spontaneous esophageal rupture and Mallory–Weiss syndrome.

Ingested caustic substances cause severe pain to the mouth, pharynx, and chest (behind the sternum and the epigastric area), and corrosive white crusts or chemical burns form in the mouth. Other clinical manifestations include gagging, excessive salivation (sialorrhea), glottic edema, dyspnea, aspiration pneumonia, hemorrhage, mediastinitis, peritonitis, and tracheoesophageal fistula. Long-term effects include wasting, long esophageal strictures, and progressive dysphagia. Progressive clinical manifestations occurring after 24 to 48 hours include damage to the kidney, liver, and possibly the central nervous system (CNS) secondary to toxic effects of the ingested substance; shock; and circulatory collapse.

Sulfuric acid is in many drain-cleaning products, and in adults, the most common cause of sulfuric acid ingestion is suicidal intentions. Strong acids have a pH of less than 2. The pH of an acid is less than 7 and greater than 0 on a 0-to-14 scale, with 7 being neutral, and the closer to 0, the stronger the acid. Many factors influence the degree of injury from caustic ingestion, but the major determinant is the amount of time that the chemical is in contact with the tissue. Ingestion of acids causes severe coughing and gagging, allowing the acid to make contact with the glottis and airway structures. Severe chemical epiglottitis and airway compromise can occur. Aspiration pneumonia is an unlikely side effect in conscious patients, but when it does occur, it increases the risk of death.

Alkalis tend to cause more harm to the esophagus and cause less injury to the stomach. Conversely, because of the resistant nature of squamous cell epithelium to acid, these acids cause more harm to the stomach and less to the esophagus. The esophagus is more sensitive to alkali substances. Alkalis with a pH greater than 11.5 tend to penetrate deeply into esophageal tissue and cause adjacent tissue damage. These burns tend to occur in areas of anatomical narrowing.

Treatment for ingestion of caustic agents includes analgesics, hydration, management of shock, nutritional support, tracheostomy, and high-dose steroids. Regularly scheduled endoscopy studies provide information to regulate steroid therapy and to develop a treatment plan. Dilation of esophageal strictures may be performed after 2 weeks.

**Safety Alert** The following procedures are contraindicated in patients who have ingested a caustic substance:

- *Emetic administration* can reintroduce the caustic substance to esophageal tissue.
- *Neutralizing agents* are not useful because the damage already occurred upon exposure to the caustic substance.
- *Nasogastric tube insertion* via blind placement can lead to esophageal perforation or induce vomiting and cause reexposure to the caustic substance.
- *Activated charcoal* is not beneficial and can interfere with endoscopy testing.

Blunt injuries most often result from motor vehicle accidents. Esophageal tears can result from the impact of the driver's chest forcefully making contact with the steering wheel. Over time, localized necrosis to the esophageal wall occurs, and fistulas can develop. Clinical manifestations of esophageal trauma from blunt injuries include coughing upon swallowing. Esophageal rupture to the lower one-third of the esophagus is usually from blunt trauma. Surgical intervention is required to repair tears, fistulas, and esophageal ruptures. Open penetrating wounds occur most often in the cervical region of the spine, resulting from sharp objects that penetrate the neck or the upper chest. Common clinical manifestations include food or saliva coming from the wound. Minor wounds are treated by placing a feeding tube for 4 to 6 days in order to control mucosal damage and promote healing. Surgical management is used to treat large, open, penetrating wounds.

Foreign-body ingestion in adults usually occurs unintentionally. Some commonly ingested objects include fish or chicken bones, glass shards, parts of false teeth, nails, needles, and large fruit stones. Prisoners have been known to swallow cutlery. Foreign bodies typically lodge in the upper esophageal sphincter. Clinical manifestations associated with foreign-body ingestion include marked dysphagia, odynophagia, swelling of the neck, severe coughing, and neck stiffness. Pain is localized to the neck and retrosternal area. Severe pain in the back and behind the sternum indicates possible mediastinitis. Impacted foreign objects can cause necrosis to the wall of the esophagus, mediastinitis, pleuritis, peritonitis with abscess formation, and possible surgical emphysema. About 95% of small foreign bodies pass through the digestive tract and leave the body later in the stool. The patient's feces should be checked for up to a week or more to assess for the passage of the foreign body.

Instrumentation and tube placement are common causes of iatrogenic esophageal perforation. Instrumentation using esophagoscopy, especially during stricture dilation, can cause perforation. Placement of nasogastric and endotracheal tubes can also cause perforation. The most common sites of iatrogenic perforation are at the three sphincters, areas of esophageal stenosis, and the pyriform sinus.

Spontaneous esophageal rupture (Boerhaave's syndrome) occurs with sudden increased intraesophageal pressure related to vomiting or stenosis. This disorder is common in patients with alcohol abuse or chronic vomiting. The clinical presentation of Boerhaave's syndrome includes hematemesis, severe pain behind the sternum or between the shoulder blades, left upper quadrant pain, hypotension, pallor, dyspnea, and circulatory collapse. Treatment for Boerhaave's syndrome requires open surgical intervention with thoracotomy and antibiotic therapy.

**Mallory–Weiss syndrome** occurs from severe vomiting that infrequently causes a fatal hemorrhage in the esophagus or the GEJ. This disorder is often associated with chronic alcohol abuse, but other causes can be malignant tumors and hyperemesis gravidarum developing during pregnancy. Clinical manifestations include pallor, tachycardia, and

possible shock. Bleeding usually resolves in 24 to 48 hours. Endoscopic or surgical intervention is necessary if bleeding does not resolve. This condition is rarely fatal.

## Management

### Medical Management

Therapeutic interventions for the treatment of esophageal trauma focus on control of any bleeding, wound management and drainage, prevention of infection, and providing nutrition. Interventions vary in relation to the cause, location, size, and degree of injury; contamination; duration of time from the injury; and the presence of other associated injuries. The clinical manifestations of esophageal trauma are often vague in relation to the amount of trauma and the potential for complications. Common clinical manifestations of esophageal trauma include pain, fever, dyspnea, and crepitus. Diagnostic tests include:

- Chest x-ray
- Chest CT
- Contrast esophagography

Medications used to treat esophageal injuries include broad-spectrum antibiotics, high-dose corticosteroids, opioid or nonopioid analgesics, and topical analgesics.

### Surgical Management

The purpose of surgical management is to control bleeding, remove damaged tissue, repair wounds, resect part of the esophagus with gastric pull-through, or replace the esophagus with a bowel segment.

### Complications

Complications of esophageal trauma include risks related to surgical or endoscopic procedures, straining, and injury. Esophageal rupture is a serious complication that is caused by external trauma or instrumentation of the esophagus, increased pressure within the esophagus from vomiting or retching, diseases of the esophagus, and corrosive esophagitis. Other complications related to esophageal trauma include:

- Infection
- Abscesses
- Subcutaneous emphysema in the neck
- Pneumothorax
- Shock
- Sepsis
- Respiratory impairment
- Esophageal mucosal burns
- Esophageal strictures
- Aspiration pneumonia
- Hemorrhage

### Nursing Management

#### Assessment and Analysis

Management of the patient with esophageal trauma centers around the type of injury and the assessment of clinical manifestations related to the injury so that complications can be reduced or eliminated. Addressing any threat of

cardiopulmonary complications is the top priority, followed by prevention of other complications, such as hemorrhage and infection, and maintaining nutritional support. Patients receive nothing by mouth (NPO) while diagnostic tests are performed to confirm the extent of the injury. Common manifestations related to the management of the patient with esophageal trauma are presented according to the type of injury.

Exposure of caustic substances in the oral cavity causes local epithelial trauma that can cause corrosive crusts or chemical burns in the mouth. Gagging, sialorrhea, glottis edema, dyspnea, hemorrhage, mediastinitis, peritonitis, tracheoesophageal fistula, perforation, kidney and liver damage, CNS damage, shock, circulatory collapse, and death are all possible consequences. Without prompt intervention, these clinical manifestations can occur as a result of accidental or intentional ingestion of a caustic substance.

Food and saliva present in a mediastinal wound can require placement of a feeding tube or surgical intervention. Patients remain NPO to allow the esophagus to heal. Irritation, mucosal ulceration, bleeding, obstruction, perforation, and death are all possible. Clinical manifestations of foreign-body ingestion include impaction of food or an object in the esophagus, usually bone fragments or meat in the esophagus. Esophageal impaction is a serious condition, and it can progressively lead to death.

Symptoms of Boerhaave's syndrome include spontaneous esophageal rupture, usually from vomiting. It can occur with a sudden increase in intraesophageal pressure and is often associated with alcohol abuse or chronic vomiting. Signs include hematemesis, pain behind the sternum and between the shoulder blades, left upper quadrant pain, hypotension, pallor, dyspnea, and circulatory collapse.

Symptoms of Mallory-Weiss syndrome occur from a tear in the esophageal mucosa or in the GEJ, usually brought on by excessive alcohol ingestion. Often, clinical manifestations resolve without treatment within 10 days. Signs include hematemesis, bloody stools, pallor, tachycardia, possible shock, and rarely death.

### Nursing Diagnoses

- **Impaired swallowing** related to esophageal trauma as evidenced by coughing, gagging, or vomiting
- **Imbalanced nutrition:** Less than body requirements related to the inability to ingest food as evidenced by inadequate caloric intake
- **Acute pain** related to esophageal trauma as evidenced by unacceptable pain score or autonomic responses (changes in respirations, heart rate, and blood pressure, and diaphoresis)
- **Impaired oral mucous membranes** related to caustic ingestion as evidenced by chemical burns or ulcerations

### Nursing Interventions

#### Assessments

- **Airway, breath sounds, and oxygenation**  
*Dependent on the location of the esophageal trauma, the airway can be compromised by esophageal rupture with gastric contents and acid spilling as well as esophageal tissue edema.*

- **Vital signs**

Pulse rate, respiration, and blood pressure may be elevated with pain. With hemorrhage, sepsis, or shock, there may be a decrease in blood pressure with a compensatory increase in heart rate. Leakage from anastomosis sites of postoperative patients may produce clinical manifestations of early shock that include fever, tachycardia, and tachypnea.

- **Chest pain**

Chest pain may be caused by esophageal trauma or damage by gastric secretions or ingestion of caustic agents.

- **Level of consciousness**

Changes in level of consciousness are associated with septic or shock states.

- **Serum electrolytes**

- Serum albumin

Albumin levels below 2.5 g/dL indicate severe protein depletion.

- Transferrin

Transferrin is needed for iron transfer, and it usually decreases with albumin.

- Serum potassium levels

Serum potassium is lost in gastric secretions, particularly if the patient requires nasogastric suctioning.

- **Complete blood count**

The red blood cell count may decrease secondary to blood loss or with malnutrition. The white blood cell count increases with the inflammation and infection associated with esophageal trauma.

- **Daily weights**

Weight loss may occur related to decreased intake secondary to esophageal trauma.

- **Actions**

- **Low intermittent esophageal and gastric suction**

Gastric and esophageal suctioning allow the esophageal mucosa to rest and heal. Low, intermittent suction provides less trauma to the mucosa than constant suction.

- **Keep patient NPO.**

Esophageal rest for more than a week allows time for the injury to heal.

- **Provide nutrition.**

Total parenteral nutrition (TPN) provides calories and protein while the patient is NPO to promote healing nutrients.

- **Administer antibiotics.**

Due to potential contamination by food or bacteria, broad-spectrum antibiotics are indicated to prevent or treat infection.

- **Administer high-dose corticosteroids**

Suppresses inflammation and help prevent esophageal strictures

- **Pain management**

Opioid and nonnarcotic analgesics are prescribed for pain. Topical analgesics and anti-inflammatory agents are used to treat burns to the oral mucosa.

- **Teaching**

- **Explain procedures, tests, medications, and discharge instructions.**

Compliance is greater when the patient understands all teaching as well as the rationale for ordered interventions.

- **Signs of infection**

Because of esophageal trauma and risk of leakage, the patient should be taught to monitor temperature and site (as applicable) for signs of redness, tenderness, or drainage.

- **Monitor weight.**

Due to the potential for impaired nutrition, it is important that the patient closely monitors for weight loss.

### Evaluating Care Outcomes

Esophageal trauma has many causes and can lead to significant changes in nutritional intake. The management of esophageal trauma can be a serious and often fatal medical emergency that may require surgical intervention. Measures taken to control bleeding, infection, and airway management are necessary to prevent progressive complications. Prompt recognition and prevention of potential complications are of vital importance in obtaining favorable outcomes.

### Connection Check 56.7

The nurse includes which information in the discharge teaching plan for the patient who sustained esophageal trauma?

- Take ordered antibiotics until your temperature is normal.
- Limit pain medications to times of severe pain.
- Check your temperature every other day.
- Notify your provider if increased drainage from the injured area is noted.

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Rodriguez's 2-year survival rate is 95% because he is HPV positive. If he were HPV negative, his 2-year survival rate would have been 65%. He has just reached his second year with an uneventful recovery from surgery and radiation therapy. He is eating, drinking, and talking well. His weight is proportionate to his height. He stopped smoking 2 years ago using Chantix. He stopped drinking bourbon but says that he drinks a six-pack of beer each week with his friends. He continues to have a supportive relationship with his girlfriend, and they are planning to get married. Mr. Rodriguez has not had a raise in salary for 2 years, and he does not always have enough money to buy his medications. He ran out of Prilosec, and he says that is why his heartburn (he has GERD) is worse; he tries to stay away from spicy foods and fatty foods, but he drinks five cups of coffee each day. He sleeps with his head elevated at least 30 degrees, and he says this helps decrease his heartburn at night.

### Case Study Questions

- What type of collaborative care referral is of highest priority for Mr. Rodriguez before starting radiation therapy?
  - Substance abuse consult
  - Dental consult
  - Nutrition consult
  - Homehealth care referral
- The nurse is screening Mr. Rodriguez for his risk of developing secondary stomatitis. What information in his history indicates the highest risk for developing secondary stomatitis?
  - He is on amitriptyline, and he rinses his mouth after each meal with antiseptic mouthwash.
  - He is on omeprazole (Prilosec), and he recently adopted a cat.
  - He started radiation therapy 10 days ago, and he is on a methylprednisolone dose pack for poison ivy.
  - He is on triamterene, and his roommate recently moved out.
- Mr. Rodriguez reflects back on what may have contributed to the development of his tongue cancer. What risk factors did Mr. Rodriguez have? (*Select all that apply.*)
  - He drank bourbon every day.
  - He smoked cigarettes.
  - He had poor oral hygiene.
  - He consumed a high-fat diet.
  - He had a sedentary lifestyle.
- Which statement made by Mr. Rodriguez indicates a need for interprofessional consultation to address his risk of Barrett's esophagus?
  - "I have cut back to drinking a six-pack of beer each week."
  - "I cannot afford to take Prilosec for my GERD."
  - "I could not afford to take my antibiotic when they told me I had *H. pylori*."
  - "My girlfriend tells me that I have bad breath."
- What statement by Mr. Rodriguez indicates the need for additional teaching about the prescribed Prilosec (Omeprazole)?
  - "I should take this medication when I eat spicy food."
  - "I need to take this medication everyday to be effective."
  - "This medicine works by decreasing the acid in my stomach."
  - "This medication helps heal inflammation in my esophagus."

### CHAPTER SUMMARY

The oral cavity is the entry point of the digestive system, and it houses the structures for breathing, chewing, tasting, and articulation. Impairment of the oral mucosa interrupts vital functions as well as sensory and social functions that allow individuals to interact and enjoy a satisfying quality of life. The cells of the mouth are especially vulnerable to injury and infection.

Stomatitis is a painful disorder that causes inflammation and ulceration of the lining of the mouth, making the delicate tissue of the oral mucosa susceptible to local and systemic infections. The causes of stomatitis are variable, ranging from infectious agents to medications, cancer treatments, irritants, vitamin deficiencies, diseases, and allergic causes. Good oral hygiene and optimal nutrition are essential in limiting the severity and complications related to stomatitis.

Hiatal hernia results from a weakened gastroesophageal junction (GEJ). Sliding hernias are often small and cause few or no symptoms. Larger sliding hernias cause symptoms related to gastroesophageal reflux disease (GERD). Chronic inflammation caused by GERD puts the patient at risk for development of Barrett's esophagus and adenocarcinoma. Type 2 paraesophageal hernias, or rolling hernias, occur when structural abnormalities allow part of the stomach to roll through the esophageal hiatus, forming a pouch of stomach above the diaphragm and next to the esophagus that can be small or large. Paraesophageal hernias left untreated can become larger over time, and the following complications can include the development of a giant intrathoracic stomach, volvulus, incarceration, and strangulation. Surgical candidates include patients with sliding hernias who are not responding to medical treatment and patients with large paraesophageal hernias.

Medication management for both hiatal hernia with reflux and GERD consists of antacids, histamine-2-receptor agonists, proton pump inhibitors, and prokinetic medications. Patients with sliding hernias usually have symptoms of GERD. Lifestyle changes such as weight control and avoiding foods and substances that decrease lower esophageal pressure can decrease the development of GERD and Barrett's esophagus.

The majority of oral cancers are squamous cell carcinomas (SCCAs). Lifestyle choices related to alcohol use, tobacco, and poor oral hygiene are well-known causes. Oral cancer does not usually present with clinical manifestations until it has progressed to later stages. The treatments for oral cancer have functional and quality-of-life implications. The prognosis of oral cancer is determined by location, size of the tumor, and metastasis using the TNM clinical classification.

Oral trauma may be a life-threatening emergency because of the risk of airway compromise secondary to soft tissue edema and bleeding in the mouth. Once the airway and bleeding are controlled, these types of injuries require surgical stabilization followed by comprehensive follow-up

care. The patient must be monitored for airway stability, nutritional intake, and potential risk for infection.

Esophageal cancer, like oral cancer, is usually asymptomatic until later stages, with a poor outcome for recovery. The esophagus is lined with squamous cells. Cancers of the esophagus typically are either SCCA or adenocarcinoma. Squamous cell carcinoma usually affects the upper two-thirds of the esophagus, whereas adenocarcinoma affects the lower one-third of the esophagus, usually at the GEJ. The development of adenocarcinoma is related to GERD. Disruption of esophageal function affects the ability of the patient to acquire adequate nutrition and maintain a healthy weight.

Surgery, radiation therapy and chemotherapy, and endoscopic and minimally invasive procedures are used to manage esophageal cancer.

Esophageal trauma interferes with the patient's ability to swallow and to obtain nourishment. Most of these injuries occur accidentally, but some are self-inflicted. Outcomes of esophageal trauma are related to early treatment, the etiology of the trauma, and the severity and location of the trauma. Esophageal rupture or perforation can lead to circulatory collapse, shock, hemorrhage, and death. Surgical and endoscopic procedures are used to treat esophageal trauma.

# Chapter 57

## Coordinating Care for Patients With Stomach Disorders

*Kristy Gorman*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of stomach disorders
2. Explaining the pathophysiological processes of stomach disorders
3. Correlating clinical manifestations to pathophysiological processes of
  - a. Gastritis
  - b. Gastroenteritis
  - c. Peptic ulcer disease
  - d. Gastric cancer
4. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the stomach
5. Discussing the medical management of:
  - a. Gastritis
  - b. Gastroenteritis
  - c. Peptic ulcer disease
  - d. Gastric cancer
6. Describing complications associated with selected disorders of the stomach
7. Developing a comprehensive plan of nursing care for patients with stomach disorders
8. Developing a teaching plan for a patient with stomach disorders

### CONCEPTS

- Assessment
- Comfort
- Digestion
- Fluid and Electrolyte Balance
- Medication
- Nutrition

### ESSENTIAL TERMS

Achlorhydria  
Acute gastritis  
Adenocarcinoma  
Atrophic gastritis  
Chronic gastritis  
Chyme  
Dumping syndrome  
Duodenal ulcer  
Erosions  
Gastrectomy  
Gastric ulcer  
Gastritis  
Gastroenteritis  
*Helicobacter pylori*  
Hematemesis  
Melena  
Occult  
Peptic ulcer disease (PUD)  
Pernicious anemia  
Pyloroplasty  
Ulcer  
Urea breath testing

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Mrs. Sharon Taylor is a 37-year-old graphic designer. Over the last several months, she has had increased episodes of a burning sensation near the midline in the epigastrium and back. Her pain has been alleviated after eating. Mrs. Taylor has had recent episodes of pain waking her up a few nights a week. Mrs. Taylor schedules a visit to her advanced practice registered nurse (APRN). While she describes the pain pattern to her provider, the provider gathers additional information. On the basis of her history, the provider refers Mrs. Taylor to an internist who orders an endoscopy. The provider explains that the endoscopy allows visualization of the esophageal, gastric, and duodenal mucosal linings, as well as allowing tissue samples to be obtained for biopsy during the procedure...

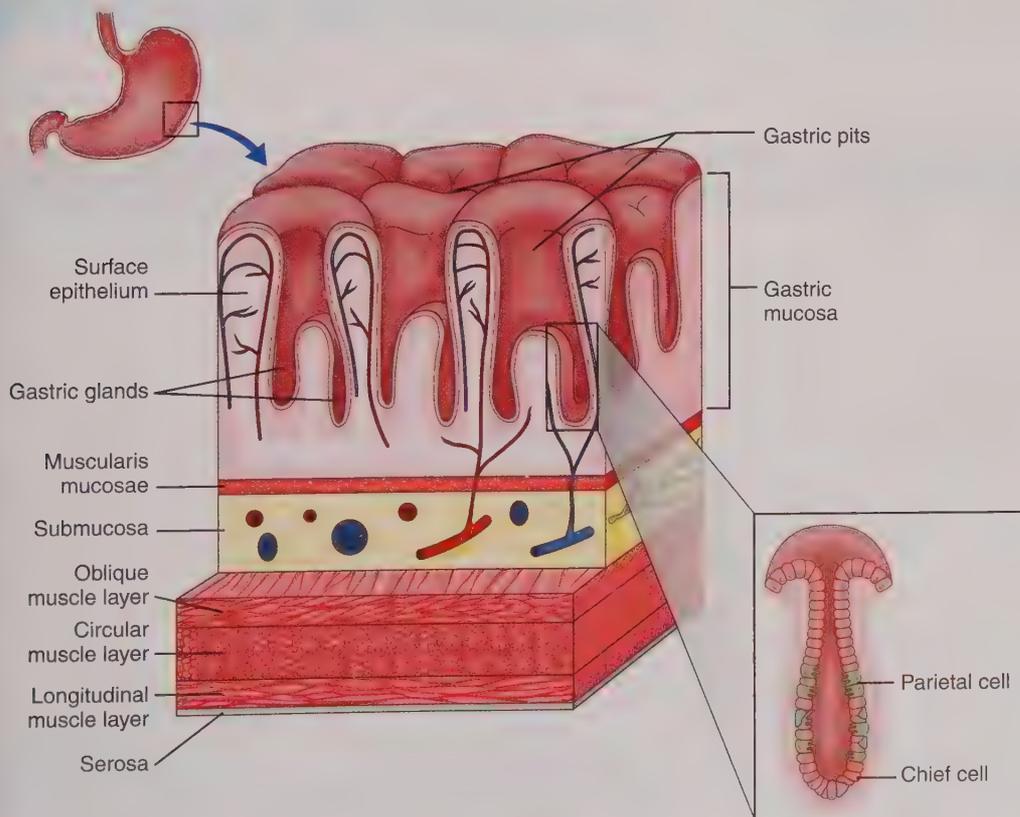

as a reservoir that permits eating large amounts of food at intervals of several hours. Food contained in the stomach is mixed, churned, and transported into the duodenum. The first stages of protein and carbohydrate digestion occur in the stomach. Very few substances are absorbed across the gastric mucosa (stomach lining), but water and alcohol are absorbed.

A person's nutritional status depends not only on the type and amount of intake but also on proper gastric functioning. Although only a few diseases affect the stomach, they can be very serious and in some cases life threatening. The most common disorders include **gastritis** (inflammation of the gastric lining), gastroenteritis, peptic ulcer disease (PUD), and gastric cancer, and each of these disorders can affect digestion and nutrition.

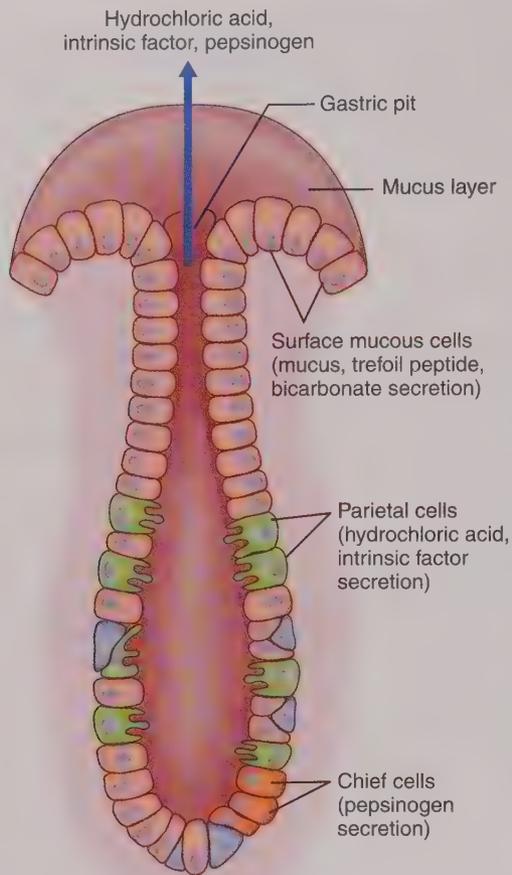

The gastric mucosa in the stomach wall contains many deep glands (Fig. 57.1), and these glands contain parietal (oxyntic) cells, which secrete hydrochloric acid and intrinsic factor, and chief (zymogen, peptic) cells, which secrete pepsinogens (Fig. 57.2). These secretions aid in the digestion and absorption of nutrients. Several of the glands open on a common chamber called the *gastric pit* at the surface of the mucosa. Mucus is secreted along with bicarbonate by mucous cells on the surface of the epithelium, creating a viscoelastic and highly alkaline gel to lubricate and protect the GI tract wall. Important mediators of these protective mechanisms include nitric oxide, intrinsic nerves, peptides, and prostaglandins. Prostaglandins exert their effect through improved mucosal blood flow, decreased hydrochloric acid

## INTRODUCTION

The stomach is part of the upper gastrointestinal (GI) system that is responsible for much of the digestive process. The stomach receives food from the esophagus and acts

**FIGURE 57.1** Microscopic anatomy of the stomach wall.

**FIGURE 57.2** Structure of a gastric gland from the fundus and body of the stomach. These acid- and pepsinogen-producing glands are referred to as “oxyntic” glands in some sources.

secretion, increased bicarbonate secretion, and enhanced mucus production. The epithelial cells in the mucosal layer of the stomach have a high turnover rate and are replaced every 4 to 5 days. Because of the regenerative abilities of the mucosal layer, injury to this layer heals rapidly without leaving scar tissue (Table 57.1).

**GASTRITIS**

Gastritis is a localized or patchy inflammation of the gastric mucosa and may be acute (lasting several hours to a few days) or chronic, resulting from repeated exposures to irritating agents or recurring episodes of acute gastritis. When the gastric mucosa is damaged by agents such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), ethyl alcohol, or bile salts, this barrier is disrupted, and hydrogen ions move into the tissue. While the hydrogen ions build up in the mucosal cells, intracellular pH (acidity) decreases, enzymatic reactions deteriorate, and cellular structures are disrupted. Aspirin and NSAIDs inhibit prostaglandin synthesis, which also disrupts the integrity of the mucosal surface. Hydrochloric acid can then diffuse back into the mucosa and injure small vessels. This causes edema, hemorrhage, and ulceration of the stomach’s lining.

**Types of Gastritis**

As described earlier, gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposures to irritating agents or recurring episodes of acute gastritis. **Acute gastritis** is characterized by an acute mucosal inflammatory process that may be accompanied by

**Table 57.1 Cell Types in the Glandular Gastric Epithelium**

Types of Cells	Characteristics
<b>Mucous cells</b>	Secrete mucus, predominately in the cardiac and pyloric glands. In gastric glands, they are called <i>mucous neck cells</i> and are concentrated in the narrow neck of the gland where it opens into the gastric pit.
<b>Regenerative (stem) cells</b>	Found in the base of the pit and neck of the gland, divide rapidly, and produce a continual supply of new cells. Newly generated cells migrate upward to the gastric surface as well as downward into the glands to replace cells that die.
<b>Parietal cells</b>	Found mostly in the upper half of the gland; secrete hydrochloric acid, intrinsic factor, and a hunger hormone called <i>ghrelin</i> . They are found mostly in the gastric glands, but a few occur in the pyloric glands.
<b>Chief cells</b>	The most numerous. Secrete the enzymes gastric lipase and pepsinogen. They dominate the lower half of the gastric glands but are absent from cardiac and pyloric glands.
<b>Enteroendocrine cells</b>	Concentrated in the lower end of a gland; secrete hormones and paracrine messengers that regulate digestion. They occur in all regions of the stomach but are most abundant in the gastric and pyloric glands.  Each of the eight kinds of enteroendocrine cells produces a different chemical messenger.

hemorrhage into the mucosa. Early clinical manifestations may include a thickened, reddened mucous membrane with extrusive rugae, or longitudinal folds. Various degrees of mucosal necrosis and inflammatory reaction occur in acute gastritis, and in severe cases, sloughing of the surface mucosa may lead to acute GI bleeding.

**Chronic gastritis** is prolonged, persistent, or intermittent inflammation of the gastric mucosa and is characterized by patchy, diffuse inflammation of the mucosal lining of the stomach. The presence of chronic inflammatory changes eventually leads to atrophy of the glandular epithelium of the stomach. The major types of chronic gastritis include *Helicobacter pylori* gastritis (the most common), autoimmune gastritis, and **atrophic gastritis** which is a type of chronic gastritis that is seen most often in older adults. *H. pylori* infection, which is prevalent in approximately half of the world's population, is known to be a key cause of chronic gastric inflammation that progresses to atrophy, characterized by total loss of fundal glands, minimal inflammation, thinning of the gastric mucosa leading to atrophy, and abnormal cellular changes. These alterations can lead to peptic ulcers and gastric cancer. The combination of bacterial factors, environmental insults, and the host immune response that drives the initiation and progression of mucosal atrophy, metaplasia, and dysplasia, leads toward gastric cancer.

## Epidemiology

Acute gastritis may be caused by chronic ingestion of irritating foods and alcohol or a complication of acute illnesses including traumatic injuries, such as burns, severe infection, hepatic, renal, or respiratory failure, or major surgery. Endotoxins released from infecting bacteria such as staphylococci, *Escherichia coli*, and *Salmonella* can lead to gastritis by immune cell infiltration and cytokine production. Bacterial and viral infections are often considered food poisoning because contaminated food is the usual route of entry.

Overuse of aspirin and other NSAIDs is a high risk factor for acute gastritis, with risk factors including alcohol, cytotoxic agents, caffeine, corticosteroids, and antimetabolites. Acute gastritis is also caused by local irritation from radiation therapy and ingestion of poisons (e.g., dichlorodiphenyl-trichloroethane [DDT], ammonia, mercury, and carbon tetrachloride).

Erosive or stress-induced gastritis (a severe form of acute gastritis) is a complication of conditions such as shock, severe trauma, or major surgery and is most likely due to inadequate gastric mucosal blood flow during periods of intense physiological stress. Adequate mucosal blood flow is important to maintain the mucosal barrier and to buffer any back-diffused hydrogen ions. When blood flow is inadequate, these processes fail, and mucosal breakdown occurs.

## Pathophysiology

The most common cause of gastritis is *H. pylori*. Other causes of gastritis include alcohol, NSAIDs, Crohn's disease, tuberculosis, and bile reflux. These agents cause injury by

different mechanisms. In general, the infectious and inflammatory causes result in immune cell infiltration and cytokine production, which damage mucosal cells. Irritating agents such as alcohol, aspirin, and bile generally work to disrupt the mucosal barrier, causing mucosal damage by back diffusion of hydrogen ions. This process allows gastric juices to come into contact with the gastric tissue, producing mucosal reddening, edema, and superficial surface erosion. Ulceration may occur and can lead to hemorrhage.

## Connection Check 57.1

The nurse is screening patients for their risk of developing acute gastritis. The nurse should consider which patient at greatest risk?

- A. A 25-year-old woman who has a vegan diet
- B. A 32-year-old man who takes ibuprofen daily
- C. A 77-year-old man who smokes
- D. An 80-year-old woman who takes low-dose aspirin daily for atrial fibrillation

Chronic gastritis and prolonged inflammation of the stomach may be caused either by chronic local irritation or by the bacterium *H. pylori*. Chronic gastritis has also been associated with the presence of antibodies to parietal cells and intrinsic factor. The intrinsic factor is critical for absorption of vitamin B<sub>12</sub>. When body stores of vitamin B<sub>12</sub> are depleted, hemoglobin cannot be synthesized and **pernicious anemia** results.

The most common form of chronic gastritis is caused by *H. pylori* infection. *Helicobacter pylori* has an estimated rate of infection of over half of the world's population and could reach up to 70% in developing countries and up to 20% to 30% in industrialized countries. The incidence of *H. pylori* increases in people older than 60, and transmission is likely person-to-person by vomitus, saliva, feces, or inadequately treated drinking water. *Helicobacter pylori* may also come from contaminated food that has not been washed well or cooked properly.

It is not known for certain how *H. pylori* spreads, so prevention is difficult. Vaccines are under development to prevent or even cure *H. pylori* infection. To help prevent infection, it is advised that people wash their hands with soap and water after using the bathroom and before eating, eat food that has been washed well and cooked properly, and drink water from a clean, safe source.

*Helicobacter pylori* is a spiral-shaped, gram-negative microorganism that can colonize the highly acidic human stomach. *H. pylori* has multiple flagella, which assist in migrating deep within the gastric and duodenal mucosa. The bacteria have the ability to sense pH and produce large amounts of urease, which buffers the acidity of the environment. Urease catalyzes the hydrolysis of urea to create ammonia and ammonium ions, resulting in the pH elevation of the environment. By creating a neutral environment, *H. pylori* reduces the viscoelasticity of the mucus, in turn permitting it to swim

freely to penetrate the mucous layer and attach to epithelial cells beneath, where it can cause inflammation over the course of lifelong infection. The reduction in the viscoelasticity impacts the integrity of the mucous layer, compromising its function as a protective barrier against acid. The persistent inflammation extends deep into the mucosa, causing destruction of the gastric glands, metaplasia (cellular changes), and atrophy (cell loss). The mechanism of atrophy has been shown to be directly related to effects of bacterial toxins and the cytokine environment within the gastric mucosa. More virulent bacterial strains and a permissive host immune response are strongly associated with atrophy and progression to severe disease.

## Clinical Manifestations

The clinical presentation of gastritis is associated with the damage to the gastric mucosa and typically includes epigastric pain, nausea and vomiting, weight loss, decreased appetite, and changes in color of the stool. Pain may be exacerbated with the ingestion of spicy foods. With atrophic gastritis, there may be no symptoms. In patients with acute gastritis or exacerbations of chronic gastritis, there may be evidence of dehydration or upper GI bleeding. With significant fluid or blood loss, the patient may develop signs of hypovolemic shock including pallor, tachycardia, and hypotension.

## Management

### Medical Management

#### Diagnosis

The diagnosis of gastritis cannot be based exclusively on clinical manifestations. The gross endoscopic diagnosis of gastritis correlates poorly with histological findings and is somewhat useless as a diagnosis without confirmatory biopsy. Additionally, there is poor correlation between clinical presentation and histological gastritis.

An upper GI x-ray series or endoscopy and histological examination of a tissue specimen obtained by biopsy may be useful for ruling out disorders that can suggest gastritis, such as gastric polyps and gastric neoplasms. If hemorrhage is suspected, stools may be tested until they are negative for occult (hidden) blood. Fecal occult blood can be detected by simple tests (e.g., guaiac, Hematest, Hemoccult) that cause color changes in samples of feces in the presence of blood.

**Urea breath testing** can be used to detect active infection with *H pylori*. A baseline breath test is first obtained. The patient then drinks a urea solution that contains a special carbon atom. *Helicobacter pylori* secretes an enzyme, urease, which breaks down the urea, releasing the carbon. Blood carries the carbon dioxide (CO<sub>2</sub>) to the lungs, and it is expelled in the breath. The amount of CO<sub>2</sub> is compared to the baseline sample. A positive urea breath test reveals low levels of exhaled carbon-13. Other tests for *H pylori* infection include serological testing and fecal antigen testing.

## Treatment

Collaborative care for the patient with acute gastritis is directed toward supportive care for relieving the clinical manifestations and removing or reducing the cause of discomfort. Healing is spontaneous and may occur within a few days. Gastrointestinal rest should be provided by 6 to 12 hours of NPO status, then slow reintroduction of clear liquids (broth, tea, gelatin, carbonated beverages), followed by ingestion of heavier liquids (cream soups, puddings, milk), and finally a gradual reintroduction of solid food. It is also important to eliminate irritating foods such as caffeine and spicy foods. If nausea and vomiting threaten fluid and electrolyte balance, IV fluids and electrolytes are ordered.

Medications are used to relieve pain and discomfort. Medications that block and buffer gastric acid secretions for pain relief are usually prescribed, including proton pump inhibitors (PPIs) and H<sub>2</sub>-receptor antagonists. Proton pump inhibitors act by inhibiting H<sup>+</sup>/K<sup>+</sup>-ATPase enzyme in the gastric parietal cells. It is this enzyme that is responsible for the production of hydrochloric acid in the stomach. Esomeprazole, lansoprazole, or pantoprazole 30 to 60 mg intravenously twice daily may be given initially, increased as necessary to maintain intragastric pH greater than 4.

Antacids are generally aluminum- or magnesium-containing compounds that decrease gastric acidity by neutralizing the acid (Maalox, Mylanta). They also have been shown to heal ulcers successfully by binding bile acids, inhibiting pepsin, promoting growth of new blood vessels in injured mucosa, increasing local prostaglandin synthesis, and binding growth factors, which increases their concentration at areas of mucosal injury. Sucralfate (Carafate) may also be prescribed. Sucralfate has no effect on gastric pH but provides a physical barrier to prevent mucosal damage by gastric acid. It does this by binding to the granulation tissue in exposed ulcer beds. The combination of antacids and sucralfate should be avoided because of the potential formation of a solid mass. Patients with chronic gastritis may require long-term parenteral or oral vitamin B<sub>12</sub> supplementation for the prevention or treatment of pernicious anemia.

Although they are not routinely recommended unless a life-threatening consequence ensues, there are a wide variety of treatment regimens available for eradicating infections in individuals with clinical manifestations of disease attributable to *H pylori*. The success of *H pylori* cure depends on the type and duration of therapy, patient compliance, and factors such as antibiotic resistance. There are various treatment regimens for *H pylori* eradication, and most include the combination of a PPI with two antibiotics for 7 to 14 days. Using combinations of antimicrobial agents reduces the risk of antibiotic-resistant *H pylori* strains. Triple therapies are recommended as first-line treatments. Quadruple therapy is recommended as second-line treatment when triple therapies fail (Table 57.2).

**Table 57.2 Common Treatment Regimens for *Helicobacter pylori***

Treatment Regimen	Eradication Rates (%)	Comments
<b>Triple Therapy</b>		
Proton pump inhibitor (PPI)	73–86	Often used as first-line therapy; in the United States, recommendation is to treat for at least 10 days
<i>plus</i>		
Clarithromycin 500 mg twice daily or metronidazole 500 mg twice daily		
<i>plus</i>		
Amoxicillin 1 g twice daily for 7–14 days		
<b>OR</b>		
PPI	70–85	May be used as first-line therapy in penicillin-allergic patients
<i>plus</i>		
Clarithromycin 500 mg twice daily		
<i>plus</i>		
Metronidazole 500 mg twice daily for 7–14 days		
<b>Quadruple Therapy</b>		
Bismuth subsalicylate 525 mg four times daily	75–90	Usually used as second-line therapy in patients who fail to respond to triple therapy
<i>plus</i>		
Metronidazole 250 mg orally four times daily		
<i>plus</i>		
Tetracycline 500 mg orally four times daily		
<i>plus</i>		
PPI twice daily (or ranitidine 150 mg orally twice daily) for 10–14 days		
<b>Levofloxacin-Based Triple Therapy</b>		
PPI twice daily	60–80	Often recommended for second-line or rescue therapy
<i>plus</i>		
Levofloxacin 250–500 mg twice daily		
<i>plus</i>		
Amoxicillin 1 g twice daily for 10 days		
<b>Sequential Therapy</b>		
PPI twice daily	83–98	Overall eradication rate greater than 90%; recommended for second-line or rescue therapy but may also be considered for initial therapy
<i>plus</i>		
Amoxicillin 1 g twice daily for the first 5 days followed by PPI twice daily		
<i>plus</i>		
Clarithromycin 500 mg twice daily and tinidazole 500 mg twice daily for the next 5 days		

From Greenberger, N., Blumberg, R., & Burakoff, R. (2016). *Current diagnosis & treatment gastroenterology, hepatology, & endoscopy* (3rd ed.). New York, NY: McGraw-Hill; Crowe, S. (2014, June). Treatment regimens for *Helicobacter pylori*. Retrieved from [www.UpToDate.com](http://www.UpToDate.com)

## Diet

The patient's daily caloric needs, food preferences, and eating pattern must be taken into consideration. The patient is instructed to avoid spicy foods and other foods noted to exacerbate symptoms. Bland, nonspicy diets and smaller frequent meals have been known to minimize gastric distress. The patient is also warned to avoid aspirin. If clinical manifestations persist, the patient may take antacids. The patient is also advised to be sure that foods and water are safe, to protect themselves against exposure to toxic substances (e.g., lead and nickel), and to quit smoking.

### Connection Check 57.2

The nurse recognizes that the treatment of *H pylori* includes which medications? (Select all that apply).

- A. PPIs
- B. Antiemetics
- C. Antibiotics
- D. NSAIDs
- E. Antacids

## Surgical Management

In the rare patient requiring surgical intervention for severe hemorrhagic gastritis, the options include vagotomy (surgery to sever the vagus nerve to reduce secretion of acid within the stomach), partial or total **gastrectomy** (removal of the stomach), or **pyloroplasty** (enlarging the pylorus opening). Such surgery is necessary only if more conservative measures have failed to control the bleeding. Surgical interventions are discussed in further detail in the Peptic Ulcer Disease section.

## Nursing Management

### Assessment and Analysis

Gastritis is a condition in which the stomach lining is inflamed and refers specifically to abnormal inflammation in the stomach lining. Many people with gastritis have no symptoms. Those who are symptomatic may experience dyspepsia—upper abdominal discomfort or pain, nausea, or vomiting. Clinical manifestations include:

- Epigastric pain
- Nausea and vomiting
- Decreased appetite
- Weight loss
- Changes in color of the stool

### Nursing Diagnoses

- **Acute pain** related to irritated stomach mucosa
- **Anxiety** related to treatment
- **Deficient knowledge** about dietary management and the disease process
- **Risk for deficient fluid volume** related to insufficient fluid intake and excessive fluid loss subsequent to vomiting

## Nursing Interventions

### Assessments

- **Vital signs**  
*Increased heart rate and decreased blood pressure are caused by fluid volume deficit from vomiting or blood loss.*
- History of presenting signs and symptoms  
*Heartburn, indigestion, and nausea and/or vomiting are clinical manifestations of gastritis. Dyspepsia (heartburn) may occur after ingestion of certain medications (aspirin/NSAIDs) or alcohol. Gastritis caused by endotoxins (food poisoning) has an abrupt onset.*
- Laboratory assessment for *H pylori*  
*Breath and stool analyses are non-invasive ways to test for H pylori. Carbon-13 urea breath test determines the presence of bacteria. Enzyme-linked immunosorbent assay (ELISA) stool testing can detect the H pylori antigen in a fresh stool specimen.*
- Serum electrolytes  
*In the patient with vomiting, the serum potassium may be low due to loss in the vomitus. With fluid deficit, the serum sodium may be elevated.*
- Intake and output  
*Pain and decreased appetite may limit the patient's intake of food and fluid, and fluid loss may lead to dizziness, tachycardia, and hypotension.*

### Actions

- **Administer IV fluids as prescribed**  
*Fluid replacement is prescribed in patients with severe fluid loss. If nausea and vomiting threaten fluid and electrolyte balance, IV fluids and electrolytes are ordered.*
- **Administer H<sub>2</sub>-receptor antagonists as prescribed**  
*H<sub>2</sub>-receptor antagonists block gastric secretions.*
- **Administer antacids as prescribed**  
*Antacids are used as buffering agents to correct the pH balance of the acidic gastric environment.*
- **Administer PPIs as prescribed**  
*Antisecretory agents (PPIs) can be used to suppress gastric acid secretion.*

### Teaching

- Immediately report **hematemesis** (vomiting of blood)  
*Hemorrhagic gastritis may lead to vomiting of blood. The vomited blood can be bright red or can have a dark "coffee grounds" appearance. Immediate correction of blood loss may be required to prevent hemorrhagic shock and is dependent on the amount of blood loss and the rate of bleeding.*
- Take medications as prescribed  
*It is important to take medications as prescribed, even if the symptoms are relieved, until discontinued by the prescriber. Teach patients not to take other over-the-counter medications if they are taking related prescribed medications, and it is best to review these medications with their healthcare provider.*
- Avoid medications and other irritants that are associated with gastric episodes  
*Read all over-the-counter drug labels that may contain NSAIDs or aspirin. Limit intake of food and spices that*

cause gastric episodes, such as caffeine, citrus juices, or hot spices. A bland, nonspicy diet combined with smaller, more frequent meals may prevent distress.

- Follow prescribed dietary teaching regarding types of foods and how to introduce back into the diet. *Gastrointestinal rest should be provided by 6 to 12 hours of NPO status, then slow reintroduction of clear liquids, followed by ingestion of heavier liquids, and finally a gradual reintroduction of solid food. It is also important to eliminate irritating foods such as caffeine and spicy foods.*

### Evaluating Care Outcomes

The patient can recover in approximately 1 day because of the ability of gastric mucosa to repair itself. The patient's appetite may be diminished for approximately 2 to 3 days. Patients with gastritis can achieve full recovery by complying with the prescribed therapy and avoiding irritating substances such as caffeine, alcohol, and NSAIDs. Expected outcomes include vital signs within normal limits, decreased pain, report of less anxiety, and compliance with the therapeutic regimen. The patient and family should be knowledgeable of the signs of gastritis and what clinical manifestations should be reported to their healthcare provider.

### Connection Check 57.3

- The nurse recognizes which gastric disorder as a complication of inadequate mucosal perfusion secondary to intense physiological stress?
- Erosive gastritis
  - Chronic gastritis
  - Duodenal ulcers
  - Esophageal reflux

## GASTROENTERITIS

**Gastroenteritis** is a self-limiting illness of the digestive system in which inflammation of the lining of the stomach and small intestines produces watery diarrhea, abdominal pain or cramping, nausea or vomiting, and sometimes fever. Most cases are infectious, although gastroenteritis may occur after ingestion of medications and chemical toxins (e.g., metals, plant substances). Gastroenteritis may also be called the “stomach flu”, traveler’s diarrhea, or food poisoning.

### Epidemiology

Infectious gastroenteritis may be caused by ingestion of a virus, bacteria, or parasite. Viruses are the leading cause of acute gastroenteritis in the United States. Viral spread may be transmitted from person to person by fecal-oral route of contaminated food and water, or by airborne transmission, as in norovirus. The viruses most commonly implicated are Norovirus and Rotavirus. Other viruses that may cause gastroenteritis include adenoviruses, echoviruses, and

coxsackieviruses. Many types of bacteria cause foodborne illnesses, and the most generally implicated are *Staphylococcus aureus*, *Salmonella*, *Shigella*, *Clostridium botulinum*, *Clostridium perfringens*, *Campylobacter* and *Escherichia coli*. Bacteria may cause gastroenteritis by several mechanisms:

- *Salmonella* and *Campylobacter* – ingesting raw or undercooked poultry, seafood, unpasteurized milk
- *Campylobacter* – ingesting raw or undercooked chicken and unpasteurized milk; also may be transmitted by dogs or cats with diarrhea
- *Salmonella* – ingesting undercooked eggs and by contact with reptiles, birds, or amphibians.
- *Shigella* – transmitted person to person by fecal-oral route or foodborne

Organisms such as *E coli* and *Clostridium* species are normal enteric flora found in the large intestine. Pathogenic strains can cause gastroenteritis, and *E Coli* O157:H7 is the strain that causes the most severe illness. Parasites such as *Ascaris*, *Enterobius*, and *Trichinella spiralis*; *Giardia* and *Cryptosporidium* may cause gastroenteritis. It is typically acquired via person-to-person transmission (often in day care centers) or from ingesting contaminated water.

Other causes of gastroenteritis may include adverse effects from antibiotics, enzyme deficiencies, food allergens and ingestion of toxins, such as poisonous plants or metals. Studies suggest that the use of acid-suppressing medications such as proton pump inhibitors (PPIs) may increase the risk of developing gastroenteritis by reducing the acidic environment that provides an initial defense against gastrointestinal infections. Proton pump inhibitor therapy is also suggested to be a risk factor for the development and recurrence of *C difficile* colitis as well as increasing the risk of *Campylobacter* gastroenteritis.

### Pathophysiology

The bowel reacts to the various causes of gastroenteritis with increased luminal fluid that cannot be absorbed. This causes abdominal pain, vomiting, severe diarrhea, followed by the depletion of intracellular fluid resulting in dehydration and electrolyte loss. Studies of rotaviruses found the virus attaches and enters mature enterocytes at the tips of small intestinal villi, causing structural changes to the small bowel mucosa. Consequently, maldigestion of carbohydrates occurs causing an accumulation in the intestinal lumen. This leads to malabsorption of nutrients and a concomitant inhibition of water reabsorption.

Bacterial gastroenteritis is less common than viral, but also results in diarrhea from various causes. Certain bacteria produce enterotoxins, exotoxins, or spread by mucosal invasion.

- Enterotoxins (produced by *E coli* and *C difficile*) adhere to the intestinal mucosa but do not invade. These toxins stimulate adenylate cyclase, which produces hypersecretion of fluid and electrolytes, resulting in watery diarrhea.

- Exotoxins are produced by bacteria such as *Staphylococcus aureus*, *C. perfringens*, and *Bacillus cereus*. These toxins generally cause nausea, vomiting, and diarrhea within 12 hours of ingestion of contaminated food. Symptoms usually resolve within 36 hours.
- Mucosal invasion occurs with bacteria such as *Shigella*, *Salmonella*, *Campylobacter*, *Clostridium difficile*, some *E. coli* subtypes that invade the mucosa of the small bowel or colon and cause small ulcerations, bleeding, protein-rich fluid excess, and secretion of electrolytes and water. The resulting diarrhea contains WBCs and RBCs and sometimes gross blood.

The *Giardia intestinalis* parasites adhere to or invade the intestinal mucosa, causing nausea, vomiting, diarrhea, and general malaise. The infection can become chronic and cause a malabsorption syndrome.

### Clinical Manifestations

The clinical presentation of gastroenteritis includes diarrhea, nausea, vomiting, anorexia, abdominal distention and discomfort, poor skin turgor, dehydration, hyperactive bowel sounds, decreased blood pressure and dry mucus membranes. *Clostridium botulinum* and some chemicals affect the nervous system, causing clinical manifestations such as headache, tingling or numbness of the skin, blurred vision, weakness, dizziness, and paralysis.

### Management

#### Medical Management

##### Diagnosis

Diagnosis is made by clinical evaluation or by stool culture, although PCR (assays used to screen for specific organisms), and immunoassays are increasingly used. Stool testing is guided by assessment findings and the organisms that are suspected based on patient history and epidemiologic factors (e.g., immunosuppression, exposure to a known outbreak, recent travel, recent antibiotic use). Cases are typically stratified into

- Acute watery diarrhea (most likely viral)
- Subacute or chronic watery diarrhea (may be parasitic)
- Acute inflammatory diarrhea without blood and presence of WBCs (may indicate bacterial)
- Acute inflammatory diarrhea with blood (test for *E. coli* and *C. difficile*)
- Diarrhea with gross blood (test for amebic dysentery, shigellosis, and *E. coli* O157:H7 infection; rule out ulcerative colitis via sigmoidoscopy)

A gram stain of a stool culture (by direct rectal swab), or blood culture may be performed to show the causative bacteria. The stool is checked for ova and parasites. Performing a rapid antigen testing of stool identifies rotavirus infection.

### Treatment

Supportive treatment, including oral or IV rehydration is all that is needed for most patients. Antidiarrheal agents such as Loperamide hydrochloride (Imodium) may be used if fever is absent and stools are free of blood and *C. difficile* or *E. coli* O157:H7 infection is not suspected. Oral bismuth subsalicylate may be given for relief of abdominal cramping. Antibiotics are prescribed only in select cases and should not be given until stool culture results are known. An antiemetic may be beneficial if the patient is vomiting.

### Diet

Initially, clear liquids are prescribed as tolerated. Oral glucose-electrolyte solutions, broth, or bouillon may prevent dehydration or treat mild dehydration. Even if vomiting, encourage the patient to take frequent small sips of such fluids; vomiting may subside with volume replacement. Gradually reintroduce foods starting with bland and easy-to-digest foods. Caffeine and milk products should be avoided.

### Nursing Management

#### Assessment and Analysis

Patient history focuses on severity of diarrhea and dehydration. The onset, frequency, quantity, and duration of diarrhea and vomiting are key factors in assessing patient status. Data regarding oral intake, urine output, and weight loss is collected and the patient is asked about recent travel history (including cruise ships), eating history, and day care history. Ruling out other diagnoses is important. Mucus or gross blood in the stool almost always indicates bacterial or parasitic infection.

#### Nursing Diagnoses

- **Acute Pain** related to inflammation
- **Diarrhea** related to GI dysfunction, infection, and toxins
- **Dysfunctional Gastrointestinal Motility** related to diet, food intolerance, nutritional status, toxins or ingested contaminated material, and treatment regimen

#### Nursing Interventions

##### Assessments

- Vital signs, including orthostatic measurements  
*Decreased intravascular fluid volume due to loss of body fluid causes a drop in blood pressure and elevated heart rate. Orthostatic vital signs are performed to assess for fluid volume deficit. Tachycardia with hypotension occurs with hypovolemia.*
- Abdomen for distention  
*Distention occurs when increased fluid and gas can't pass freely through the GI tract.*
- Bowel sounds and bowel elimination pattern  
*Hyperactive bowel sounds can be characterized as loud, gurgling, splashing, or rushing; they're higher pitched and occur more frequently than normal bowel sounds. Hyperactive bowel sounds follow sudden nausea and vomiting.*

- Serum electrolytes, BUN, and creatinine  
*Evaluates hydration and acid-base status in patients who appear seriously ill. Potassium and other electrolytes may be lost with severe diarrhea. Severe dehydration and acidosis are life-threatening.*
- Intake and output  
*The patient is at risk of fluid loss due to vomiting and diarrhea associated with the gastroenteritis. Tracking intake (including oral fluids, IV fluids and flushes, IV medications, tube feedings and flushes, and liquid medications, as well as fluid output, including urine, liquid stool, vomitus, blood, and drainage from tubes), provides important data regarding fluid status.*
- Perineal skin status  
*Skin breakdown and infection may result from diarrhea.*
- Skin and mucous membranes for signs of dehydration  
*Decreased skin turgor occurs with moderate to severe dehydration. Other findings include dry oral mucosa, dry and furrowed tongue, and increased thirst.*
- Pain level and effectiveness of interventions  
*It is important to recognize the characteristics (type, severity, onset, etc) and duration of the pain to guide ongoing assessment and determine the possible causes.*

### ■ Actions

- Perform hand hygiene  
*Meticulous hand hygiene is practiced to prevent spread of the contagion. Use alcohol-based hand rub (ABHR) on hands before and after direct patient contact, before donning and after removing gloves, after contact with body fluids, mucous membranes, nonintact skin, or wound dressings if hands aren't visibly soiled. Wash hands with soap and water when hands are visibly soiled with blood or another body fluid or after potential exposure to *C. difficile*, *Bacillus anthracis*, or *Norovirus*.*
- Administer IV fluids if the patient is unable to tolerate clear liquids; if IV fluids are needed, ensure patent IV access.  
*The patient is at risk of fluid and electrolyte imbalance due to vomiting and diarrhea. Vomiting may subside with volume replacement.*
- Administer prescribed medications, such as antidiarrheals  
*Antidiarrheals, such as loperamide, decrease peristalsis and decreases the number of bowel movements.*
- Give clear liquids or oral rehydration solutions  
*Replaces lost fluids and electrolytes.*
- Allow uninterrupted rest periods.  
*Provide bed rest with convenient access to a toilet or bedpan.*
- Apply venous thromboembolism (VTE) prophylaxis  
*Decreased intravascular volume, along with decreased mobility, increase the risk for thromboembolism*
- Provide meticulous perineal care, including sitz baths if indicated  
*Performing warm sitz baths three times per day will relieve anal irritation*
- Provide frequent oral care, including lip emollients  
*Fluid deficit increases the risk of dry oral mucous membranes and cracked lips.*

### ■ Teaching

- Include the patient's family or caregiver in teaching  
*Compliance with teaching often increases when patient and family are both included in the teaching*
- Dietary modifications  
*Clear liquids initially and then progressing the diet as the nausea, vomiting, and diarrhea subside.*
- Preventive measures, especially when traveling  
*Explain that traveler's diarrhea is caused by inadequate sanitation and occurs after bacteria-contaminated food or water is ingested.*
- Proper food preparation  
*Bacteria can contaminate food at any time during growth, harvesting or slaughter, processing, storage, and shipping. Foods may also be contaminated with bacteria during food preparation in a restaurant or home kitchen. Bacteria multiply quickly when the temperature of food is between 40 and 140 degrees. Thoroughly cooking food kills bacteria.*
- Preventive measures  
*Rotavirus immunization is part of the recommended infant vaccination schedule. To prevent recreational waterborne infections, people should not swim if they have diarrhea. Infants and toddlers should have frequent diaper checks and should be changed in a bathroom and not near the water. Swimmers should avoid swallowing water when they swim.*

### Evaluating Care Outcomes

Effective outcomes are demonstrated when the patient consumes the prescribed diet without diarrhea, nausea or vomiting. The patient exhibits balanced intake and output and demonstrates no further signs of fluid volume loss. The patient identifies pain intensity on a pain scale and rates the pain consistently. The patient has normal laboratory values and stable vital signs. Preventive measures include the patient identifying causative factors of gastroenteritis and demonstrating prevention behaviors.

## PEPTIC ULCER DISEASE

An ulcer in the GI tract may be defined as a break in the lining of the mucosa, with considerable depth and involvement of the submucosa. Erosions are breaks in the surface epithelium that do not have measurable depth. The term **peptic ulcer disease (PUD)** is used broadly to include ulcerations and erosions in the stomach and duodenum from a variety of causes. This is because pepsin, which is proteolytic in acidic solution, plays a major role in causing the mucosal breaks regardless of the cause of the provoking agent (e.g., *H. pylori*, aspirin, or an NSAID).

### Types of Peptic Ulcers

There are two major forms of peptic ulcers: **duodenal ulcers** and **gastric ulcers**, both of which are chronic. Duodenal ulcers make up approximately 80% of peptic ulcers, affect the proximal part of the small intestine following a chronic course, and are characterized by remissions

and exacerbations (with complications that necessitate surgery in approximately 5% to 10% of patients). Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus.

## Epidemiology

Peptic ulcer disease is very common in the United States, with approximately 4.5 million individuals (new cases and recurrences) affected per year. The majority of peptic ulcers occur in people between 25 and 64 years of age, and the lifetime prevalence of PUD in the United States is equal among men and women. An estimated 15,000 deaths per year occur as a consequence of complicated PUD (e.g., GI hemorrhage, abdominal or intestinal infarction, perforation, and penetration).

In the past, stress and anxiety were thought to be causes of PUD, but research has shown that the principal risk factors of PUD are *H pylori* infection and NSAID use. Infection with the gram-negative bacterium *H pylori* may be acquired through ingestion of contaminated food and water. Familial tendency (such as type O blood) has been reported as a predisposing factor but now is thought to stem mainly from intrafamilial infection with *H pylori*. There is also a connection between peptic ulcers and certain medical conditions such as chronic obstructive lung disease and chronic renal failure, but the cause is unclear. Other causes include exposure to irritants, trauma, psychogenic factors, and normal aging. Alcoholic beverages stimulate gastric acid production, and high concentrations of alcohol to the gastric mucosa cause mucosal injury. Cigarette smoking may predispose people to PUD and may interact with *H pylori* and NSAIDs to increase mucosal injury. Smoking also impairs ulcer healing and increases ulcer recurrence. Studies demonstrate that cigarette smoke and the active ingredients in cigarettes are associated with death of mucosal cells, inhibition of cell renewal, decreased GI mucosa blood flow, interference with the mucosal immune system, and promotion of tumor growth. In rare cases, peptic ulcers are found in patients with a gastrin-secreting tumor causing profound acid secretion as part of Zollinger-Ellison syndrome (Box 57.1).

## Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (hydrochloric acid) and pepsin. Erosions result from the corrosive action of acid gastric juice on a vulnerable epithelium caused by an imbalance between mucosal defenses and acid/peptic injury. A damaged mucosa cannot secrete enough mucus to act as a barrier against gastric acid. Depending on the circumstances, the ulcer may penetrate only the mucosal surface, or it may extend into the smooth muscle layers. Healing of the smooth muscle layers involves replacement with scar tissue. The mucosal layers that cover the scarred muscle layer have the ability to regenerate; however, the regeneration is often imperfect, which contributes

## Box 57.1 Risk Factors for Peptic Ulcers

- *Helicobacter pylori* infection
- NSAID and aspirin use
- Excessive smoking and alcohol ingestion
- Other medications (e.g., potassium chloride, concomitant use of steroids with NSAIDs, bisphosphonates, sirolimus, mycophenolate mofetil, fluorouracil)
- Neoplasia
- Acid hypersecretory disorders (e.g., Zollinger-Ellison syndrome)
- Hyperparathyroidism
- Crohn's disease
- Sarcoidosis
- Myeloproliferative disorder
- Systemic mastocytosis
- Other rare infections (e.g., cytomegalovirus, herpes simplex, tuberculosis)
- Critically ill patients with severe burns, head injury, physical trauma, or multiple organ failure

Source: Greenberger, N., Blumberg, R., & Burakoff, R. (2016). *Current diagnosis & treatment gastroenterology, hepatology, & endoscopy* (3rd ed.). New York, NY: McGraw-Hill.

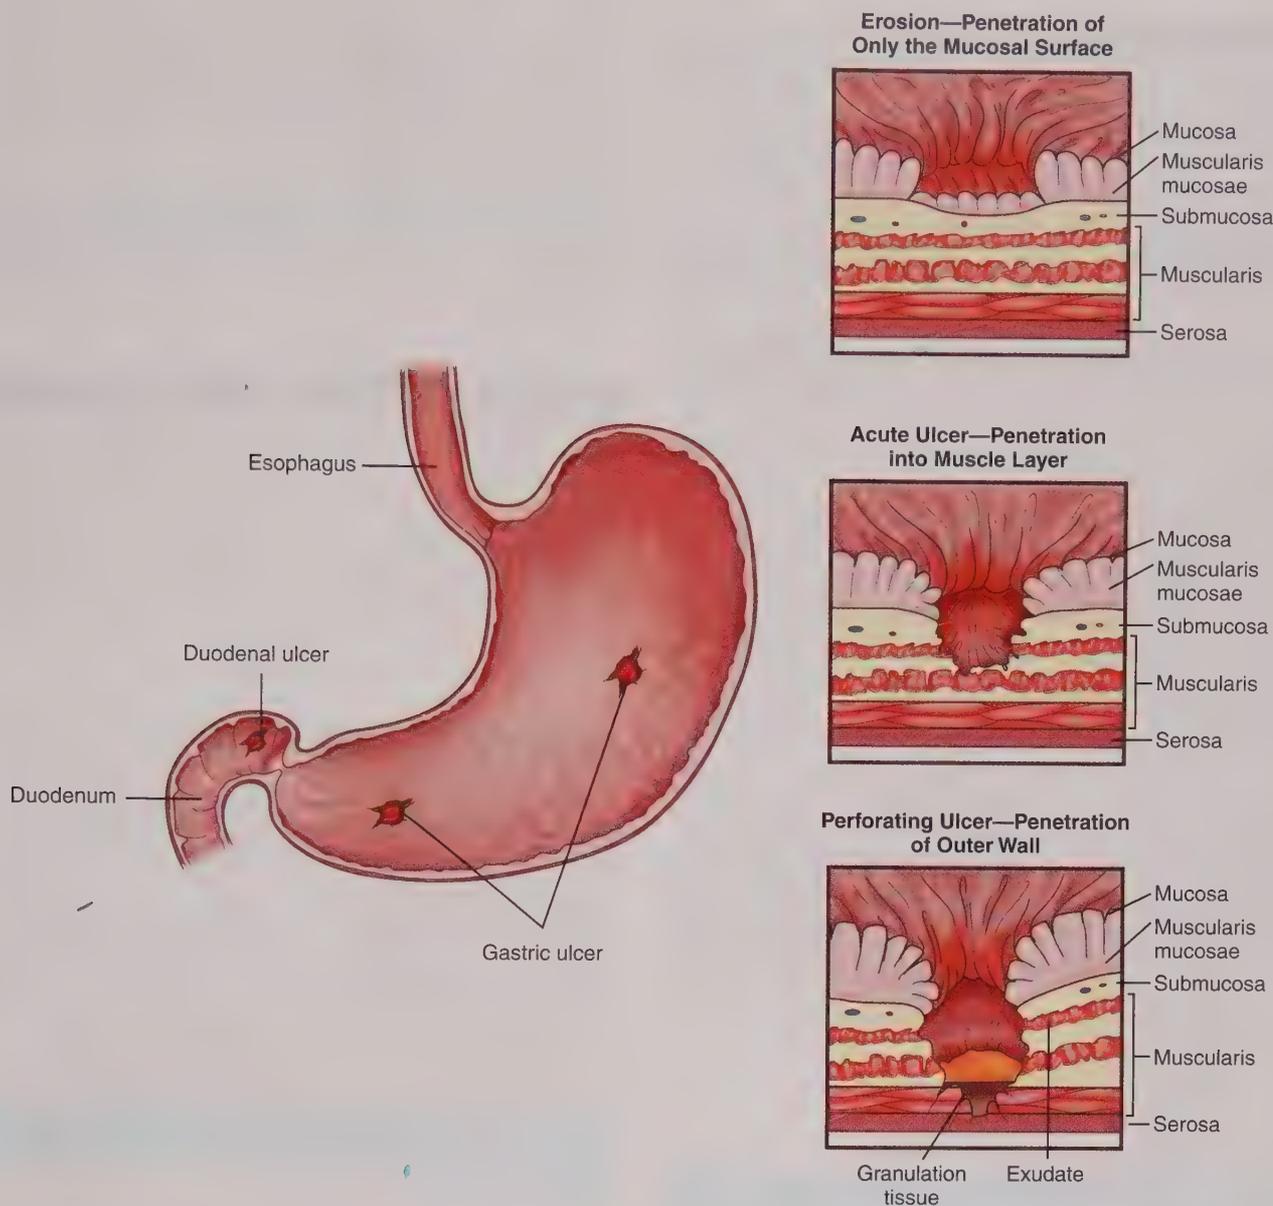

to repeated episodes of ulceration. An ulcer may penetrate the outer wall of the stomach or duodenum, but this is rare (Fig. 57.3).

In a peptic ulcer resulting from *H pylori*, acid is not the dominant cause of bacterial infection but contributes to the consequences. *Helicobacter pylori* releases a toxin that promotes mucosal inflammation and ulceration, stimulating the release of cytokines and other mediators of inflammation that contribute to mucosal damage. Damage to gastroduodenal mucosa allows for decreased resistance to bacteria, and thus infection from *H pylori* bacteria may occur.

Peptic ulcer disease resulting from NSAIDs has both topical and systemic origins. Damage to the cells may occur when NSAIDs diffuse across the mucosal layer and into epithelial cells because they also inhibit the production of prostaglandins that protect epithelial cells in the GI tract from acid-related damage. Inhibition of prostaglandin synthesis increases gastric acid and pepsin secretion, decreases bicarbonate, reduces gastric mucosal blood flow, and decreases mucus production. This disrupts the integrity of the mucosal surface, allowing gastric acid to diffuse back into the mucosa and injure small vessels, leading to edema, hemorrhage, and ulceration of the stomach's lining.

## Clinical Manifestations

The clinical presentation of PUD depends on ulcer location and patient age. Many patients (particularly older adults) have few or no clinical manifestations. Pain is the most common symptom. Burning epigastric pain aggravated by fasting and improved with food or antacids (which neutralize the acid) is a symptom complex associated with a *duodenal ulcer*. Pain may also awaken the patient from sleep because of nocturnal gastric acid secretion.

**FIGURE 57.3** Peptic ulcers. Erosions result from the corrosive action of acid gastric juice on a vulnerable epithelium caused by an imbalance between mucosal defenses and acid/peptic injury. A damaged mucosa cannot secrete enough mucus to act as a barrier against gastric acid. Depending on the circumstances, the ulcer may penetrate only the mucosal surface, or it may extend into the smooth muscle layers as an acute ulceration. The ulcer may also penetrate the outer wall of the stomach or duodenum and perforate the outer wall.

With a *gastric ulcer*, pain is triggered or worsened by eating, usually occurring shortly after meals with little or no relief from antacids. It is believed that the pain occurs when the increased acid content of the stomach and duodenum erodes the lesion and stimulates the exposed nerve endings. Contact of the lesion with acid stimulates a local reflex mechanism that also initiates contraction of the adjacent smooth muscle.

The pain is usually located over a small area near the midline in the epigastrium near the xiphoid and may radiate below the costal margins into the back or, rarely, to the right shoulder. Superficial and deep epigastric tenderness and voluntary muscle guarding may occur with more extensive lesions. An additional characteristic of ulcer pain is periodicity,

as the pain tends to recur at intervals of weeks or months. During an exacerbation, it occurs daily for a period of several weeks and then remits until the next recurrence.

**Safety Alert** Do not make assumptions about pain. Acute pain may be indicative of a complication, such as perforation (sudden, intense epigastric pain and rigid abdominal muscles), or it may be totally unrelated to peptic ulcer disease (e.g., pancreatitis, coronary heart disease, or gallbladder disease). The nurse needs to ensure a comprehensive evaluation of the pain, particularly with an acute onset.

### Connection Check 57.4

The nurse correlates which clinical manifestation to the pathophysiology of a gastric ulcer?

- Pernicious anemia
- Constipation
- Acute epigastric pain after eating
- Hypertension

### Connection Check 57.5

The nurse is caring for a 33-year-old woman who has been taking aspirin for back pain and has experienced a sudden episode of tachycardia and feeling faint. She also vomited coffee-ground emesis and passed a tarry stool but has no complaints of pain or heartburn. The patient wants to know why there was no sign of pain as a warning signal prior to the sudden bleeding. What is the nurse's best response?

- Pain is the most common sign of NSAID-induced gastric injury, so the patient must have a high pain tolerance.
- NSAIDs cause damage to epithelial cells, which inhibit the enteric nervous system response of the GI tract.
- NSAID-induced gastric injury often is without symptoms, and life-threatening complications such as GI bleeding can occur without warning.
- NSAIDs have anti-inflammatory and analgesic effects, preventing the patient from feeling any pain as a warning sign.

## Management

### Medical Management

#### Diagnosis

A diagnosis of a peptic ulcer may be suspected in patients presenting with epigastric pain but needs to be differentiated from other conditions with similar clinical manifestations, such as gastroesophageal reflux disease, biliary tract disease, hepatitis, pancreatitis, abdominal aortic aneurysm, gastroparesis, functional dyspepsia, neoplasia, mesenteric ischemia, and myocardial ischemic pain. Although peptic ulcers can be diagnosed during upper endoscopy, laboratory and radiological tests may help narrow the diagnosis. Some patients with peptic ulcers are anemic because of acute bleeding or chronic blood loss. Liver function tests and levels of amylase and lipase are evaluated for hepatitis and pancreatitis. An abdominal ultrasound may reveal gallstone disease or an abdominal aortic aneurysm. An electrocardiogram and measurement of cardiac enzymes may be used to evaluate myocardial causes of pain. Lastly, an upper GI and small bowel x-ray series with upright and lateral decubitus views showing free air indicates perforation.

Because of its increased sensitivity and specificity, upper GI endoscopy is the preferred procedure for evaluation of PUD, as compared with barium upper GI x-rays.

Endoscopy or esophagogastroduodenoscopy confirms the ulcer and permits cytology studies and biopsy to rule out *H pylori* or cancer. Noninvasive testing for PUD includes serum antibody testing, urease breath testing, and stool antigen testing. A complete blood count (CBC) is collected to rule out ulcer perforation, peritonitis (increased white blood count), and anemia. A fecal occult blood test is performed to check for blood in stools, and an ELISA is collected to detect Immunoglobulin G (IgG) antibodies to *H pylori* in the serum.

### CASE STUDY: EPISODE 2

The endoscopy is performed at an outpatient clinic near Mrs. Taylor's home 2 weeks after visiting her APRN. The endoscopy reveals several peptic ulcers. A tissue sample is taken from Mrs. Taylor's stomach lining. The tissue sample is positive for *H pylori*, a gram-negative bacterium that infects the stomach...

### Connection Check 57.6

A 67-year-old male is suspected of having a peptic ulcer. The nurse monitors for a decrease in which diagnostic value with GI hemorrhage in this patient?

- Reticulocyte count
- Hematocrit
- Prothrombin time
- IgG antibodies to *H pylori*

### Medications

The key goals of medication therapy include pain relief, ulcer healing, prevention of ulcer recurrence, and reduction of complications. Acid suppression remains a mainstay in healing both duodenal and gastric ulcers and in preventing recurrence. Therapy in patients who are *H pylori*-positive with active or previously documented ulcers is focused on eradicating *H pylori* infection and healing the ulcer. The objective of therapy in patients with NSAID-induced PUD is to heal the ulcer and remove the offending agent.

Antacids neutralize gastric acid, whereas the use of  $H_2$ -receptor antagonists decreases acid production.  $H_2$ -antagonists such as ranitidine, nizatidine, cimetidine, or famotidine block gastric acid secretion stimulated by histamine, gastrin, and acetylcholine. Patients with peptic ulcers or those who must continue NSAID therapy for some other disorder should be treated with PPIs such as omeprazole, lansoprazole, or pantoprazole for as long as the NSAID is used. Proton pump inhibitors block the final stage of hydrogen ion secretion by blocking the action of the gastric parietal cell proton pump. Other agents can be used to enhance mucosal defenses. Misoprostol, a prostaglandin E analog, has been shown to prevent gastric mucosal damage in chronic users of NSAIDs. Sucralfate

(Carafate) is more commonly used because it acts locally to enhance mucosal defenses. Sucralfate selectively binds to necrotic ulcer tissue and serves as a barrier to acid, pepsin, and bile and can directly absorb bile salts.

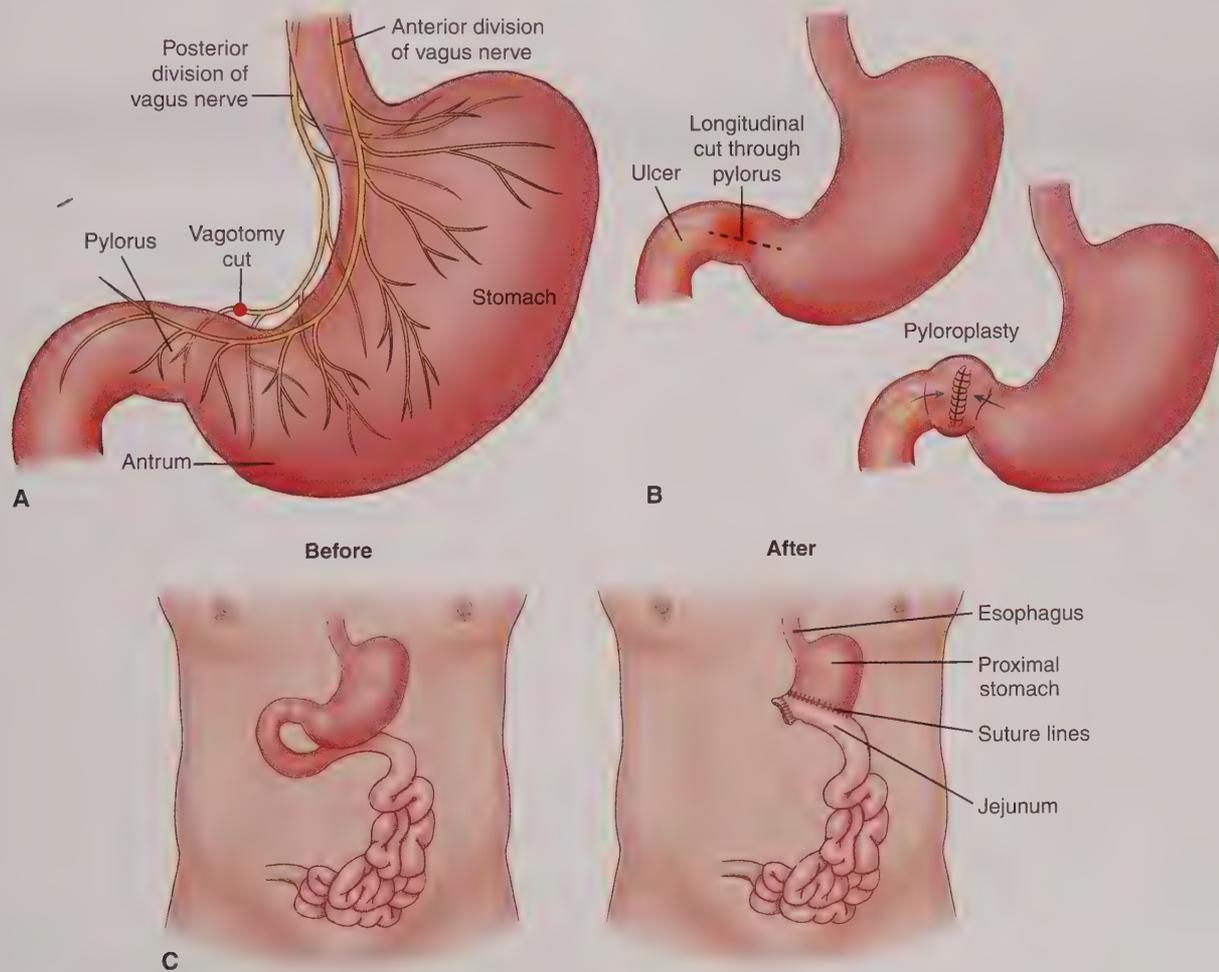

### Diet

The patient with PUD should avoid dietary irritants such as spices, alcohol, and caffeine. Consuming six small meals or small hourly meals is encouraged, along with intake of adequate fluids. If GI bleeding is evident, the patient should have nothing by mouth. Discourage smoking because it slows the rate of healing and increases the frequency of relapses.

### Surgical Management

With the increased effectiveness of medications to treat PUD, surgical treatment is usually only required with nonhealing and bleeding ulcers. Minimally invasive procedures involving endoscopic approaches allow ulcers to be removed or bleeding controlled. More conventional surgical

interventions are indicated for perforation, lack of response to conservative treatment, suspected cancer, or other complications. Gastric cancer must always be considered in patients with a gastric ulcer or gastric outlet obstruction. Surgery for PUD is dependent on type, location, and extent of the ulcer. Today, most patients having a procedure for PUD undergo oversewing of a bleeding ulcer, or patch of a perforated ulcer, or distal gastrectomy. Major operations include bilateral vagotomy, pyloroplasty, and gastrectomy (Fig. 57.4). The parietal cell vagotomy is safe (mortality risk less than 0.5%) and causes minimal side effects. The vagotomy severs the vagal nerve supply to the proximal two-thirds of the stomach, where the majority of the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus and the remaining abdominal viscera. The parietal cell vagotomy decreases total gastric acid secretion by approximately 75%, and GI side effects are rare. Considerations for PUD surgery should include whether *H. pylori* infection is present, the need for NSAID therapy, previous treatment, and the

**FIGURE 57.4** Various types of operations currently popular for treating duodenal ulcer disease. A, Bilateral vagotomy; The vagotomy severs the vagal nerve supply to the proximal two-thirds of the stomach, where the majority of the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus and the remaining abdominal viscera. B, Pyloroplasty; Enlarging the pylorus opening to allow stomach contents to empty more easily. C, Distal gastrectomy. Involves removing a section of the stomach with reattachment to the jejunum.

likelihood of future compliance with treatment. Pyloroplasty involves enlarging the pyloric opening allowing the stomach to empty more easily and is usually only performed after conservative medical treatments have failed. The distal gastrectomy involves removing the section of the stomach that is developing ulcers and attaching it to the jejunum.

### Connection Check 57.7

The nurse monitors for which clinical manifestations in the patient diagnosed with a duodenal ulcer? (Select all that apply.)

- Intermittent abdominal pain, which is relieved after eating and taking antacids but becomes worse at night
- Nausea and vomiting
- Right upper quadrant tenderness and is positive for occult blood in stool
- Complaints of heartburn or regurgitation and vomiting
- Bloating and flatulence

### Complications

The most common complications of PUD are GI hemorrhage, abdominal or intestinal infarction, perforation and penetration into attached structures, obstruction, and peritonitis. There is also an increased risk of gastric adenocarcinoma, a malignant tumor arising from glandular tissue, in patients with *H pylori*. Hemorrhage is caused by bleeding from granulation tissue or erosion of an ulcer into an artery or vein. A tear in the mucosa at the gastroesophageal junction (Mallory-Weiss syndrome) can occur as a result of severe vomiting, trauma, or seizures (Table 57.3; Box 57.2).

Peritonitis is defined as inflammation and infection of the serosal membrane that lines the abdominal cavity and contained organs. Bacteria invade the peritoneum after inflammation and perforation of the GI tract. Protein-filled fluid and electrolytes accumulate in the peritoneal cavity causing the peritoneum to become inflamed and edematous. The inflammation may be localized as an abscess, or diffuse extending throughout the peritoneum.

**Table 57.3 Complications of Peptic Ulcer Disease**

Complications of Peptic Ulcer Disease	Characteristics
<b>Gastrointestinal bleed</b>	<ul style="list-style-type: none"> <li>● May be sudden, severe, and without warning</li> <li>● Symptoms of pain may not be present (common with NSAID use)</li> <li>● Acute hemorrhage: sudden weakness; dizziness; cold, moist skin; passage of loose, tarry stools and coffee-ground emesis</li> <li>● Circulatory shock may develop depending on amount of blood loss</li> </ul>
<b>Penetration</b>	<ul style="list-style-type: none"> <li>● Ulcer crater penetrates through adjacent organs: small bowel, pancreas, liver, or biliary tree</li> <li>● Referred pain to sites other than the abdomen, intense and persistent</li> <li>● Gradual increase in pain severity and frequency</li> </ul>
<b>Perforation</b>	<ul style="list-style-type: none"> <li>● Ulcers on the anterior wall of stomach or duodenum</li> <li>● Release of gastrointestinal contents into peritoneum</li> <li>● Peritonitis causes sudden, intense epigastric pain</li> <li>● Abdomen is tender to palpation, abdominal muscles are rigid, and hypoactive or absent bowel sounds</li> <li>● Abdominal distention and third spacing</li> <li>● <i>Perforation is a serious medical condition requiring immediate attention</i></li> </ul>
<b>Obstruction</b>	<ul style="list-style-type: none"> <li>● Caused by edema, spasm, or contraction of scar tissue</li> <li>● Interference with free passage of gastric contents</li> <li>● Symptoms of early satiety, epigastric fullness and heaviness post meals, gastric reflux, weight loss, and abdominal pain</li> <li>● Severe obstruction: vomiting of undigested food</li> </ul>

## Box 57.2 Gastrointestinal Bleeding

Hematemesis, the vomiting of blood, is the hallmark of upper gastrointestinal bleeding. Bright red blood in the emesis is indicative of active bleeding. Coffee-ground emesis indicates older blood that has had time to be reduced by acid in the stomach. Melena is black, tarry stools with a foul odor due to the degradation of blood in the small intestine and colon.

### Nursing Management

#### Assessment and Analysis

Collection of patient history includes causes and risk factors for gastritis and PUD, with careful attention to aspirin and NSAID use. The physical examination includes:

- General appearance and height and weight relationship
- Abdominal examination including shape and contour
- Bowel sounds and tenderness to palpation
- Presence of obvious or occult blood in vomitus and stool

The patient with PUD may be asymptomatic or may experience periods of exacerbation and remission of clinical manifestations, with remissions lasting longer than exacerbations. Clinical manifestations may include:

- Left epigastric pain described as heartburn or indigestion accompanied by feeling of fullness or distention
- The pain usually is rhythmic and frequently occurs when the stomach is empty—between meals and at 1 or 2 o'clock in the morning.
- Increasingly severe and constant localized abdominal pain that increases with movement and respirations may indicate progressing peritonitis.
- Possible referral of pain to the shoulder or thoracic area
- Anorexia, nausea, and vomiting
- Inability to pass stools and flatus
- Hiccups

Because epigastric pain can also signal myocardial infarction, a 12-lead electrocardiogram is performed, and the patient is placed on telemetry to monitor for any dysrhythmias. Nursing care priorities include reducing discomfort, maintaining nutritional status, and preventing or rapidly identifying and intervening for potential complications. In a patient admitted with an acute bleed related to PUD, the immediate priorities of care are restoring blood volume and cardiac output.

#### Nursing Diagnoses

- **Acute pain or chronic pain** related to physical (gastric and/or duodenal mucosal) injury
- **Deficient knowledge** about prevention of symptoms and management of PUD

- **Disturbed sleep pattern** related to discomfort
- **Risk for deficient fluid volume** related to loss of blood

### Nursing Interventions

#### Assessments

- **Vital signs**  
*Vital signs including orthostatic measurements; increased heart rate and decreased blood pressure are caused by fluid volume deficit from vomiting. Orthostatic vital signs are performed to assess for fluid volume deficit. Loss of blood volume may cause orthostatic hypotension with syncope or dizziness upon standing. Orthostatic changes are present if there is a decrease of more than 20 mm Hg in systolic blood pressure, a decrease of 10 mm Hg in diastolic blood pressure when going from a supine to an upright position.*
- **Gastric pH as ordered, check emesis, and feces for occult blood**  
*The gastric Ph provides data regarding the acidity of gastric secretions. Monitoring for occult blood helps identify slow bleeding or recurrent hemorrhage.*
- **Use of alcohol or other medications, including aspirin and other NSAIDs**  
*NSAIDs break down the gastric mucosal barrier and result in local gastric mucosal injury. Alcohol is irritating to the gastric mucosal. Cigarette smoking is associated with death of mucosal cells, inhibition of cell renewal, and decreased GI mucosa blood flow.*
- **Serum electrolytes and blood urea nitrogen (BUN)**  
*Electrolytes are lost through vomiting, gastric drainage, and diarrhea. Careful monitoring is essential to identify possible shock and to intervene at an early stage. Serum potassium levels may be decreased with vomiting. Digestion and absorption of food in the GI tract may cause elevated BUN levels.*
- **Pain, including exacerbating and relieving factors.**  
*Food can act as an antacid by neutralizing gastric acid for approximately 30 to 60 minutes. Afterward, gastric acid secretion may increase. Foods that increase pain should be avoided.*
- **Diet, including pattern of food intake, eating schedule, and foods associated with pain**  
*This helps increase patient awareness and identifies whether nutrient intake is adequate.*
- **CBC**  
*If the patient is experiencing GI bleeding, hemoglobin and hematocrit values may be low. The WBC count may be elevated with inflammation or infection.*
- **Blood culture and/or peritoneal fluid culture**  
*A positive culture for the offending organism will guide the choice of antibiotic or antifungal therapy.*
- **Weight**  
*In the patient with increased pain or early satiety, intake of nutrients may be decreased, and the patient may exhibit weight loss.*

- Clinical manifestations of abscess formation, including persistent abdominal tenderness and fever.  
*An abscess may lead to fistula formation, septicemia, respiratory compromise, bowel obstruction, shock, and/or liver failure.*

### ■ Actions

- Maintain IV infusions and administer blood products as prescribed  
*IV fluids and blood products are given to restore blood volume and oxygen-carrying capacity.*
- Administer prescribed medication therapy  
*Pain relief can be achieved by giving prescribed medications such as PPIs before breakfast and antacids 1 to 3 hours after meals. Interventions for PUD related to H pylori are aimed at reducing pain related to the infection and promoting healing of the gastric mucosa.*
- Administer medications to reduce gastric acidity as ordered  
*Reducing the acidity of gastric secretions reduces the risk of bleeding.*
- Assist with gastric lavage, as indicated for GI bleeding; irrigate the nasogastric tube with room temperature saline as ordered  
*Irrigation helps remove irritating blood from the gut and may slow bleeding.*
- Prepare the patient and his family for upper endoscopy or surgery as planned  
*Endoscopy or emergency surgery may be performed to repair the bleeding site or sclerose bleeding vessels.*
- Limit food intake after the evening meal; eliminate bedtime snacks  
*Eating before bed can stimulate gastric acid and pepsin production, increasing the chance of night-time pain.*
- Document and report complaints of anorexia, fullness, nausea, vomiting, or symptoms of dumping syndrome  
*Problems with gastric emptying may be associated with PUD or surgery to treat PUD. It is important to monitor and report symptoms because a change in therapy or food intake may be necessary. Dumping syndrome develops secondary to concentrated, partially digested food entering the small bowel rapidly, causing abdominal distention.*
- Pain documentation to include location, character, timing and relationship to meals, and measures that relieve or aggravate the pain;  
*Monitoring for changes in pain is important in evaluating outcomes of therapies and to inform preventive measures.*

### ■ Teaching

- Take medications as prescribed  
*H<sub>2</sub>-receptor antagonists block gastric secretions. Antacids are used as buffering agents to correct the pH balance of the acidic gastric environment. Antisecretory agents (PPIs) can be used to suppress gastric acid secretion. Teach patients not to take other over-the-counter medications if they are taking related prescribed medications.*

- Avoid eating within two hours of bedtime.  
*Eating late increases the production of gastric acid that may irritate gastric lining*
- Advise patients to avoid risk factors such as overuse of aspirin and NSAIDs, spicy foods, and beverages that contain caffeine  
*Such foods and fluids have stimulatory effects on gastric acid secretion.*

### Evaluating Care Outcomes

Indicators that the patient with PUD has decreased pain include expressed feelings of increased comfort and pain control. The patient reports pain at a level of three or lower on a 0 to 10 scale. The patient consumes the prescribed diet without nausea or vomiting. The patient demonstrates no further signs of fluid volume loss.

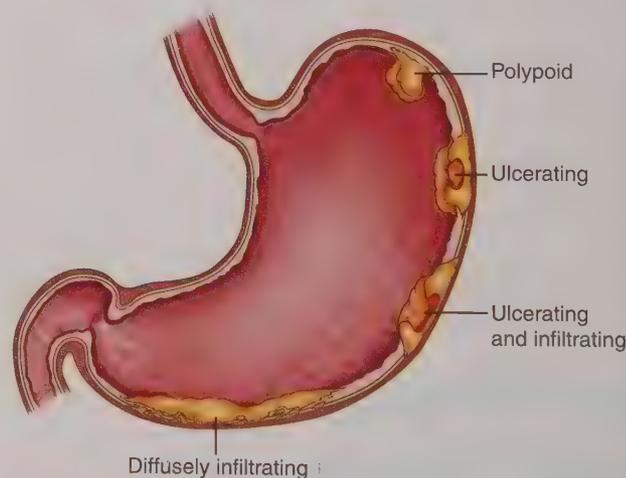

### Connection Check 57.8

The nurse incorporates which information into the teaching plan for a patient diagnosed with a duodenal ulcer?

- A. "You will probably have increased pain after eating."
- B. "Smoking cigarettes can make the PUD worse."
- C. "Antacids are not usually effective for the pain."
- D. "Eating bland foods will aid in healing."

### GASTRIC CANCER

Gastric cancer is cancer of the GI tract classified according to gross appearance (polypoid, ulcerating, ulcerating and infiltrating, or diffuse; Fig. 57.5) and is one of the most common forms of cancer worldwide. The prognosis is dependent on the stage of the disease at the time of diagnosis, and the 5-year survival rate is approximately 23%.

**FIGURE 57.5** Gross appearance of gastric cancer. Gastric cancer is classified according to gross appearance noted as polypoid, ulcerating, ulcerating and infiltrating, or diffusely infiltrative.

## Epidemiology

The incidence of gastric cancer varies widely, being highest in Hispanics, African Americans, and Asian Americans. It is more common in lower socioeconomic groups and affects males two times more often than females. Gastric cancer represented the leading cause of cancer-related mortality in the United States until the 1930s, and it was the leading cause of cancer-related deaths worldwide until the late 1980s, when lung malignancies peaked in occurrence. Although the overall incidence of stomach cancer in the United States has declined in the past 75 years, it is the second leading cause of cancer mortality worldwide.

Causes of gastric carcinomas are unknown. Diet appears to be a significant factor, with a diet rich in foods with additives such as smoked foods, pickled vegetables, and salted fish and meat increasing the risk of gastric cancer. Dietary nitrates are also proposed as a possible cause of gastric cancer. Gastric bacteria, more common in the **achlorhydric** (low hydrochloric acid) stomach of patients with atrophic gastritis, convert nitrate into nitrite, a proven carcinogen. The reduced consumption of nitrate-rich preserved foods has been suggested as a cause of the dramatic decrease in gastric cancer seen in North America and Western Europe.

The risk of gastric cancer is greater in patients with low gastric acidity (**achlorhydria**), such as those with severe atrophic gastritis associated with intestinal metaplasia and pernicious anemia. Chronic atrophic gastritis is by far the most common precursor for gastric cancer, and the prevalence of atrophic gastritis is higher in older age groups but can occur in people younger than 40 years of age.

Other related factors include chronic inflammation of the stomach, high alcohol consumption, smoking, family history, and *H pylori* infection. Patients with *H pylori*-associated ulcers have a three- to six-fold increased risk of gastric malignancy later in life. Because *H pylori* infection has been shown to cause gastric cancer, its elimination forms the cornerstone of eradication of gastric cancer. Many patients with *H pylori* infections have already developed atrophic gastritis, which is the precursor disorder to gastric cancer (see Evidence-Based Practice).

## Evidence-Based Practice

### Gastric Cancer and *Helicobacter pylori*

*Helicobacter pylori* is associated as a risk factor for development of gastric cancer. In an effort to more clearly explain the relationships between *H pylori* and gastric cancer, a prospective, double-blind, placebo-controlled, randomized trial was conducted on 470 patients who had undergone endoscopic resection of early gastric cancer or high-grade adenoma. The patients were randomized into two groups; one receiving *H pylori* eradication therapy with antibiotics, and the other receiving a placebo. The two

outcomes measured were metachronous gastric cancer detected on endoscopy one year after treatment, and improvement in glandular atrophy in a 3-year follow up examination. Findings demonstrated that patients with early gastric cancer in the treatment group had lower rates of cancer as well as improvement in the grade of gastric atrophy.

Choi, I.J., Kook, M.C., Kim, Y.I., Cho, S.J., Lee, J.Y., Kim, C.G., Park, B. & Nam, B. (2018). *Helicobacter pylori* therapy for the prevention of metachronous gastric cancer. *The New England Journal of Medicine*, 378(12), 1085–1095.

## Pathophysiology

A gastric adenocarcinoma is a malignant epithelial tumor that infiltrates the mucus-producing cells of the stomach and is most frequently found in the distal portion (pylorus and antrum). Gastric carcinogenesis is a multifactorial and multistep process, starting from chronic gastritis and progressing over many years to atrophy, intestinal metaplasia, dysplasia, and eventually adenocarcinoma. The risk of developing gastric cancer correlates best with the severity and extent of atrophic gastritis and gastric atrophy. Inadequate acid secretion in patients with atrophic gastritis creates an alkaline environment that allows bacteria (e.g., *H pylori*) to multiply and act on nitrates in food. Nitrates interact with amino acids in the stomach to form carcinogenic nitrosamines. The nitrosamines are converted to nitrites, which are a major risk factor for gastric cancer.

Approximately 95% of gastric cancers are adenocarcinomas, commonly classified as an *intestinal type* and a *diffuse type*. The intestinal type is associated with chronic atrophic gastritis, severe intestinal metaplasia and dysplasia, and tends to be less aggressive than the diffuse type. The diffuse type is associated with an invasive growth pattern in dispersed clusters of uniform-sized malignant cells that infiltrate the submucosa, causing thickening of the stomach wall (arising beneath normal-appearing epithelium). Metastases occur early because of the rich blood and lymphatic supplies to the stomach.

## Clinical Manifestations

Unfortunately, stomach cancers often are asymptomatic until late in their course, and the disease is often quite advanced, and metastases are usually present at the time of diagnosis. Clinical manifestations, when they do occur, are essentially nonspecific and include indigestion, anorexia, weight loss, vague epigastric pain, vomiting, and an abdominal mass. The patient may experience ulcer-like pain unrelieved by antacids, typically occurring after meals. Because these symptoms are vague, patients and healthcare providers tend to dismiss symptoms or treat

the patient for acid disease, which makes early detection difficult. While the disease progresses, the patient may be anorexic and cachectic at the time of diagnosis. An abdominal mass may be palpable, and erosion of the gastric tumor into a large perigastric vessel may cause life-threatening hemorrhage. Massive hematemesis or **melena**, black tarry stools with a foul odor due to the degradation of blood in the small intestine and colon, are uncommon, but secondary anemia may occur after occult blood loss.

## Management

### Medical Management

#### Diagnosis

Diagnosis of gastric cancer is accomplished by a variety of techniques including barium x-ray studies, endoscopic studies with biopsy, and cytological studies of gastric secretions. Barium x-rays of the GI tract with fluoroscopy show changes that suggest gastric cancer, including a tumor or filling defect in the outline of the stomach, loss of flexibility, and atypical gastric mucosa with or without ulceration. A chest x-ray may reveal metastasis.

Esophagogastroduodenoscopy is the visual examination of the lining of the esophagus, stomach, and upper duodenum using a flexible fiber-optic endoscope. This procedure identifies the cancer and helps rule out other diffuse gastric mucosal abnormalities by allowing direct visualization. Biopsy of visible gastric mucosal lesions can be obtained to determine the presence of cancer cells. Computed tomography (CT) and endoscopic ultrasonography may be used to determine the spread of a diagnosed stomach cancer. This allows evaluation of the depth of the tumor and presence of lymph node involvement for staging of the cancer.

Laboratory studies such as CBC may reveal anemia, evidenced by low hematocrit and hemoglobin values. Patients may have macrocytic or microcytic anemia associated with decreased iron or vitamin B<sub>12</sub> absorption. Liver function study results (e.g., bilirubin and alkaline phosphatase) may be elevated with metastatic spread of the cancer to the liver. Carcinoembryonic antigen radioimmunoassay may be elevated. A stool guaiac may test positive.

#### Medications

There are no specific medications for gastric cancer. Radiation and chemotherapy have not shown to be useful as primary treatment methods in stomach cancer because the disease is often widely spread to other abdominal organs upon diagnosis, and they are typically used for palliative purposes or to control metastatic spread of the disease. Antiemetics such as ondansetron, dronabinol, or metoclopramide are common regimens for nausea and vomiting control secondary to side effects of the therapy. Opioid analgesics are used for pain management, and vitamin supplementation is given for deficiencies.

**Safety Alert** Nausea and feelings of early satiety are common side effects of chemotherapy, which may impair nutrient consumption, indicating a need to institute enteral or parenteral feedings. Early nutrition screening and assessment can help to identify and minimize nutritional problems. It is important for data to be both subjective and objective when assessing the ability to consume adequate nutrients.

### Surgical Management

Gastric dysplasia is the universal precursor to gastric adenocarcinoma. Patients with severe dysplasia should be considered for gastric resection if the abnormality is widespread or multifocal. In patients with early stages of gastric cancer, laparoscopic surgery (minimally invasive surgery) plus adjuvant chemotherapy (anthracycline such as 5-fluorouracil) or radiation may be a curative option. However, long-term survival rates with surgery alone remain suboptimal for all but the earliest gastric cancer.

### Complications

**Dumping syndrome**, also known as rapid gastric emptying, is the most common complication after a partial gastrectomy. Alterations in the gastric anatomy after surgery or interference in its extrinsic innervation following a vagotomy may alter gastric emptying. After pyloric resection or bypass, concentrated **chyme** (partially digested food) may enter the small bowel rapidly, causing abdominal distention, inappropriate gut hormone release, and rapid glucose absorption. Early clinical manifestations (15-30 minutes after a meal) include dizziness, tachycardia, pallor, sweating, diarrhea, and palpitations. Signs of late dumping (1-3 hours after a meal) include symptoms of hypoglycemia such as weakness, sweating, and dizziness. Both can be life-threatening. Dumping syndrome is managed primarily by planning dietary intake to allow smaller boluses of undigested food to enter the intestine. Meals are small and more frequent. Liquids and solids are taken at separate times instead of together to facilitate adequate nutritional intake. Other complications of gastrectomy include wound infections, leaking of anastomotic sites, strictures, and internal bleeding.

### Nursing Management

#### Assessment and Analysis

Patients with early gastric cancer may have no clinical manifestations. However, the main clinical manifestations of early gastric cancer may include:

- Indigestion (heartburn)
- Abdominal pain/discomfort, initially relieved by antacids or nutrition changes
- Feeling of fullness
- Epigastric, back, or retrosternal pain
- Anorexia

While the tumor grows, these signs and symptoms become more severe and do not improve with dietary changes or antacids. Clinical manifestations of advanced gastric cancer include:

- Nausea and vomiting
- Obstructive symptoms
- Iron-deficiency anemia
- Palpable epigastric mass
- Enlarged lymph nodes
- Weakness and fatigue
- Weight loss
- Metastasis

### Nursing Diagnoses

- **Pain** related to the tumor mass
- **Anxiety** related to the disease and anticipated treatment
- **Fear** related to well-being or potential death
- **Imbalanced nutrition: less than body requirements** related to early satiety or anorexia leading to decreased intake

### Nursing Interventions

#### ■ Assessments

- **Physical examination, assessing for signs of metastasis**  
*Carefully assess the patient's abdomen for distention and/or a palpable mass, which may suggest hepatomegaly from metastasis. Percuss to detect ascites. Also palpate the patient's lymph nodes, especially the supraclavicular and axillary nodes. Hard, enlarged lymph nodes result from metastasis. Examine the patient for other assessment findings that depend on the extent of disease and location of metastasis.*
- **Hematocrit and hemoglobin**  
*With advanced disease, hematocrit and hemoglobin levels may be decreased because of anemia secondary to hematemesis or melena. Macrocytic or microcytic anemia results from decreased vitamin B<sub>12</sub> absorption due to lack of intrinsic factor*
- **Serum electrolytes**  
*Electrolytes are lost through vomiting, gastric drainage, and diarrhea. Serum potassium levels may be decreased with vomiting. Digestion and absorption of blood in the GI tract may cause elevated BUN levels.*
- **Bilirubin and alkaline phosphatase**  
*Abnormal bilirubin and alkaline phosphatase occur with advanced disease and hepatic metastasis.*
- **A modified oral glucose tolerance test with hematocrit measurement**  
*Blood glucose levels between 120 and 180 minutes after drinking the solution, an increase in hematocrit of more than 3 percent at 30 minutes, and a rise in pulse rate of more than 10 beats per minute after 30 minutes confirms dumping syndrome.*
- **Comprehensive pain assessment**  
*Include location, characteristics, onset/duration, frequency, quality, intensity or severity, and precipitating factors. A pain management plan is developed on the basis of the patient's response to pain.*

#### • **Early signs of dumping syndrome**

*Symptoms include vertigo, increased heart rate, syncope, sweating, pallor, and palpitations. Early manifestations of dumping syndrome may occur within 30 minutes of eating and are a result of the rapid emptying of contents into the small intestine. Late dumping syndrome occurs 90 minutes to 3 hours after eating and is caused by excessive insulin release. Both can be life threatening. Alterations in the gastric anatomy after surgery or interference in its extrinsic innervation following a vagotomy may alter gastric emptying. After pyloric resection or bypass, concentrated chyme may enter the small bowel rapidly, causing abdominal distention, inappropriate gut hormone release, and rapid glucose absorption.*

- **Patient's level of anxiety (moderate, severe, or panic) and the reality of the threats represented in the patient's current situation**  
*The level of anxiety and the reality of the perceived threat influence what type of intervention is appropriate. A patient in panic may need medical intervention, whereas those with moderate or severe anxiety are often managed by counseling and teaching new coping skills.*
- **Assess the possible need for end-of-life care**  
*Gastric cancer and its treatment may cause debilitating adverse effects. Hospice programs can help both the patient and family learn symptom management and coping techniques.*

#### ■ **Actions**

- **Encourage the patient to eat small, frequent portions of nonirritating foods that are high in protein and calories along with dietary supplements**  
*Meals must be nutritionally adequate to promote healing. Adding vitamins and minerals, calories, or other nutritional components may be needed for the patient who is unable to eat a nutritionally adequate diet. Total parenteral nutrition may be necessary to maintain weight and nutrition and allow the GI tract to heal.*
- **Encourage the patient and family to verbalize feelings, concerns, and fears related to the diagnosis, prognosis, and treatment**  
*Because disease is usually advanced at the time of diagnosis, provide grief counseling and refer the patient and family to cancer support groups or hospice services as appropriate.*
- **Prepare the patient and family physically and emotionally for surgery as indicated**  
*Surgical resection is the preferred method for treating gastric cancer and may include total gastrectomy and partial gastrectomy. Surgery may be curative or palliative. Palliative resection may improve the quality of life if the patient is suffering from obstruction, hemorrhage, or pain.*

### Teaching

- Provide information to both the patient and family or caregiver.

*Review the disorder, diagnostic testing, and treatment, including surgery and combination chemotherapy*

- Discuss medications to be included in the chemotherapy plan

*Include drug names, dosages, routes of administration, expected results, and frequency of administration*

- Provide information approximately pain and precipitating factors

*The patient will be able to monitor discomfort and when to intervene as appropriate.*

- Teach the patient and family about high-calorie, high-protein meals

*Meals must be nutritionally adequate to promote healing.*

- Teach the patient and family about nutritional supplements

*Additional vitamins and minerals, calories, dietary fiber, and other supplements may be added to the diet of a patient with inadequate food intake.*

- Provide information about the signs of Dumping Syndrome and what can make this more likely to happen

*The patient is more likely to have this problem if they had surgery to take out all or part of the stomach. High sugar foods may cause the stomach to empty too fast. Avoid foods such as sweetened cereals, donuts, cakes, rolls, pastries, candies, cookies, soda, juice, or syrup.*

- Teach the patient relaxation techniques and coping strategies

*Relaxation techniques help reduce stress and promote healing. Techniques include deep breathing, guided visualization, and progressive relaxation.*

### Evaluating Care Outcomes

The major goals for the patient with gastric cancer include absence of infection, stable weight, reduced anxiety, optimal nutrition, relief of pain, and adjustment to the diagnosis. Expected outcomes for the patient include consuming prescribed diet without nausea or vomiting, expressing feelings of decreased anxiety, and verbalizing pain and effectiveness of comfort measures.

## Making Connections

### CASE STUDY: WRAP-UP

Mrs. Taylor's treatment of the peptic ulcers and infection includes two antibiotics, a PPI, and bismuth salts. She is instructed to take the entire course of her medications and to follow up with the internist in 6 months for a repeated endoscopy. The provider explains that failure to be compliant with the medication regimen may cause antibiotic resistance and persistent infection.

### Case Study Questions

1. The nurse is monitoring Mrs. Taylor, who has been diagnosed with a peptic ulcer. Which assessment finding most likely indicates perforation of the ulcer?
  - A. Bradycardia
  - B. Numbness in the legs
  - C. Sudden and severe epigastric pain
  - D. Nausea and vomiting
2. Mrs. Taylor is scheduled for a vagotomy and asks the nurse about the purpose of this procedure. Which response by the nurse is most accurate?
  - A. Diminishes stress reactions
  - B. Heals the gastric mucosa
  - C. Reduces the stimulus to acid secretions
  - D. Decreases food absorption in the stomach
3. The nurse is monitoring for the early clinical manifestations of dumping syndrome. Which findings are consistent with this complication?
  - A. Sweating and pallor
  - B. Bradycardia and indigestion
  - C. Double vision and chest pain
  - D. Abdominal cramping and pain
4. The nurse is reviewing the medication record regarding Mrs. Taylor's PUD. Which medication, if noted on the patient's record, will the nurse question?
  - A. Rabeprazole sodium (AcipHex)
  - B. Furosemide (Lasix)
  - C. Indomethacin (Indocin)
  - D. Propranolol hydrochloride (Inderal)
5. The healthcare provider has ordered a blood test for *H. pylori*. How does the nurse prepare the patient for this diagnostic test?
  - A. Instructing the patient not to consume food or liquids after midnight
  - B. Giving an oral suspension of glucose 1 hour before the test
  - C. Explaining that a small dose of radioactive isotope will be used
  - D. Telling the patient that no special preparation is needed

## CHAPTER SUMMARY

Gastritis is an inflammation of the gastric mucosa caused by any of several conditions, including infection (*Helicobacter pylori*), medications (NSAIDs, alcohol), stress, and autoimmune disorders (atrophic gastritis). Many cases are asymptomatic, but dyspepsia and GI bleeding sometimes occur.

Diagnosis is by endoscopy. Treatment is directed at the underlying cause, although it often includes acid suppression and, for *H pylori* infection, antibiotics.

Gastroenteritis is an inflammatory process of the digestive system. Infectious gastroenteritis is typically caused by ingestion of a virus, bacteria, or parasite, with viruses the leading cause of acute gastroenteritis. Clinical manifestations include vomiting and diarrhea that may lead to dehydration and hypovolemia. Definitive treatment is based on identification of the cause of the gastroenteritis. Nursing priorities include monitoring fluid and electrolyte status, administering treatments focused on elimination of the causative agent, as well as treating the diarrhea, and ensuring adequate hydration and nutrition.

Hematemesis is vomiting of red blood and indicates upper GI bleeding. Coffee-ground emesis results from bleeding that has slowed or stopped and indicates older blood that has had time to be reduced by gastric acid in the stomach. Patients with chronic blood loss may present with clinical manifestations of anemia (e.g., weakness, easy fatigability, pallor, chest pain, dizziness). Patients with less significant degrees of bleeding may simply have mild tachycardia (heart rate > 100 bpm). Orthostatic changes in pulse (a change of > 10 bpm) or blood pressure (a drop  $\geq$  10 mm Hg) often develop after acute loss of greater than or equal to 2 units of blood.

*Helicobacter pylori* is a common gastric pathogen that causes gastritis, peptic ulcer disease (PUD), and gastric cancer. Infection may be asymptomatic or result in varying degrees of dyspepsia. Diagnosis is by urea breath test and testing stool samples. Treatment is with a proton pump inhibitor plus two antibiotics.

A peptic ulcer is defined as an erosion of the GI mucosa, typically in the stomach (gastric ulcer) or the proximal region of the duodenum (duodenal ulcer), that may penetrate only the mucosal surface, or it may extend into the smooth muscle layers. Virtually all ulcers are caused by *H pylori* infection or NSAID use. Symptoms typically include burning epigastric pain that is often relieved by food. Diagnosis is by endoscopy and testing for *H pylori*. Treatment involves acid suppression, eradication of *H pylori* (if present), and avoidance of NSAIDs.

The etiology of gastric cancer is multifactorial, but *H pylori* plays a significant role. Symptoms include early satiety, obstruction, and bleeding but are likely to occur late in the disease. Diagnosis is by endoscopy, followed by CT and endoscopic ultrasound for staging. Treatment is mainly surgery; chemotherapy may provide a temporary response. Long-term survival is poor except for those with local disease. Gastric cancer is often diagnosed late in the disease because symptoms may be vague or nonexistent. Encourage all patients with complaints of dysphagia, a sensation of gastric fullness, or heartburn to seek medical evaluation.

# Chapter 58

## Coordinating Care for Patients With Intestinal Disorders

*Vickie M. Lester*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of infectious and noninfectious intestinal disorders
2. Correlating clinical manifestations with the pathophysiological processes of:
  - a. Hernias
  - b. Hemorrhoids
  - c. Irritable bowel syndrome
  - d. Inflammatory bowel disease
  - e. Celiac disease
  - f. Diverticulitis
  - g. Appendicitis
  - h. Colorectal cancer
  - i. Abdominal trauma
3. Describing the diagnostic results used to confirm the diagnoses of selected disorders of the intestine
4. Discussing the medical management of:
  - a. Hernias
  - b. Hemorrhoids
  - c. Irritable bowel syndrome
  - d. Inflammatory bowel disease
  - e. Celiac disease
  - f. Diverticulitis
  - g. Appendicitis
  - h. Colorectal cancer
  - i. Abdominal trauma
5. Describing complications associated with selected disorders of the intestine
6. Developing a comprehensive plan of nursing care with intestinal disorders
7. Developing a teaching plan for a patient with intestinal disorders

### CONCEPTS

- Assessment
- Bowel Elimination
- Cellular Regulation
- Comfort
- Digestion
- Infection
- Inflammation
- Medication
- Nutrition
- Perfusion
- Safety

### ESSENTIAL TERMS

Abdominoperineal resection  
Abscess  
Anastomosis  
Colectomy  
Colostomy  
Cullen's sign  
Diverticulum  
Dyspepsia  
Ecchymosis  
Eructation  
Familial adenomatous polyposis (FAP)  
Fecalith  
Fissure  
Fistula  
Gluten  
Grey Turner's sign  
Hemicolectomy  
Hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome  
Herniorrhaphy  
Ileostomy  
Kock (Koch) pouch  
McBurney's point  
Metastasis  
Narcotic bowel syndrome  
Ostomy  
Proctocolectomy  
Rovsing's sign  
Stoma  
Strictures  
Tenesmus  
Turner's sign

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Jack Conner is a 17-year-old male who has been experiencing abdominal pain and has recently noticed blood in his stool. He has been awakening at night frequently to have bowel movements, all grossly bloody and watery. He has only recently let his parents know of these problems, and an appointment is made with his primary healthcare provider. Jack is a high school senior who is involved in theatre and choir activities in school...

## INTRODUCTION

The intestinal system is composed of the small and large intestines. The main functions of the intestinal system are digestion, absorption, and elimination of waste products. The small intestine is approximately 20 ft (6 m) in length and extends from the pylorus to the ileocecal valve, which connects the small intestine to the large intestine. The small intestine's primary function is digestion and absorption of nutrients across the intestinal wall into the circulation. Enzymes are secreted throughout the small intestine to aid in the breakdown of food into absorbable nutrients. There are three sections to the small intestine:

- Duodenum—attaches to the pylorus and is approximately 10 in. (25 cm) long
- Jejunum—approximately 8 ft (2.5 m)
- Ileum—approximately 12 ft (3.5 m)

The large intestine is approximately 5 to 6 ft in length (1.5–1.8 m) and extends from the ileocecal valve to the anus. The large intestine's primary function is absorption of water. There is also some absorption of electrolytes, although not to the extent of absorption in the small intestine. Feces is formed in the large intestine where microorganisms break down proteins that were not absorbed in the small intestine. It also serves as a reservoir for feces until defecation. The large intestine is divided into three sections:

- Cecum—approximately 2 to 3 in. (5–8 cm)
- Colon
  - Ascending colon—located on the right side of the abdomen extending upward, bending at the hepatic flexure to become the transverse colon
  - Transverse colon—located horizontally across the abdomen from the hepatic flexure to the splenic flexure, becoming the descending colon
  - Descending colon—lies on the left side of the abdomen from the splenic flexure extending downward to the sigmoid colon

- Sigmoid colon—the lower “S-shaped” curve extending to the rectum
- Rectum—approximately 7 to 8 in. (17–20 cm) extending to the anus

The vermiform appendix is located behind the cecum and is approximately 3 to 4 in. (8–10 cm) long. It is an accessory organ of the intestinal system but has no known function.

## INTESTINAL DISORDERS

### Hernias

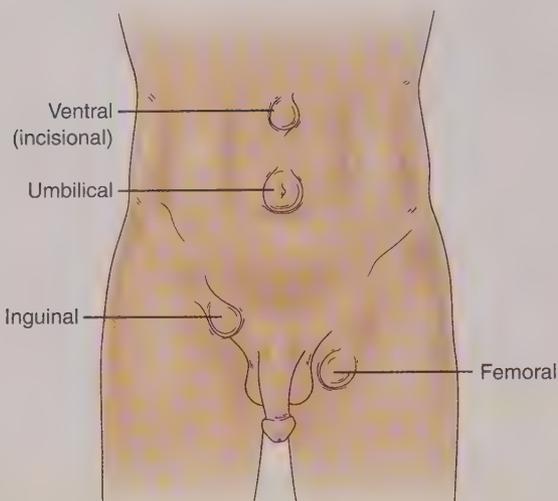

#### Epidemiology

A hernia is a protrusion of abdominal contents through an area of weakened muscle in the abdominal cavity and is one of the oldest recorded afflictions of mankind. Hernias can be congenital or acquired and typically occur because of weakened abdominal muscles accompanied by increased abdominal pressure. There are approximately 700,000 inguinal hernia repairs performed in the United States each year with an estimated direct annual cost of \$2.5 billion. Inguinal hernias are more common in men, whereas femoral hernias are more common in women. Ventral or incisional hernias develop in previous surgical incision sites usually as a result of infection or the patient had poor wound healing after surgery. Approximately 10% to 15% of patients with abdominal incisions develop a ventral hernia. Indirect inguinal hernias are the most common type and occur only in men. Risk factors for developing a hernia are obesity, smoking, excessive wound tension, malnutrition, pregnancy, and certain medications such as immunosuppressive agents.

#### Pathophysiology

Although a hernia can occur anywhere in the body, it most frequently occurs in the abdominal cavity, with the intestines protruding through an abnormal opening (Fig. 58.1). If the contents can easily be placed back into the abdominal cavity manually or by lying down, it is known as reducible. If the contents cannot be placed back into the abdominal cavity, it is known as irreducible or incarcerated. In patients with an incarcerated hernia, it can become strangulated, affecting intestinal flow and/or blood supply. If the blood supply is obstructed, it is then known as a strangulated hernia, and the patient may present with symptoms of an intestinal obstruction.

Common causes of hernias may include straining (straining to urinate or have a bowel movement), lifting heavy objects, sudden twists, pulls or muscle strain, weight gain, and chronic cough. Another cause may be a weakened area of abdominal muscle due to a previous abdominal surgery. While people age, muscular tissues become infiltrated and replaced by adipose and connective tissue, which also increases the risk of development of a hernia.

**FIGURE 58.1** Types of hernias. Inguinal hernias occur between the abdomen and the thigh and protrude through weakened muscles of the lower abdomen through the inguinal canal. Femoral hernias form due to fat enlargement in the femoral canal causing the pull of contents from the peritoneum into the hernia sac. Femoral hernias typically present below the inguinal ligament. Umbilical hernias are due to increased abdominal pressure and are typically caused by the omentum or peritoneal fat that incarcerates into the hernia. Ventral hernias form from a previous abdominal surgical incision and usually manifest as a bulge along the incision.

## Types of Hernias

### Inguinal

Approximately 96% of groin hernias are inguinal, and they are more common in males than females. In the groin between the abdomen and the thigh, intra-abdominal fat or part of the small intestine protrudes through weakened muscles of the lower abdomen through the inguinal canal. There are two types of inguinal hernias.

**Indirect Inguinal Hernia.** Also known as congenital hernias, indirect inguinal hernias develop in the womb. In the male fetus, the spermatic cord and testicles normally descend through the inguinal canal into the scrotum. If the inguinal ring does not close normally after birth, the muscle is weak causing fat or intestine to slide through this weakness. In the female fetus, the female organs or small intestine slides into the groin through the weakened abdominal muscles. Although indirect inguinal hernias are congenital, they may not become obvious until later in life.

**Direct Inguinal Hernia.** This type of hernia occurs only in males, and it is due to connective tissue degeneration that causes weakened muscles in adulthood. Fat or small intestine slides through the weakened muscle into the groin. The most common symptom of groin hernias is a feeling of heaviness or discomfort that is most noticeable when straining or lifting. The pressure is released when the patient stops straining or lies down. If the patient is experiencing significant pain, incarceration or strangulation should be suspected. Inguinal hernias typically present above the inguinal ligament and extend below it.

### Femoral

Approximately 4% of groin hernias are femoral. Femoral hernias are more common in females than males. Fat in the femoral canal enlarges and pulls contents from the peritoneum into the hernia sac. Forty percent of femoral hernias present as an incarcerated or strangulated hernia and must be treated as an emergency. Femoral hernias typically present below the inguinal ligament.

### Umbilical

Umbilical hernias occur more frequently in women than men and are due to increased abdominal pressure, usually related to obesity or multiparity (giving birth to more than one child). It is typically the omentum or peritoneal fat that incarcerates (constricts blood flow) into the hernia. Umbilical hernias can also be congenital and appear in infancy. Many congenital umbilical hernias close in the first 12 to 18 months of life, and surgical repair is rarely recommended until a child is approximately 3 years old.

### Ventral or Incisional

Ventral hernias form from a previous abdominal surgical incision. They may be due to inadequate healing from an infection, inadequate nutrition, smoking, immunosuppressive medications, connective tissue disorders, or obesity. The highest incidence occurs with midline abdominal wound incisions, with upper abdominal incisions having a higher incidence than lower abdominal incisions. Abdominal wound dehiscence can also lead to a ventral hernia. With ventral hernias, the patient complains of a bulge in the abdominal wall along an old incision site.

### Clinical Manifestations

Patients with hernia typically present with a bulge or visible swelling, often associated when coughing or bearing down. Other clinical manifestations include an ache that radiates into the area of the hernia. Strangulation clinical manifestations include abdominal distention, nausea, vomiting, pain, fever, and tachycardia. This is a medical emergency, and the patient must be prepared for surgery immediately to prevent the development of gangrene.

### Management

#### Diagnosis

Hernias are typically diagnosed based on physical examination alone, but if this is not definitive, a herniography (a radiographical examination of a hernia after the introduction of a contrast medium), ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) can confirm the diagnosis. A CT scan or MRI may be needed to differentiate between inguinal and femoral hernias.

#### Surgical Management

The most common treatment of hernias is surgery. If the patient is a poor surgical risk, a truss, or binder, may

be applied. A truss is a firm pad held in place against the hernia by a belt that reduces the hernia and prevents contents from protruding through the weakened muscle. The truss may be unilateral or bilateral, and the hernia must be reduced prior to the application of the truss. There are also similar products for other types of hernia. The surgical procedure to repair a hernia is called a **herniorrhaphy**. Often the patient may have a synthetic or biological material, called *mesh*, placed to reinforce the area of weakness and prevent recurrence of the hernia. When mesh is used during the surgical repair, the procedure is called a *hernioplasty*. The mesh reinforces the defective area and enhances a lower incidence of recurrence. Herniorrhaphy may be performed through laparoscopic surgery or through an open laparotomy. Surgical repair using laparoscopy generally has a shorter recovery time. Many hernia repairs are now performed on an outpatient basis. If the hernia has strangulated, the surgery is more extensive, and the patient will be hospitalized. A temporary **colostomy**, a surgically created opening on the abdomen in which the large intestine is connected for the elimination of fecal matter, may be required in extensive surgeries.

Postoperative management of the patient undergoing surgery for hernia repair is similar to the care of patients undergoing any other abdominal surgery with the exception of encouraging the patient to cough. Coughing places pressure on the site of repair and increases the incidence of recurrence of the hernia. The patient should be instructed to splint the surgical area when coughing to provide support.

### Complications

Complications of hernias include strangulation of the intestine, which impedes intestinal flow and the blood supply to the intestines. This can result in intestinal obstruction and/or necrosis of bowel tissue. A bowel resection may be necessary. Complications related to surgery with general anesthesia to correct hernias include nausea, vomiting, urinary retention, sore throat, and headache. As with any surgery requiring anesthesia, early ambulation and deep breathing prevent complications such as pneumonia and venous thromboembolism (VTE). Recurrence of the hernia can occur, requiring the patient to undergo another surgery for repair. Wound infections can occur, but they are rare unless the patient has undergone an extensive surgery.

**Safety Alert** The patient with a strangulated hernia may present with clinical manifestations of an intestinal obstruction. This is an emergency, and the patient must be prepared for immediate surgery to prevent gangrene from developing. Strangulation signs and symptoms include abdominal distention, nausea, vomiting, pain, fever, and tachycardia.

## Nursing Management

### Assessment and Analysis

The clinical manifestations of hernias are closely related to their location and type of hernia. The clinical presentation of hernia typically includes:

- Bulging or swelling at the site of the hernia
- Ache that radiates in the area of the hernia
- Feelings of fullness or pressure in the area of the hernia

In the case of a strangulated or incarcerated hernia, the patient may present with painful engorgement of the hernia, nausea, vomiting, and abdominal distention.

### Nursing Diagnoses

- **Acute pain** related to the surgical incision
- **Knowledge deficit** related to postoperative care and home care

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Increased heart rate and respirations may be indicative of pain and/or bleeding. Elevated temperature may be indicative of infection.*
- Pain  
*Pain results from the surgical incision and manipulation of abdominal contents during the surgical repair. Adequate pain management allows the patient to resume normal activities sooner.*
- Intake and output  
*Urinary retention is a complication as a result of the effects of general anesthesia. If the surgery is performed in an outpatient setting, the nurse should have the patient urinate and measure this recording before discharge. If the patient is admitted to the inpatient facility, intake and output should be measured for 24 hours to ensure that the patient is not retaining urine.*
- Surgical site  
*The surgical site should be well-approximated. Swelling or drainage may be indications of early infection.*

#### ■ Actions

- Deep breathing and early ambulation  
*Promote lung expansion and prevent atelectasis and VTE*
- Administer pain medications as needed  
*Pain medication is essential for the patient to recover to an optimal level and to prevent complications such as atelectasis and VTE. Pain results from the surgical incision and manipulation of abdominal contents during the surgical repair. Adequate pain management allows the patient to resume normal activities sooner.*
- Give patient prescription for pain medication prior to discharge  
*The patient will require pain medications at home, and this will promote the patient to return to normal activities of daily living.*

- Apply ice pack to scrotum and elevate scrotum  
*The ice pack and elevation are used to reduce swelling; a scrotal support may also be used to reduce swelling and elevate the scrotum.*
- Begin diet with clear liquids, advancing diet as tolerated to patient's preoperative diet  
*Nausea and vomiting are common after anesthesia, and the patient should exercise steps to prevent nausea and vomiting.*

### ■ Teaching

- Coughing is discouraged.  
*Coughing causes undue pressure on the surgical site and can possibly lead to recurrence of the hernia. If coughing is necessary, the surgical site should be splinted with pillows to prevent pressure on the site.*
- Avoid heavy lifting for several weeks  
*Heavy lifting can place undue pressure and straining on the surgical site and lead to reoccurrence of the hernia.*
- Pain management techniques  
*The patient will be discharged with a prescription for pain medication. The nurse should teach the patient about the medication and to avoid driving or operating machinery while taking this medication. If the pain is unrelieved by the medication, this should be reported to the healthcare provider.*
- Observe incisions for redness, swelling, heat, and drainage, which indicate infection. The patient should report fevers, chills, and increasing pain to their healthcare provider.  
*These are clinical manifestations of infection and should be reported to the healthcare provider as soon as possible.*

### Evaluating Care Outcomes

Patients recovering from hernia repair surgery return to their previous level of functioning within 6 to 8 weeks after surgery depending on the extent of the surgical repair. The patient who is experiencing surgery for a recurrence of a previous hernia repair may require a longer healing time. Like other postoperative patients, outcomes include stable vital signs, absence of infection, and normal bladder and bowel function. In the event a patient is a poor surgical candidate, outcomes focus on patient comfort and ensuring a clear understanding of the clinical manifestations of strangulation.

### Connection Check 58.1

The nurse correlates strangulated hernias with which finding?

- Impede blood flow of the intestines
- Result from pressure on an old surgical incision
- Lead to bouts of diarrhea
- A hernia in which contents can be placed back into place

## Hemorrhoids

### Epidemiology

Hemorrhoids are swollen or dilated veins in the anorectal area. Simply, they are varicose veins of the rectum. They may be caused or precipitated by straining during defecation, prolonged constipation, heavy lifting, prolonged standing and sitting, portal hypertension (as in cirrhosis), increased intra-abdominal pressure, pregnancy, obesity, and heart failure. It is a common disorder that affects both men and women but is more frequently reported by women.

### Pathophysiology

Hemorrhoids are internal (lying above the dentate line) or external (lying below the dentate line). The anus is approximately 4-cm long, with the dentate line approximately in the center. Internal hemorrhoids cannot be seen on visual inspection (Fig. 58.2). Hemorrhoids can become prolapsed or protrude through the anal canal. A strangulated hemorrhoid is trapped by the anal sphincter, compromising blood flow to the vein in the hemorrhoid. Hemorrhoids may also become thrombosed or clotted.

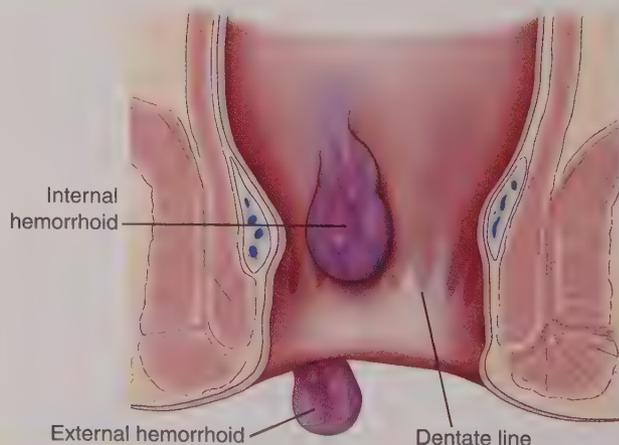

A standard grading system is used for the grading of internal hemorrhoids according to severity of prolapse and serves as a guide for treatment:

- Grade I: The hemorrhoids do not prolapse.
- Grade II: The hemorrhoids prolapse on defecation but reduce spontaneously.
- Grade III: The hemorrhoids prolapse on defecation and must be reduced manually.
- Grade IV: The hemorrhoids are prolapsed and cannot be reduced manually.

The grading system, however, does not account for other factors such as size, number of hemorrhoids, pain, bleeding, and any other comorbidities the patient may have.

### Clinical Manifestations

Approximately 40% of hemorrhoids are asymptomatic. Bleeding is almost always painless and is observed as bleeding during a bowel movement and usually associated with

**FIGURE 58.2** Hemorrhoids. Hemorrhoids are internal (lying above the dentate line) or external (lying below the dentate line).

internal hemorrhoids. External hemorrhoids are associated with itching, irritation, and pain of the rectal area. Clinical manifestations of hemorrhoids include pain and pruritus in the rectal area. Bleeding may occur and is usually seen on the toilet tissue but may also be streaked in the stool. The hemorrhoid may be prolapsed or protruding from the rectum. Some hemorrhoids may prolapse during defecation and spontaneously return after defecation. Pain symptoms may range from mild to severe.

## Management

### Medical Management

External hemorrhoids are diagnosed by visual inspection. Internal hemorrhoids are diagnosed by digital examination, anoscopy (procedure involving a small, tubular instrument inserted into the anal canal for inspection), and sigmoidoscopy. Treatment of hemorrhoids is usually conservative and involves relief of symptoms and associated pain. Cold packs and sitz baths (warm water baths covering the hips and buttocks) three or four times a day reduce some swelling and decrease pain. If conservative therapy does not alleviate symptoms within 3 to 5 days, the patient needs to be referred to a primary care provider. The patient is encouraged to consume adequate fluid and fiber intake to decrease constipation associated with hemorrhoids. Stool softeners may also be recommended. Topical nitroglycerin (0.4%) ointment may be used to decrease pain caused by thrombosed hemorrhoids as well as topical nifedipine. There are a number of over-the-counter preparations available in creams and suppositories used to treat hemorrhoids. A variety of combinations of ingredients are available for the treatment of hemorrhoids and are listed in Table 58.1.

### Surgical Management

Surgical intervention is seldom required for external hemorrhoids unless the hemorrhoid is thrombosed (internal or external). In this situation, surgical evacuation may be done in the provider's office. Patients seen within 48 to 72 hours after thrombosis occurs may benefit from surgical incision and evacuation.

Patients with grade IV and some with grade III may require definitive treatment with surgery. Surgery is usually

done on an outpatient basis. Several surgical techniques are used:

- **Rubber-band ligation**—this is the most widely used technique. The hemorrhoid is identified by using an anoscope. A rubber band is placed around the base of the hemorrhoid, which constricts circulation, causing the hemorrhoid to slough off in 2 to 4 days.
- **Bipolar, infrared, and laser coagulation**—this technique uses bipolar current or infrared or laser light, which causes coagulation and necrosis of the hemorrhoid, leaving fibrosis in the submucosal layer.
- **Sclerotherapy**—involves injecting a sclerosing agent (an agent that causes formation of scar tissue) directly into the hemorrhoid, which causes an inflammatory reaction leading to the vessel drying up and disintegrating.
- **Cryosurgery**—uses liquid nitrogen to freeze the hemorrhoid. This procedure is usually associated with intense pain and is not the first method of choice.
- **Hemorrhoidectomy**—excision of the vein. The area may be left open to heal by secondary intention, or it may be closed with sutures. Closing the area with sutures is less painful for the patient but has a higher risk of infection.

### Complications

Complications following surgery for hemorrhoids include infection, pain, urinary retention, fecal impaction, damage to the sphincter, bleeding, and abscess formation, which involves a localized collection of pus. Although infection is rare, it is something the patient needs to be aware of. Fecal impaction occurs as a result of inadequate pain management, with the person being afraid to have a bowel movement, or as a result of opiate usage. The patient will likely have the fecal impaction manually removed under anesthesia. Urinary retention occurs because of rectal spasms and pain.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations of hemorrhoids include rectal pain and itching that may be accompanied by bleeding. The management is based on severity of clinical manifestations, location and response to conservative therapy.

**Table 58.1 Medications Used for the Treatment of Hemorrhoids**

Ingredient/Classification	Examples of Medications	Action
<b>Local anesthetics</b>	Benzocaine, dibucaine, lidocaine	Provide temporary relief from burning, itching, and pain
<b>Protectants/Emollients</b>	Cocoa butter, lanolin, white petroleum, zinc oxide, mineral oil, cod liver oil, or shark liver oil	Form physical barrier on the skin to prevent irritation of the perianal region
<b>Astringents</b>	Calamine, zinc oxide, witch hazel	Promote skin dryness, which helps relieve itching, irritation, and inflammation
<b>Corticosteroids</b>	Hydrocortisone	Reduce inflammation

### Nursing Diagnoses

- **Acute Pain** associated with inflammation in the rectal area
- **Knowledge deficit** associated with the care of hemorrhoids and/or postoperative care
- **Risk for altered bowel elimination: constipation** associated with fear of pain with bowel movements

### Nursing Interventions

#### ■ Assessments

- **Vital signs**

*A fever may be indicative of an infection and should be reported to the healthcare provider. An increased heart rate and/or respirations may be indicative of pain.*

- **Visual inspection of rectal area**  
*The rectal area may appear reddened secondary to itching. Postoperatively, it may appear swollen from manipulation during surgery. There should not be significant drainage or bleeding.*
- **Frequency and character of bowel movements**  
*The patient often tries to avoid having a bowel movement due to painful defecation, particularly after surgery because of the increased pain associated with bowel movements. This can lead to constipation and should be avoided because this will further increase pain and perhaps bleeding at the surgical site.*
- **Bowel habits postoperatively compared with preoperative pattern**  
*If the patient becomes constipated after surgery, this can lead to increased pain with each subsequent bowel movement.*
- **Pain**  
*Pain results secondary to the surgical procedure, and associated inflammation. Adequate pain management allows the patient to resume normal activities sooner.*
- **Intake and output**  
*Urinary retention may occur because of rectal spasms and pain.*

#### ■ Actions

- **Administer pain medications**  
*The first bowel movement after surgery may be painful, and the patient needs to take an analgesic prior. Fainting has occurred during bowel movements early after surgery because of the intensity of the pain along with vagal stimulation.*
  - **Local anesthetics**  
*Provide temporary relief from burning, itching, and pain*
  - **Astringents**  
*Promote skin dryness, which helps relieve itching, irritation, and inflammation*
  - **Corticosteroids**  
*Reduce inflammation*
  - **Protectants/emollients**  
*Form physical barrier on the skin to prevent irritation of the perianal region*
- **Provide cold packs and sitz baths**  
*These interventions are used to reduce swelling and pain*

- **Administer laxatives**

*Bulk laxatives (hydrophilic psyllium) require the use of increased fluids, or they can result in constipation. If the patient has not had a bowel movement within 3 days after surgery, a mild laxative may be ordered.*

- **Apply local moist heat**  
*Local moist heat can be used to provide comfort but should be avoided in the immediate postoperative period because of an increased risk of bleeding.*

#### ■ Teaching

- **Care of surgical site**  
*The area should be washed gently and patted dry to keep the surgical area free from contaminants that may cause infection.*
- **Measures to prevent constipation**  
*Prevention of constipation is imperative during the postoperative period because the patient may avoid having a bowel movement in fear of increasing pain. Include good sources of fiber; include whole grain and raw vegetables and fruits. Regular bowel habits are important for the patient in the postoperative period for avoiding constipation. Increasing fluids and fiber in their diet helps prevent constipation. Over-the-counter stool softeners such as docusate sodium may also be used. The use of narcotic analgesics may increase the chances of developing constipation.*
- **Avoid straining to have a bowel movement and avoid sitting for long periods of time**  
*Straining and sitting for long periods of time can increase inflammation and pain associated with hemorrhoids.*
- **Avoid stimulant laxatives**  
*Stimulant laxatives should be avoided because they are irritating and habit-forming.*
- **Nonpharmacological methods of reducing pain**  
*Cold packs and sitz baths alleviate some pain associated with hemorrhoids. The use of sitz baths can be used for cleansing as well as having a soothing effect, and they can be used three or four times a day and after bowel movements.*
- **Contact the healthcare provider if unable to urinate**  
*Urinary retention may occur because of rectal spasms and pain.*

### Evaluating Care Outcomes

The patient who has undergone surgery for hemorrhoids usually returns to a normal level of functioning within just a few weeks. Because hemorrhoid surgery is usually performed on an outpatient basis, the patient and family need to demonstrate understanding of what is normal in the recovery process as well as of what is abnormal. The patient should demonstrate adequate pain management to prevent constipation without adding to the chances of constipation with narcotic analgesics. The patient and family acknowledge the importance of contacting the healthcare provider if the patient is not able to urinate after discharge.

## Connection Check 58.2

Which interventions are considered conservative treatments for hemorrhoids? (Select all that apply.)

- A. Hemorrhoid creams and ointments
- B. Sitz baths
- C. Over-the-counter analgesics
- D. Cryosurgery
- E. Rubber-band ligation

## Irritable Bowel Syndrome

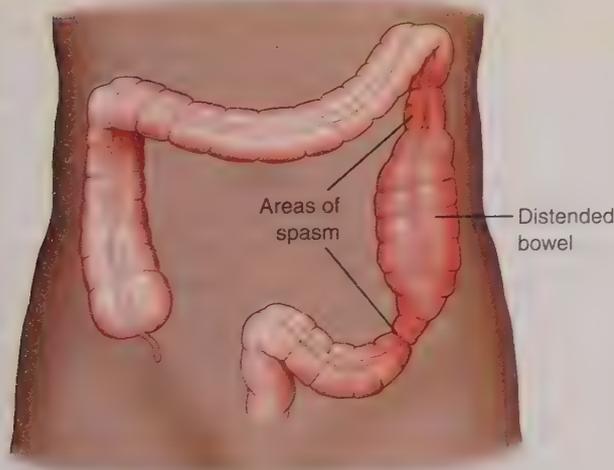

### Epidemiology

The exact cause of IBS is unknown. The mucosal lining of the bowel remains essentially unchanged with symptoms. Other names that may be used for IBS include spastic colon, nervous digestion, and spastic colitis, and is characterized by areas of bowel spasm and dilation (Fig. 58.3). It is associated with other conditions such as fibromyalgia, chronic fatigue syndrome, gastroesophageal reflux disease, functional dyspepsia, noncardiac chest pain, depression, anxiety and somatization.

Irritable bowel syndrome (IBS) is a functional disorder of the intestines of unknown etiology with no known cure. It occurs twice as often in women as in men, and often clinical manifestations worsen with a woman's menstrual cycle, suggesting a hormonal component. It is most often diagnosed between the ages of 30 and 50 years, and accounts for approximately 25-50% of all referrals to gastroenterologists. The prevalence of IBS in North America is estimated to be 10% to 15%.

### Pathophysiology

Irritable bowel syndrome is a complex and often misunderstood functional disorder characterized by abdominal pain

**FIGURE 58.3** Irritable bowel syndrome. Irritable bowel syndrome is characterized by areas of bowel spasm and dilation.

and altered bowel habits for which no other pathophysiological cause can be found. There are four sub-types of IBS:

1. IBS-C (constipation dominant)
2. IBS-D (diarrhea dominant)
3. IBS-M (mixed, or alternating from diarrhea to constipation)
4. IBS unclassified (meets IBS diagnostic criteria but cannot be accurately categorized with the other 3)

Although the exact cause of IBS is unknown, there are many theories regarding the pathophysiology of this disorder, as well as an area of intense research. Possible theories include:

- **Gastrointestinal motility:** Motility abnormalities are noted in some patients with IBS. There have been observations involving increased frequency and irregularity of luminal contractions, prolonged transit time in IBS-C (causing too much water to be absorbed in the small intestine), and increased motor response in IBS-D (causing too little water being absorbed in the small intestine). However, no predominant pattern of motor activity has emerged as a marker for IBS.
- **Visceral hypersensitivity:** Increased sensation and sensitivity to intestinal activity have been noted in patients with IBS. The enteric nervous system extends from the esophagus to the anus and contains as many neurons as the spinal cord. One chemical mediator, 5-hydroxytryptamine (5-HT), or serotonin, may be implicated in IBS. Approximately 95% of serotonin is found in the gastrointestinal tract. Serotonin levels have been found to be increased in patients with IBS. Serotonin is released into the gastrointestinal tract initiating an intestinal reflex. The visceral hypersensitivity also has an exaggerated response to various stimuli in the gastrointestinal system such as balloon-distention studies.
- **Intestinal inflammation:** Increased numbers of lymphocytes have been noted in both the large and small intestines in patients with IBS. Increased numbers of mast cells have also been noted in the terminal ileum, jejunum, and colon of IBS patients. There has been a correlation between abdominal pain and the presence of activated mast cells in proximity to colonic nerves.
- **Postinfectious:** Often the patient with IBS may report previous long-lasting infectious gastroenteritis causing increased intestinal permeability, low-grade inflammation, and increased flatulence due to bacterial fermentation.
- **Bacterial overgrowth:** There have been conflicting reports in the research as to the possibility of small intestinal bacterial overgrowth as being a possibility for IBS and continues to be an area of ongoing research.
- **Food sensitivity:** Certain foods may precipitate abdominal pain in patients with IBS.

- **Carbohydrate malabsorption:** Although still under investigation, fructose, sorbitol, and lactose contribute to gastrointestinal symptoms such as flatus, pain, bloating, belching, and altered bowel habits.
- **Gluten sensitivity:** A few studies have explored the possibility of an overlap between celiac disease and IBS-D. These patients respond to gluten-free diets. Celiac disease should be ruled out, however.
- **Genetics:** A genetic component has been noted for some patients with IBD, although research is ongoing.
- **Psychosocial dysfunction:** Anxiety and depression may play a role in patients with IBS. A history of physical and/or sexual abuse has also been implicated. Stress has been shown to alter gastrointestinal motility in both IBS as well as in patients with normal bowel habits.

### Clinical Manifestations

The clinical presentation of IBS includes diarrhea, constipation, flatus, and abdominal pain that may vary based on classification. Patients most often report left lower quadrant pain accompanied by abdominal distension and alternating bouts of diarrhea and constipation. The pain increases after eating and is relieved with bowel movements. Due to the pain and abdominal cramping, the patient may become anorexic with noticeable weight loss.

### Management

Treatment for IBS is symptom-based. No one treatment is effective for all patients with IBS, and therefore treatment is highly individualized. A trusting and therapeutic relationship must be established. It is not life threatening, but symptom management may be a lifelong struggle. There are many clinical trials under way, and therefore treatment recommendations are limited. Patients are encouraged to keep a diary of diet, episodes of stress, and triggers associated with the onset of symptoms.

### Medical Management

#### Diagnosis

There are no diagnostic tests that show a definitive diagnosis of IBD. However, a number of tests may be performed to rule out other pathophysiological causes for concern. These tests may include flexible sigmoidoscopy, colonoscopy, CT scan, lactose intolerance tests, stool cultures, and blood tests. After organic causes have been ruled out, the Rome IV or Manning Criteria are used to make the diagnosis of IBS.

The Rome IV Diagnostic Criteria for Functional Gastrointestinal Disorders is one of the most common diagnostic instruments. The patient must have had recurrent abdominal pain or discomfort at least 1 day per week in the last 3 months associated with two or more of the following:

- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

The Manning Criteria is another tool used in the diagnosis of IBS. The more clinical manifestations the patient has, the greater likelihood of being diagnosed with IBS.

- Pain relieved with defecation
- More frequent stools at the onset of pain
- Looser stools at the onset of pain
- Visible abdominal distention
- Passage of mucus
- Sensation of incomplete evacuation

Based on clinical presentation and results of these two tools, an individualized management plan is developed.

### Treatment

Medications used to treat IBS are listed in Table 58.2. The focus of medical management is on controlling spasm, minimizing diarrhea, releasing neurotransmitters to promote peristalsis, and addressing depression. Cognitive-behavioral therapy, relaxation, stress management, acupuncture, hypnosis, and Chinese herbs have also been noted to be successful in the treatment of IBS. A diet high in fiber may help control symptoms associated with IBS because a bulkier stool reduces tension on the sigmoid colon.

**Dietary Modification.** The patient with IBS is encouraged to maintain a food diary and note any foods that trigger symptoms. A diet low in fermentable oligo-, di-, and monosaccharides and polyols (FODMAPs) are noted to improve symptoms for IBS. These short-chained carbohydrates are poorly absorbed and cause some abdominal bloating. Examples of foods that should be avoided include fructose, apples, pears, mangoes, cherries and wheat. Patients eliminate FODMAPs from their diet for 6 to 8 weeks. After resolution of symptoms, they are gradually re-introduced to determine tolerance for specific foods. Patients should also be encouraged to avoid gas-producing foods. Some patients benefit from avoiding lactose, as well. Nonceliac gluten sensitivity (NCGS) has been thought to affect IBS-D patients but the evidence has been inconsistent.

**Complementary and Alternative Therapies.** Relaxation techniques, acupuncture, hypnosis, and hypnotherapy can decrease IBS symptoms. Probiotics (types of “good” bacteria that are thought to improve health) often help the symptoms in some patients. It has been suggested that some patients with IBS may not have enough “good bacteria,” and taking probiotics may help ease clinical manifestations. Although the benefits of probiotics are not completely understood, there have been some general benefits including suppressed growth or epithelial binding by pathogenic bacteria and improved function of intestinal barriers. Regular exercise, yoga, massage, or meditation may be effective ways of relieving stress and anxiety. Some Chinese herbs have demonstrated some relief but should be used with caution and only under the advice of the healthcare provider. The following herbs have demonstrated some relief of IBS:

- Peppermint (*Mentha piperita*) and fennel (*Foeniculum*) are natural antispasmodics and have anti-inflammatory

**Table 58.2 Medications Used for Treatment of Irritable Bowel Syndrome**

Classification	Medications	Action
<b>Antispasmodic agents</b>	Dicyclomine (Bentyl, Antispas)	Anticholinergic and antimuscarinic components that block acetylcholine, relaxing smooth muscle spasm and GI motility; inhibit gastric secretion
<b>Antidiarrheals</b>	Loperamide (Imodium)	Slow bowel transit, enhance water absorption, and strengthen anal sphincter tone, resulting in fewer stools but does not relieve pain
	Diphenoxylate hydrochloride (Lomotil)	Decreases motility, propulsion, and secretions
<b>Guanylate cyclase agonists</b>	Linaclotide (Linzess) for IBS-C despite treatment with osmotic laxatives	Stimulates intestinal fluid secretion and transit
<b>Serotonergic agents</b>	Tegaserod* (Zelnorm) for IBS-C in female patients	Agonist activity causes release of other neurotransmitters and results in increased peristalsis, increased intestinal secretion, and decreased visceral sensitivity
	Alosetron** (Lotronex) for refractory IBS-D in female patients	Limits gastrocolic reflexes, which can slow transit time and improve muscle tone
<b>Selective type-2 chloride channel (ClC-2) activator</b>	Lubiprostone for IBS-C in women	Increases fluid secretion in the small intestine and is believed to enhance colonic motility by increasing intraluminal volume
<b>Antidepressants</b>		Low doses of antidepressants have been shown to decrease pain
<b>Selective serotonin reuptake inhibitors (SSRIs)</b>	Paroxetine (Paxil); fluoxetine (Prozac); sertraline (Zoloft)	SSRIs inhibit serotonin uptake and may increase pain threshold while decreasing transit time
<b>Tricyclic antidepressants (TCAs)</b>	Amitriptyline (Elavil); imipramine (Tofranil); nortriptyline (Pamelor); desipramine (Norpramin)	TCAs block norepinephrine reuptake and are believed to slow transit time and improve pain tolerance

GI, Gastrointestinal; IBS, irritable bowel syndrome; IBS-C, irritable bowel syndrome with constipation; IBS-D, irritable bowel syndrome with diarrhea.

\*Tegaserod was pulled from the market in March 2007 because of increased risk of heart attack and stroke in patients with a previous history of or risk factors for cardiovascular disease. It is currently available only through the FDA's Emergency Investigational New Drug protocol.

\*\*Alosetron was pulled from the market in 2000 after cases of ischemic colitis and severe constipation were reported. It can be prescribed for women with severe IBS-D if the clinician enrolls in a special program and is intended for severe cases of IBS-D who have not responded to other treatments.

properties. They relax smooth muscle in the intestines and help expel gas.

- Herbal teas such as chamomile (*Chamaemelum nobile*) have gentle antispasmodic properties.
- Ginger—helps control nausea and expel gas

**Safety Alert** There is a reported increase in the use of herbal remedies in recent years. Medicinal

herbs are classified as dietary supplements and are not regulated as medications in the United States. When patients choose to self-administer herbal remedies, teaching must be provided to make them aware that many herbal remedies can interfere with medications they are taking, and the healthcare provider should be consulted. Patients are taught to obtain information related to the herbal

medication of their choice from reputable sources. Some online sources include:

- Natural Medicines Comprehensive Database
- Natural Medicines Research Collaboration
- ConsumerLab
- Medline Plus Drugs and Supplement Directory
- National Institutes of Health National Center for Complementary and Alternative Medicine Herb Fact Sheets
- NIH Office of Dietary Supplements

### Complications

Complications associated with IBS often involve psychosocial concerns such as social isolation related to frequent diarrhea. Patients can be referred to support groups to develop strategies to manage changes in physical

functioning caused by IBS, such as spasm, constipation and diarrhea. If certain food groups are avoided because of onset of symptoms, patients may not be receiving all the nutrients they need. Clinical manifestations may overlap with other conditions, and it is important that other causes be ruled out before making a diagnosis of IBS. Fluid volume deficit and hypokalemia are also complications when the patient has bouts of frequent diarrhea.

## Nursing Management

### Assessment and Analysis

Patients can often associate foods that may trigger symptoms and keeping a diary can assist in identifying these trigger foods. Patients often associate a stressful situation with the onset of symptoms, and the diary helps to identify these sources of stress and find better ways of dealing with them. Patients with IBS may also complain of anxiety, sleep disturbances, and difficulty concentrating. A thorough pain assessment is necessary to rule out a pathophysiological cause of pain.

Clinical manifestations for IBS include intermittent abdominal pain and altered bowel habits. The most frequent complaint of abdominal pain is in the left lower quadrant with relief after defecation. Other clinical manifestations may include abdominal distention and bloating, anorexia, excessive flatulence, **dyspepsia** (heartburn), **eructation** (belching), a continual urge to defecate, and a sense of incomplete evacuation. Nausea and increased pain may be associated with meals. For the patient with IBS-D, there may be mucus in the stool but not blood. In the patient with IBS-D, nocturnal diarrhea is uncommon and is usually indicative of an organic disease. The patient usually appears well and does not exhibit significant weight loss.

### Nursing Diagnoses

- **Chronic pain** related to spasms and increased motility
- **Ineffective coping** related to the psychosocial effects of IBS
- **Ineffective health maintenance** related to living with a chronic disease

### Nursing Interventions

#### Assessments

- **Vital signs**  
*Elevated heart rate and blood pressure may develop secondary to severe pain. Fever may develop secondary to dehydration, inflammation or infection.*
- **Intake and output**  
*With frequent bouts of diarrhea, the patient is at increased risk of fluid volume deficit.*
- **Serum electrolytes**  
*The patient is at risk of hypokalemia during bouts of diarrhea. Additionally, the serum sodium and blood urea nitrogen may be elevated secondary to dehydration.*

- **Pain**  
*The most frequent complaint of abdominal pain is in the left lower quadrant with relief after defecation and is most likely due to the intestinal spasm and dilation.*
- **Bowel pattern**  
*Patients with IBS may have constipation, diarrhea, or a combination of both.*
- **Weight**  
*The patient is at risk of weight loss, particularly during exacerbations of IBS.*
- **Psychosocial assessment**  
*Because onset of symptoms is often associated with stress, a thorough psychosocial assessment can reveal triggers.*

#### Actions

- **Administer ordered IV solutions**  
*Based on the degree of fluid volume deficit that results from diarrhea, IV replacement fluids are ordered. A common solution is 0.45NS with potassium supplementation.*
- **Establish a trusting relationship**  
*Irritable bowel syndrome is often thought of as a psychological illness rather than a physical illness. A therapeutic, trusting relationship is necessary for the patient to have an open relationship with the caregiver, providing empathy and support.*
- **Avoid foods that exacerbate clinical manifestations of IBS**  
*Caffeine and alcohol increase gastrointestinal motility and irritate the gastrointestinal mucosa. Indigestible carbohydrates such as beans produce increased gas, leading to abdominal discomfort.*
- **Establish a regular bowel routine**  
*Drinking six to eight glasses of water per day helps to regulate stool frequency. Increase physical activity to promote GI motility.*
- **Implement complementary and alternative medicines that may relieve symptoms**  
*Complementary and alternative therapies often help relieve symptoms associated with IBS but should be used only under the advice of the provider.*
  - **Peppermint (*Mentha piperita*) and fennel (*Foeniculum*)** are natural antispasmodics and have anti-inflammatory properties. They relax smooth muscle in the intestines and help expel gas.
  - **Herbal teas such as chamomile (*Chamaemelum nobile*)** have gentle antispasmodic properties.
  - **Ginger**—helps control nausea and expel gas
- **Make appropriate referrals to**
  - Dietitians
  - Psychological counseling
  - Support groups  
*Irritable bowel syndrome is a complex disease of unknown etiology that requires an interprofessional approach including a dietitian, case manager, and psychiatric approaches.*

#### Teaching

- **Avoid trigger foods that exacerbate clinical manifestations**  
*Trigger foods that cause the patient to have symptoms are different for every patient. Common foods that seem to*

trigger abdominal discomfort include caffeine, alcohol, eggs, wheat products, and beverages containing sorbitol or fructose. Caffeine and alcohol may irritate the gastrointestinal tract. Lactose intolerance is common. These foods may increase gastrointestinal motility, leading to increased abdominal pain and/or diarrhea.

- **Keep a diary**

The diary can assist the patient in identifying sources of stress and trigger foods that exacerbate symptoms.

- **Consume regular meals and drink 8 to 10 cups of liquid per day**

Regular meals enhance the promotion of regular bowel habits. Adequate fluid intake helps regulate stool consistency and frequency.

- **Encourage regular exercise and 7 to 8 hours of sleep each night**

Regular exercise and adequate sleep are important for both regular bowel habits and managing stress and anxiety.

- **Smoking cessation techniques**

Smoking has also been associated with IBS, and patients therefore should be taught about the effects of smoking and offered smoking cessation counseling. Nicotine increases gastrointestinal motility, which can lead to increased pain and/or diarrhea.

### Evaluating Care Outcomes

Irritable bowel syndrome remains a mysterious and often complex syndrome of unknown etiology, with varying effects on different individuals, making it difficult to manage. Expected outcomes in the management of IBS include stable vital signs and weight, decrease in clinical manifestations, and patient's understanding and adherence to nutritional and activity recommendation to manage this chronic disease. Another desired outcome in the care of the patient with IBS is establishing a trusting relationship because these individuals often feel as if the healthcare provider sees them as having a psychological illness rather than a physical illness.

### Connection Check 58.3

The nurse recognizes which findings as diagnostic for IBS?

- Rome IV and/or Manning Criteria
- CT scan of the abdomen shows inflammatory process
- Blood urea nitrogen and creatinine are elevated
- Patient has abdominal pain and a psychiatric diagnosis

## Inflammatory Bowel Disease

### Epidemiology

Inflammatory bowel disease (IBD) is an umbrella term for two very similar chronic diseases of the gastrointestinal tract: Crohn's disease and ulcerative colitis. It is estimated that 1.6 million Americans currently suffer from IBD in America. The incidence of IBD is higher in the United States, Canada, the United Kingdom, Sweden, and Norway, with Canada having the highest incidence in the world. The

risk is higher among Ashkenazi Jewish populations of Europe and American Jews of European descent. Diagnosis can occur at any age but is more likely to occur between the ages of 15 and 35. The annual estimated financial burden (direct and indirect costs) of IBD in the United States is \$14.6 billion to \$31.6 billion. Traditionally, IBD has been considered a predominately Caucasian disease, but the incidence among African Americans is steadily increasing.

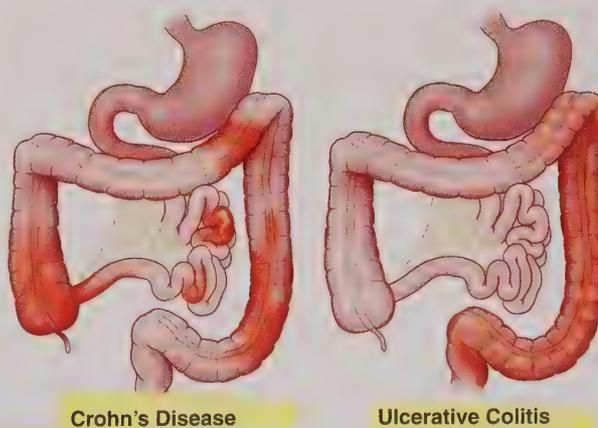

### Pathophysiology

The exact cause of IBD is unknown, but it has been linked to genetic predisposition, environmental conditions, and defects in immune regulation. This genetic predisposition may manifest as an overactive immune response to bacteria located in the gastrointestinal tract. It may then be triggered by an environmental response such as infection, medication, or smoking. Whereas the immune system usually attacks foreign invaders, in people with IBD, the immune response has an inappropriate response in the intestinal tract causing inflammation. The inflammation affects the ability to absorb nutrients resulting in diarrhea and weight loss in some patients.

There have been some studies to examine dietary influences in the development of IBD. Some trigger foods which may be implicated include hypersensitivity to cow's milk in infancy and refined sugar intake, particularly in Crohn's disease. Dietary fiber has been noted to possibly decrease the risk of Crohn's disease but not ulcerative colitis.

### Clinical Manifestations

Inflammatory bowel disease is chronic in nature, and the severity ranges from mild to severe, with periods of remission and exacerbations. Exacerbations often are precipitated by physical or emotional stress. Although there are similarities, there are also many differences between Crohn's disease and ulcerative colitis (Fig. 58.4). Similarities include persistent diarrhea; abdominal pain or cramps; fever; weight

**FIGURE 58.4** Inflammatory bowel disease. Crohn's disease manifests patchy involvement throughout all layers of the bowel. It may skip areas of the bowel and can occur anywhere in the gastrointestinal tract from mouth to anus. Ulcerative colitis begins in the rectum and proceeds in a continuous, diffuse pattern toward the cecum.

loss; fluid imbalances; malnutrition; mouth ulcers; anemia; blood from the rectum; joint, skin, or eye irritations; and delayed growth. Extraintestinal manifestations seen in IBD include uveitis (intraocular inflammatory disorder), sclerosing cholangitis (inflammation of the hepatic ducts), nephrolithiasis (renal stones), cholelithiasis (gallstones), joint disorders, skin disorders, and oral ulcerations. Table 58.3 demonstrates differences between Crohn's disease and ulcerative colitis, with a focus on the anatomical and functional differences. Patients with Crohn's disease are at higher risk for cancer of the small bowel, whereas patients with ulcerative colitis

are at higher risk for colon cancer after having the disease for a long period of time. Although there is no medical cure for either disease, a **colectomy** (removal of the large intestine) cures ulcerative colitis in the gastrointestinal tract. However, having a colectomy does not cure the extraintestinal manifestations associated with ulcerative colitis. Patients with Crohn's disease who undergo surgical resection of diseased sections of the bowel are at increased risk of reoccurrence at the sites of the **anastomoses**, the area where the two sections of the bowel were reattached after removal of diseased bowel.

**Table 58.3 Comparison of Crohn's Disease and Ulcerative Colitis**

Characteristic	Crohn's Disease	Ulcerative Colitis
<b>Region/Location affected</b>	Terminal ileum (most common), sometimes colon with patchy involvement throughout all layers of the bowel, skip lesions; can occur anywhere in the GI tract from mouth to anus	Colon, rectum; begins in the rectum and proceeds in a continuous, diffuse pattern toward the cecum
<b>Distribution of lesions</b>	Transmural, all layers	Mucosa and submucosa only of the colon
<b>Characteristic stool</b>	Loose, semifformed	Frequent, watery, with blood and mucus
<b>Number of stools per day</b>	5–6 soft, loose, nonbloody	10–20 liquid, bloody
<b>Granuloma</b>	Common	Occasional
<b>Fistula, fissure, abscess</b>	Common	Rare
<b>Stricture, obstruction</b>	Common	Rare
<b>Malabsorption, malnutrition</b>	Yes	Not common or minimal incidence
<b>Etiology</b>	Unknown	Unknown
<b>Peak incidence age</b>	15–35 years	15–25 years and 55–65 years
<b>Complications</b>	Fistulas, nutritional deficiencies	Hemorrhage, nutritional deficiencies
<b>Need for surgery</b>	Frequent	Infrequent; cure with colectomy
<b>Fever (intermittent)</b>	Common	During acute attacks
<b>Weight loss</b>	Common, may be severe	Rare
<b>Tenesmus</b>	Rare	Common
<b>Cobblestone appearance of mucosa</b>	Common	Rare
<b>Pseudopolyps</b>	Rare	Common
<b>Small bowel involvement</b>	Common	Minimal, only backwash into ileum
<b>Fistulas</b>	Common	Rare
<b>Strictures</b>	Common	Occasional
<b>Anal abscess</b>	Common	Rare
<b>Perforation</b>	Common (transmural)	Common (toxic megacolon)
<b>Recurrence after surgery</b>	Common at site of anastomosis	Cure with colectomy

Patients with IBD usually present to the healthcare provider with abdominal pain, diarrhea, fluid and/or electrolyte imbalances, and weight loss.

### CASE STUDY: EPISODE 2

Mr. Conner presents to his primary care provider with complaints of abdominal pain and bloody stools (12–14 stools per day). He describes that he has been having bright red blood in his stools for 6 months with abdominal pain that began shortly thereafter. On examination, abdominal pain is diffuse in location and sharp in character. A stool sample reveals watery consistency with blood streaks and “pus” or “droplets of fat” floating on top of the stool along with spasms of the anal sphincter and persistent desire to empty the bowel. On the basis of his clinical presentation, a colonoscopy is scheduled...

#### Crohn's Disease

Crohn's disease can affect any portion of the gastrointestinal tract from mouth to anus, although it is more common in the terminal ileum and colon. It is transmural, affecting all layers of the bowel. It is not uniform in appearance and is noted for having skip lesions with normal-appearing bowel between lesions. The lesions cause deep ulcerations between layers of edematous tissue, creating a cobblestone appearance. With each exacerbation, the intestines become more scarred, which then leads to less ability to absorb nutrients. Because Crohn's disease is transmural, it may actually penetrate the bowel wall, leading to complications such as fistulas, abscesses, and peritonitis. **Fistulas** are abnormal tracts between two or more body areas; patients with Crohn's disease may develop anovaginal and rectovaginal fistulas. Strictures and adhesions are also common. Diarrhea is less severe than in ulcerative colitis. Stools are typically soft or semiliquid and do not usually contain blood unless there has been a perforation. Nutritional deficits arise from the inability to absorb nutrients, and electrolyte disturbances are common. Abdominal pain is usually worse in the right lower quadrant.

#### Ulcerative Colitis

Ulcerative colitis affects the large intestine and involves only the mucosa and submucosa. The disease spreads uniformly beginning at the rectum and spreading upward toward the cecum. The small intestine is rarely involved. Diarrhea is common, often with more than 20 stools per day with losses of several liters of fluid per day. Blood, mucus, and pus are common with ulcerative colitis. Another clinical manifestation includes abdominal pain and tenderness that is worse in the left lower quadrant. Patients may manifest **tenesmus** which involves spasms of the anal sphincter and persistent desire to empty the bowel. Additionally, a lesion called a *crypt abscess* releases secretions that result in purulent discharge from the bowel mucosa.

Abscesses may form in ulcerated areas. Scar tissue is common, interfering with absorption of nutrients. Whereas there is no known cure for Crohn's disease, a total colectomy is a surgical cure for ulcerative colitis.

#### Indeterminate Colitis

In rare cases, healthcare providers are unable to determine if the patient has ulcerative colitis or Crohn's disease and are therefore given the diagnosis of indeterminate colitis. This resembles ulcerative colitis more than Crohn's disease.

#### Management

The primary goals of treatment are to rest the bowel and control the inflammation. Other goals are to combat infection, correct malnutrition, alleviate stress, provide symptomatic relief, and improve quality of life. The treatments include medications, surgery, and correction of nutritional deficits and involve many psychosocial needs. Although IBD cannot be cured with medication, there are medications to help control the disease and treat or prevent exacerbations. The medications most often used to treat IBD are listed in Table 58.4.

#### Diagnosis

Colonoscopy, sigmoidoscopy, and barium enema are commonly used in the diagnosis of both Crohn's disease and ulcerative colitis. The colonoscopy findings may assist in differentiating Crohn's disease and ulcerative colitis. In the patient with Crohn's disease, the colonoscopy detects early mucosal changes including inflammation, stricture, and fistulae. In ulcerative colitis, findings from colonoscopy include swollen, friable bowel mucosa with multiple ulcerations. Barium enema results may provide data regarding the depth of disease involvement. In patients with IBD, additional diagnostic tests include complete blood count, serum electrolytes, serum albumin, and stool samples for pathogens. However, in rare cases the healthcare provider is unable to determine whether the patient has Crohn's disease or ulcerative colitis (Indeterminate Colitis).

#### Medical Management

Fluid and electrolyte management is crucial for the patient with ulcerative colitis. When the bowel is inflamed, and the patient is exhibiting severe diarrhea, absorption of fluids and nutrients is compromised. The patient is encouraged to rest frequently to decrease bowel motility.

#### Medications

The patient with IBD is taught the importance of adhering to prescribed medication management (see Table 58.4). Medications often have unpleasant side effects, which should be reported to the provider prior to discontinuation of use.

#### Nutrition

Malnutrition is common with IBD and can lead to many other complications such as poor wound healing, decreased muscle mass, and a decreased immune system. Dietary considerations are highly individualized depending on which portion of the bowel is affected. Nutritional abnormalities

**Table 58.4 Medications Used to Treat Inflammatory Bowel Disease**

Classification	Medications	Action
<b>5-Aminosalicylates</b>	Sulfasalazine (Azulfidine, Azulfidine EN-Tabs), mesalamine (Asacol, Pentasa, Rowasa, Canasa, and Lialda), olsalazine (Dipentum), and balsalazide (Colazal)	Block production of prostaglandins and leukotrienes to decrease inflammation. May be given orally or rectally to reduce inflammation. These medications are contraindicated if patient is allergic to aspirin. Sulfasalazine is contraindicated in patients allergic to sulfa. These medications are effective in both achieving and maintaining remission. They are used primarily to treat ulcerative colitis. They are effective in 2–4 weeks after initiation.
<b>Antimicrobials</b>	Metronidazole (Flagyl, Protostat) and ciprofloxacin	Help control clinical manifestations in Crohn's disease but ineffective in ulcerative colitis. They are also used to treat secondary infections. They reduce small intestinal bacterial overgrowth and reduce flares.
<b>Glucocorticoids</b>	Dexamethasone (prednisone) and budesonide (Entocort)	Decrease inflammation but should be given for short periods of time during exacerbations and tapered appropriately because of long-term side effects. These medications are effective in achieving remission but not maintaining. Steroids must be used with caution because they also impair immune resistance, which then causes a decrease in healing of fistulas and abscesses. Budesonide (Entocort) is a newer nonsystemic steroid that has fewer side effects and is useful in treating exacerbations but not useful during remission.
<b>Biologic therapies</b>	Biologic therapies used include infliximab (Remicade), certolizumab (Cimzia), adalimumab (Humira), and natalizumab (Tysabri)	Alter a person's immune response. They alter an inflammatory protein called tumor necrosis factor (TNF). Although these medications have been traditionally used as second-line agents, some providers are recommending them earlier in treatment. This group of medications has many toxic side effects such as blood dyscrasias, infection, pancreatitis, and digestive intolerance and should be used with caution.
<b>Immunomodulators</b>	Azathioprine (Imuran), mercaptopurine (Purinethol), cyclosporine (Sandimmune, Neoral, and Gengraf), and methotrexate	Modifies the activity of the immune system to decrease inflammation; may be used for long-term therapy
<b>Antidiarrheals</b>	Diphenoxylate hydrochloride and atropine sulfate (Lomotil) and loperamide (Imodium)	Provide symptomatic relief and bowel rest. These medications must be used with caution because they can cause colon dilation.

can be caused by a number of problems including malabsorption, decreased food intake, medications, and/or intestinal losses. The patient may need to be hospitalized for bowel rest and receive total parenteral nutrition (TPN). In Crohn's disease, monthly B<sub>12</sub> injections may be necessary because of the inability of the ileum to absorb this nutrient. Other nutritional deficits include zinc, potassium, magnesium, and vitamins. Liquid vitamin preparations are usually necessary because tablets or capsules may be excreted intact because of the frequency of diarrhea. Albumin levels are frequently used to determine nutritional status, but other factors may alter albumin levels such as inflammation, infection, or cancer. There is also no gold standard for measuring vitamin and mineral deficiencies. Being aware of the clinical manifestations associated with vitamin deficiencies helps guide treatment. Foods to avoid include

milk, gluten, caffeine, cocoa, chocolate, citrus juices, cold or carbonated drinks, nuts, seeds, popcorn, and alcohol.

#### **Complementary and Alternative Medicines**

Complementary and alternative medicines (CAMs) are estimated to be used by 30% to 50% of patients with IBD, although patients are often reluctant to mention this to their provider for fear of being judged because some providers may not have adequate knowledge of CAMs. Some examples of CAMs being used include marijuana, turmeric and curcumin, fish oil, probiotics, aloe vera, *Andropogon paniculata* (e.g., India echinacea), *Boswellia* (e.g., frankincense), *Tripterygium wilfordii* Hook F (thunder god vine), wheat grass, and wormwood. Research data vary widely, recommendations are inconsistent and these herbs are not regulated by the Food and Drug Administration (FDA).

Other therapies include acupuncture and moxibustion, mind-body therapies, and exercise.

### Psychosocial Management

Although there is no evidence to suggest that IBD is a psychosomatic illness, exacerbations may occur during times of emotional or physical stress. Poor quality of life has been implicated in many studies because of the chronic nature of the disease. The inability to control clinical manifestations can disrupt lives because patients fear of being away from home because of the frequency of diarrhea. Eating is frequently associated with the onset of abdominal pain, causing mealtimes to become unpleasant. A thorough assessment of support systems, stress-producing factors, and coping mechanisms is essential. Studies have shown that patients often have maladaptive coping skills that affect peers, family, and others.

When caring for patients with IBD, it is important to consider their stage of growth and development at the time of diagnosis as the average age when diagnosis is made is generally 15 to 35 years of age. Patients with IBD are concerned with how others view them, and this impacts self-esteem. There may be a perceived, or actual, loss of independence, sense of control, privacy, body image, healthy self, peer relationships, self-confidence, productivity, and ways of expressing sexuality, therefore increasing risk of depression. There is also the problem of embarrassment in using public bathrooms and shame with the individuals with ostomies. Depression and anxiety are common in the patient with IBD and should be treated accordingly. Patients often do not discuss these concerns with their healthcare provider, and therefore it often goes untreated. Pharmacological and non-pharmacological treatments may be necessary. Continuous follow-up by the primary care provider is also necessary.

### Surgical Management

Surgery for Crohn's disease is reserved for patients for whom medical management has failed and/or who experience complications from the disease. These complications may include strictures, abscesses, intestinal obstruction, perforation, hemorrhage, or cancer. When a diseased portion of the bowel is removed, it frequently recurs in another section of the bowel. Nevertheless, surgery does not cure Crohn's disease.

Patients with ulcerative colitis for whom medical management has failed or who have experienced complications may undergo a colectomy and be cured of the disease but not of the extraintestinal manifestations. Many patients with ulcerative colitis undergo surgery. An example of a patient for whom medical management has failed may include therapy that includes excessive long-term side effects such as high-dose corticosteroids. Having a colectomy for those patients for whom medical management has failed has demonstrated an improved quality of life. The standard procedure for ulcerative colitis is an ileal pouch anal anastomosis (IPAA). The entire colon and rectum are removed, a pouch is created to collect waste, and the patient is able to defecate

normally. Patients with ulcerative colitis may undergo a **proctocolectomy** with permanent ileostomy, which includes the removal of the colon and rectum and permanent closure of the anus. The ileostomy is permanent. Another procedure includes the creation of a continent ileostomy (**Kock or Koch pouch**) after proctocolectomy. A portion of the ileum is used to create a reservoir that can be catheterized to remove stool. Pouch failure is more common in patients with indeterminate colitis. Box 58.1 provides an overview of surgical options for patients with ulcerative colitis.

### Complications

Patients with inflammatory bowel disease have the potential for many complications in both the gastrointestinal tract and extraintestinal structures. Perineal abscesses and fistulas occur in up to one-third of patients with Crohn's disease, and strictures and fistulas are more common in the patient with Crohn's disease. Extraintestinal complications include joint swelling and pain, ankylosing spondylitis, osteoporosis, kidney stones, eye inflammation, mouth sores, and skin lesions. During inflammation, the patient may experience fever, anorexia, and malaise. Anal **fissures**, tears in the anal wall, or painful ulcers develop secondary to severe bouts of diarrhea. Intestinal obstruction occurs secondary to inflammation and edema. Fibrosis and scarring over time may also cause narrowing of the bowel, leading to an obstruction. Malnutrition frequently develops because of malabsorption of nutrients, severe diarrhea, and anorexia due to the fear that eating may cause an exacerbation of symptoms. In Crohn's disease, the small bowel is affected most often, and malabsorption is more common in this population. Anemia from hemorrhage and malnutrition may lead to patients needing blood transfusions and patients are often prescribed iron supplements to treat anemia.

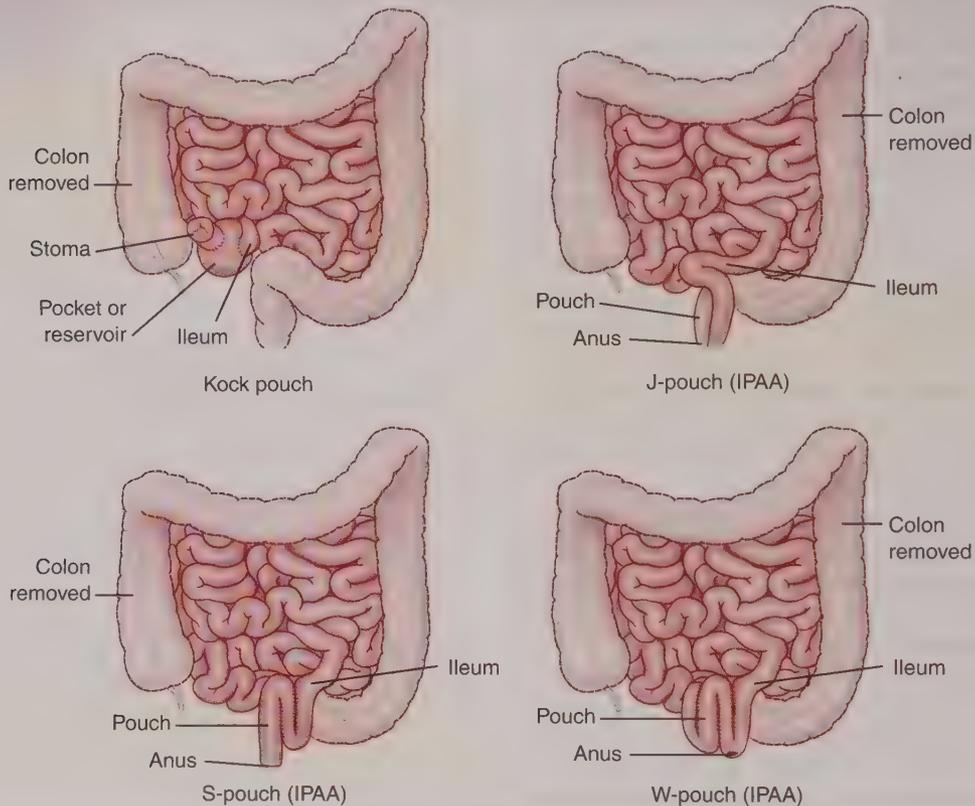

Surgical complications may include anal canal strictures, pelvic sepsis, pouch failure, fecal incontinence, pouch dysplasia/cancer, sexual dysfunction, and female infertility. Chronic pouchitis is a complication associated with the IPAA procedure in approximately 20% of patients in the first year and 50% after five years. Early clinical trials suggest one probiotic preparation may be effective in the prevention of recurrent pouchitis. This preparation, VSL#3, contains four *Lactobacillus* species, three *Bifidobacterium* species, and one strain of *Streptococcus salivarius* subspecies *thermophilus*.

Fistulas are more common with Crohn's disease. The presence of a fistula can often cause other complications such as sepsis, skin irritations, and malnutrition, dehydration, and fluid and electrolyte imbalances. Fistulas are very difficult to treat, and collaboration with a wound and ostomy nurse is essential. Surgery is often necessary to repair some fistulas. Bowel rest and TPN are frequently used for the treatment of fistulas. Types of fistulas that may occur include:

- Enterocutaneous fistula (between skin and intestine)
- Enteroenteral fistula (between intestine and intestine)
- Enterovesicular fistula (between bowel and bladder)
- Enterovaginal fistula (between bowel and vagina)

## Box 58.1 Surgical Options for Ulcerative Colitis

- Proctocolectomy with permanent ileostomy—the colon and rectum are removed, and the anus is closed. The ileostomy is permanent.
- Proctocolectomy with continent ileostomy (Kock pouch)—the colon is removed. The distal portion of the ileum is used to create a pouch, which serves as a reservoir for stool. The patient then must insert a catheter into the pouch several times a day to eliminate the stool.
- Abdominal colectomy with ileoanal anastomosis—the colon is removed, and the ileum is sutured to the anal canal. Leakage of stool is a problem for these patients.
- Colectomy, mucosal proctectomy, and ileal pouch-anal canal anastomosis (IPAA)—performed in a two-step procedure. In the first procedure, the colon and rectal mucosa are removed. An ileoanal reservoir is created by using a portion of the ileum. A temporary ileostomy is created. After the pouch heals (usually in 2–3 months), a second surgery is performed, and the ileostomy is reversed; the pouch serves as a reservoir for stool. The patient then has normal continence of the bowel.

Skin irritation and excoriation often occur because of intestinal secretions being rich in enzymes; protection of the skin is of utmost importance. The skin may come in contact with intestinal secretions through fistulas and **ostomies**, surgical openings in an organ, such as an **ileostomy** (opening in the ileum) and **colostomy** (opening in the colon). The anus can also become irritated from frequent diarrhea. Toxic megacolon (colonic dilation of greater than 5 cm) occurs more commonly in ulcerative colitis and requires emergency colectomy. It usually occurs during an acute exacerbation. Bacterial overgrowth contributes to toxic megacolon. Perforation of the bowel with possible peritonitis can also occur because of the deep ulcerations in the intestines. **Strictures** or narrowing of the bowel usually occur because of fibrosis and scar tissue and require surgery

to correct. Fluid and electrolyte losses caused by excessive diarrhea can lead to fluid and electrolyte disturbances and must be treated accordingly, with magnesium and potassium being of particular importance.

*Short bowel syndrome* can occur if more than 100 cm of small bowel is removed because absorption is greatly affected. The jejunum is where most carbohydrate and protein absorption takes place, and the ileum is where absorption of fats, fat-soluble vitamins, and  $B_{12}$  takes place. If the jejunum alone is removed, the ileum assumes the function of fat absorption. The removal of the ileum accounts for more complications because it is responsible for the absorption of fats, vitamins, bile salts, and  $B_{12}$ . Patients having 50% to 70% of the small intestine removed experience malabsorption but can usually be managed with dietary modification,

oral nutrition supplements, and medications. If removal exceeds 75% of the small intestine, the patient requires long-term TPN or intestinal transplantation. Whether or not the colon is left intact also plays a role in the treatment of short bowel syndrome. The colon absorbs water, electrolytes, and fatty acids although in smaller amounts. Short bowel syndrome may leave the patient TPN dependent.

Although much less common, pulmonary complications may occur. Inflammation of the trachea, bronchi and bronchioles may develop before or after bowel resection. IBD-associated serositis (inflammation of serous membrane such as the pleura, pericardium or peritoneum) may occur as pleural effusions or pericarditis. Pulmonary necrobiotic nodules are a rare extra-intestinal manifestation of Crohn's disease. These are lung nodules that can cavitate and are composed of inflammatory cells with necrosis. Pulmonary complications appear to be associated with medications used to treat IBD.

Chronic abdominal pain affects many patients with IBD, many of whom are treated with narcotic pain relief medications. Many of these patients also experience an overlap of IBS-IBD, which has also been associated with the clinical manifestations of chronic abdominal pain. Pain management for the patient with IBD can prove to be a challenge. Narcotics slow intestinal activity and should be used with caution. Stress and other psychosocial factors can lead to an increased pain perception in this patient population. Chronic narcotic use in these patients can lead to narcotic bowel syndrome. Thought to be underdiagnosed, **narcotic bowel syndrome** is characterized as chronic, intermittent, and cramping abdominal pain associated with the effects of the narcotic analgesic wearing off. The patient therefore takes additional narcotics to relieve the pain, and this leads to a vicious cycle of chronic abdominal pain. Narcotic bowel syndrome often goes undiagnosed for long periods of time. It is estimated that about 4% to 6% of people using long-term opioids develops the syndrome. There must be an established trusting relationship between the patient and the healthcare provider because the patient may go elsewhere for treatment seeking more pain medications which may cause the situation to become worse. Treatment involves weaning the patient off all narcotic pain medications. The patient may be placed on long-acting narcotics to assist with treatment of withdrawal. Antidepressant and anti-anxiety medications may also be used to treat symptoms associated with withdrawal. Nonpharmacological therapies should also be initiated.

## Nursing Management

### Assessment and Analysis

Assessment of intake and output and daily weights will help determine nutritional status of patients with suspected IBD. Frequent diarrhea leads to extreme losses of fluids and potassium, or hypokalemia. Patients with IBD are often victims of social isolation because of the fear of incontinence in public or having the need to be close to a bathroom at all times. Moreover, patients with IBD often

report exacerbations as related to a stressful event. Clinical manifestations include persistent diarrhea, abdominal pain or cramps, fever, weight loss, fluid imbalances, mouth ulcers, anemia, melena, as well as extraintestinal manifestations including uveitis, sclerosing cholangitis, nephrolithiasis, cholelithiasis, joint disorders, and skin disorders.

### Nursing Diagnoses

- **Deficient fluid volume** associated with diarrhea
- **Diarrhea** associated with intestinal inflammation and malabsorption of nutrients
- **Imbalanced nutrition:** less than body requirements related to the inability to absorb nutrients secondary to inflammation
- **Ineffective coping** associated with chronic disease

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*With significant fluid loss, the patient may develop signs of decreased fluid volume including a low-grade fever, elevated heart rate, and decreased blood pressure.*
- Nutritional intake  
*Assisting the patient to maintain an intake diary will assist in monitoring nutritional status. Frequent diarrhea is associated with malabsorption of nutrients.*
- Frequency and characteristics of stools and note any presence of blood  
*Excessive losses result in complications such as fluid and electrolyte imbalances. Blood may be noted in the stool of the patient with ulcerative colitis but is unusual with Crohn's disease.*
- Intake and output  
*Patients often do not attempt to eat or drink in fear of exacerbating clinical manifestations. Urine output should be monitored for at least 30 mL/hr to provide information regarding renal perfusion.*
- Daily weight  
*Weight is the best measure for nutritional needs.*
- Fluid and electrolyte status  
*Patients tend to lose many electrolytes through diarrhea, particularly potassium and magnesium.*
- Psychosocial assessment and support systems  
*The patient frequently is a victim of social isolation because of fears of incontinence and/or frequent trips to the bathroom.*

#### ■ Actions

- Encourage smaller frequent meals  
*Decreases gastric motility*
- Encourage the patient to engage in mealtimes with family  
*Mealtimes often become unpleasant experiences, and patients often isolate themselves from the rest of the family.*
- Encourage periods of rest  
*Help decrease gastric motility and conserve energy*
- Establish a therapeutic relationship  
*Helps develop trust between patient and healthcare provider*

- Make appropriate referral to interprofessional team  
*Inflammatory bowel disease is a complex disease and requires a team approach including a case manager, dietitian, and any local support groups.*
- Pain management  
*Positioning and maintaining a quiet environment may promote comfort. Pain medications may be ordered; if administered, monitor for side effects like constipation.*
- Provide meticulous skin care  
*The patient having frequent diarrhea needs special attention to the rectal area because the feces contain enzymes that may cause excoriation to the skin surrounding the anus.*

### ■ Teaching

- Importance of adequate nutrition  
*Malnutrition due to malabsorption is common with the patient with IBD. Adequate nutrition is required for healing and maintaining a stable weight. A daily multi-vitamin may be prescribed, but vitamins with iron may be controversial due to poor tolerance and may worsen symptoms. Reducing fiber and fat intake during exacerbations, drinking plenty of fluids, and avoiding milk and milk products during exacerbations are also important to the patient's teaching.*
- Indications, actions and side effects of prescribed medications, which may vary (see Table 58.4)  
*If the patient has a good knowledge of his or her medications, compliance will increase.*
- Importance of regular follow-ups and annual colonoscopy  
*Regular follow-ups and colonoscopy are necessary because cancer can develop, particularly with ulcerative colitis.*

### Evaluating Care Outcomes

Inflammatory bowel disease affects individuals in varying degrees, making it difficult to determine exact evaluation criteria for all patients. The patient with IBD should have a good understanding of the importance of maintaining a healthy weight because malnutrition is a common problem. Demonstrating stable vital signs, fluid and electrolyte balance, and stable weight are important outcomes. The patient who has failed medical management may undergo surgery to control clinical manifestations of the disease. Ulcerative colitis is typically more receptive to treatment and can be cured with surgery. Crohn's disease is much more difficult to treat, and patients experience varying levels of success to treatments.

## Celiac Disease

### Epidemiology

Celiac disease is a genetic autoimmune disorder that damages the small intestine. It is related to eating foods containing gluten found in wheat, barley and rye. Gluten is not only found in foods, such as bread and pasta, but also in some hair and skin care products. It can be very serious, causing long-lasting problems, particularly with malabsorption. Some people may have gluten sensitivity with some of the same clinical manifestations while not

having celiac disease, while others may have an allergy to wheat while not having celiac disease. It is important to recognize that if a person cannot have gluten in their diet, it does not necessarily mean they have celiac disease.

Celiac disease is more common in Caucasians, especially in those of European descent, and females. It also has familial tendencies, with heritability estimates ranging from 57% to 87%. It is more common in people with Down syndrome, Turner's syndrome, and Type 1 diabetes. It is estimated that 1 of every 141 people in America are affected, with many undiagnosed.

### Pathophysiology

When people with celiac disease eat gluten, they experience an immune reaction that attacks the small intestine causing inflammation and leading to damage to the intestinal villi, lengthening of intestinal cysts, and mucosal lesions. Because the small intestine is where most absorption takes place, these intestinal changes can lead to malabsorption/malnutrition issues. Left untreated, patients can develop other autoimmune disorders such as type 1 diabetes, dermatitis herpetiformis, and autoimmune thyroiditis. There are rare cases of patients who continue to have symptoms and trouble absorbing nutrients even while maintaining a gluten-free diet. These individuals have refractory celiac disease. The intestines are severely damaged, and the patient may need to receive total parenteral nutrition (TPN) to meet their nutritional needs.

### Clinical Manifestations

The clinical presentation of celiac disease in adults is related to intestinal mucosal damage that causes diarrhea (often foul smelling, light in color and frothy), steatorrhea, flatulence, weight loss, and other signs of malabsorption. The patient may also present with fatigue and weakness related to malabsorption and malnutrition. In severe cases of celiac disease that is associated with longstanding impaired absorption, severe abdominal pain and increased bleeding tendencies may be observed. Celiac disease is often difficult to diagnose because the clinical manifestations are similar to other diseases such as irritable bowel syndrome (IBS) and lactose intolerance, and the patient must be persistent in getting the correct diagnosis.

Some patients present with atypical symptoms and only minor gastrointestinal complaints. These patients may exhibit symptoms of anemia, dental enamel defects, osteoporosis, arthritis, neurological symptoms, infertility, and increased transaminases. Although they do not exhibit the same gastrointestinal symptoms, they can have severe mucosal damage and a biopsy is necessary. Approximately 20% of patients diagnosed in childhood recover completely with a gluten-free diet and continue to have latent disease into adulthood. They remain asymptomatic and regain normal villous architecture, but still require regular follow-ups.

Peripheral neuropathies have been noted in up to 50% of patients with celiac disease which can be associated with vitamin deficiencies and does not seem to improve with a gluten-free diet.

## Management

### Medical Management

#### Diagnosis

Diagnosis of celiac disease is done through blood tests for antibodies against gliadin, genetic tests and biopsy. Gliadin is a water-soluble glycoprotein in the gluten of wheat. Gluten is a group of proteins found in barley, oats, rye and wheat that give flour its stickiness. The most sensitive test for celiac disease is antitissue transglutaminase antibody (anti-tTG), IgA by enzyme-linked immunosorbent assay. A finding of greater than 10 unit/mL is consistent with a diagnosis of celiac disease. Other diagnostic studies, primarily aimed at determining the degree of malabsorption and malnutrition, include CBC, serum electrolytes, coagulation profile, and liver function tests.

#### Treatment

The only treatment for celiac disease is lifelong adherence to a gluten-free diet. Ingesting even a small amount can trigger intestinal damage. Following the gluten-free diet can still take months to several years to heal the intestine in the adult patient, but approximately 70% of patients see improvement within 2 weeks of being gluten-free. Once the intestines are healed, new villi grow and absorption from food is restored. One of the issues with following a gluten free diet is the presence of gluten in products that are not typically associated with these grains, such as salad dressings, puddings, sausage, and soy sauce.

Because some medications may contain gluten, patients should consult their healthcare provider or pharmacist as to any medications, prescription or over-the-counter, that may contain gluten. They usually contain only minimal amounts and may be taken without causing symptoms. While some skin and hair products may contain gluten, it is important to know that this can transfer from hand-to-mouth unknowingly, making it important to read labels.

Management of celiac disease includes six key elements and can be remembered by using the acronym, CELIAC:

- Consult a dietician
- Education about the disease
- Lifelong adherence to gluten-free diet
- Identify and treat malabsorption and malnutrition
- Access support groups (like the Celiac Foundation)
- Continue management through an interdisciplinary team

Patients with latent celiac disease are not advised to be on a gluten-free diet but should be monitored. If clinical manifestations develop, a biopsy is indicated.

Dietary advice for all patients with celiac disease includes:

- No foods containing wheat, rye, or barley in all forms
- Soybean flour, tapioca flour, rice, corn, buckwheat, quinoa, and potatoes are safe
- Distilled alcoholic beverages, vinegars, and wine are safe
- Beer, ales, lagers, and malt vinegars should be avoided
- Oats may be introduced with caution as the research is mixed

After initiation of the gluten-free diet, the patient is monitored at 4 to 6 weeks for a complete blood count (CBC), vitamin B<sub>12</sub>, iron studies, liver enzymes, and serologic tests: IgA anti tissue transglutaminase (tTG) or IgA (or IgG) deamidated gliadin peptide (DGP). Serum IgG antigliadin and IgA endomysial antibody levels fall when the patient adheres to a strict gluten-free diet.

#### Complications

Malnutrition and malabsorption are the most common complications of celiac disease because most absorption of nutrients takes place in the small intestine. Complications associated with changes to the intestinal mucosa and the malabsorption include anemia, osteopenia, and osteoporosis.

### Nursing Management

#### Assessment and Analysis

Because of the damage to the intestinal mucosa associated with the immune response to gluten, the patient presents with gastrointestinal complaints. The clinical manifestations are directly related to the intestinal wall changes and include:

- Diarrhea
- Flatulence
- Abdominal bloating (due to distension secondary to fluids and gas)
- Steatorrhea
- Weakness, fatigue
- Weight loss
- Anemia
- Orthostatic hypotension
- Hypocalcemia

#### Nursing Diagnoses

- **Imbalanced nutrition: less than body requirements** associated with the inability to absorb nutrients
- **Knowledge Deficit** associated with gluten-free diet
- **Risk for dysfunctional gastric motility** associated with inadequate absorption of nutrients

#### Nursing Interventions

##### ■ Assessments

- Vital signs  
*Due to diarrhea, there is an increased fluid loss that may lead to signs of hypovolemia, including decreased blood pressure, orthostatic hypotension, and tachycardia. The temperature may be elevated due to the inflammatory process or fluid volume deficit.*
- Serum electrolytes  
*There may be increased loss of potassium due to the diarrhea, and decreased absorption of calcium due to intestinal mucosal damage. With hypocalcemia, the patient may demonstrate Chvostek or Trousseau signs.*
- CBC  
*Anemia may develop secondary to malabsorption of key nutrients, as well as potential intestinal bleeding due to mucosal wall destruction.*
- Intake and output  
*Diarrhea leads to an increased loss of fluids through the bowels. Urine output may be decreased due to hypovolemia.*

- Stool characteristics  
*Diarrhea develops secondary to damage to the surface of the intestinal wall. The diarrhea may be watery, frothy, light in color, with a foul odor*
- DXA (Dual energy x-ray absorptiometry)  
*The patient is at risk of osteopenia and osteoporosis secondary to malabsorption of calcium*
- Current knowledge of the gluten-free diet  
*Assessment of the patient's current knowledge needs to be established before beginning any teaching. Gluten may be in foods and products that the patient does not associate with this protein found in wheat, rye, and barley.*

#### ■ Actions

- Refer patient to a dietician knowledgeable in celiac disease for gluten-free diet teaching  
*It is always important to involve other members of the healthcare team with more expertise in an area in order to enhance the patient's knowledge*
- Refer to support group for celiac disease  
*Support groups help the patient to learn more about the disease as well as coping strategies used by others*
- Develop a trusting relationship  
*A trusting relationship is necessary in all patient encounters and assists the patient in sharing important information with a non-judgmental approach*
- Encourage patients to ask about gluten-free choices when dining out  
*If gluten-free choices are not on the menu, the patient can help encourage the restaurant to include these choices in the future*

#### ■ Teaching

- Use dishwasher for plates, utensils, pans, etc. exposed to gluten  
*Use of the dishwasher eliminates gluten residue that may be on others' plates, utensils, etc.*
- Diet adherence to the gluten-free diet  
*A lifelong commitment to a huge change in their diet can be very difficult for many patients; particularly if they only had mild symptoms*
- Read food labels  
*It is important to know how to read food labels and recognize if gluten is a part of the food choice*
- Importance of consistent follow up with primary healthcare provider  
*Because celiac disease is a chronic condition, the patient needs to be monitored for subtle signs of the disease in order to minimize complications.*
- Gluten-free resources (applications include Allergy Eats Mobile, Dine Gluten Free, and Find Me Gluten Free)  
*Patients who are knowledgeable are more likely to be compliant with dietary restrictions. The applications also allow more flexibility in finding restaurants where gluten options are available.*

#### Evaluating Care Outcomes

After the patient has reportedly been adhering to a gluten-free diet and is without clinical manifestations, it is still important to follow-up as recommended by the provider for serum laboratory tests confirming that the gluten-free diet is alleviating the inflammation associated with the disease. The dietary changes require a lifelong commitment and the success is monitored by serial anti-tTG levels. If the patient is noncompliant and/or the clinical manifestations persist, it is important to continue educating the patient as to the long-term effects of the chronic inflammation in the small intestine as well as the inability to absorb nutrients properly. Patients with well-managed celiac disease demonstrate stable weight, normal bowel movements, and stable electrolytes.

### Diverticulitis

#### Epidemiology

A **diverticulum** is a small, pouchlike protrusion or herniation, most often occurring in the gastrointestinal tract, particularly the colon. It is more common in Western industrialized societies and is more common in older people. It occurs most frequently in the left colon and is thought to be related to the lack of fiber in the diet, obesity, and lack of physical activity (see Evidence-Based Practice: Diverticulitis and Whole Fiber). In Africa and Asia, the incidence is much lower, and it tends to affect the right side of the colon more frequently as well as younger populations. It is also less common in vegetarians. The incidence increases with age, with diverticulitis found in 30% to 50% of adults over the age of 60 and increasing to 65% by age 85. Men are more affected than women in younger patients, whereas females are more affected in older patients. Risk factors for diverticulosis include increasing age, obesity, smoking, low-fiber diet, heredity, and some medications (NSAIDs, acetaminophen, oral corticosteroids, and opiates). There has also been an association between eating red meat and high-fat diets with the risk of diverticular complications.

### Evidence-Based Practice

#### Diverticulitis and Whole Fiber

It has been previously reported that patients with diverticular disease should not consume whole pieces of fiber such as seeds, corn, and nuts, and this continues to be a routine practice in patients with diverticular disease. The rationale was that these undigested fragments can become lodged in the diverticulum and induce an episode of diverticulitis. Pemberton (2018) states that this theory is unproven.

Pemberton, J. H. (2018). Acute colonic diverticulitis: Medical management. Retrieved from <https://www.uptodate.com/contents/acute-colonic-diverticulitis-medical-management>

## Pathophysiology

Diverticulitis is generally extraluminal, occurring on the outside of the colon, and is often referred to as an *outpouching* (Fig. 58.5). Diverticulosis is the presence of diverticula that are noninflamed. Many patients with diverticulosis are asymptomatic and may not even know they have the condition. Diverticulitis is an inflammation and/or infected diverticula. Diverticulitis most often occurs in the colon, most commonly in the sigmoid colon.

When a patient has diverticula, the colon wall thickens and becomes rigid. Without adequate fiber intake, more water is absorbed from the stool. This slows transit time and makes it more difficult for the stool to pass through the colon. This then causes increased intraluminal pressure from constipation and straining, which is thought to lead to the formation of diverticula. Dietary fiber is thought to act by producing a larger, bulkier stool that results in a wider-bore colon, which is less likely to develop diverticula.

Diverticula seem to occur at points of weakness in the intestinal wall. Food can become entrapped in the diverticula, and when it mixes with normal bacterial flora, this leads to decreased blood supply, forming a mass called a **fecalith** or dried, hard, concrete-like stool. The diverticular wall is eroded by increased intraluminal pressure or hard, dried food particles. This process leads to inflammation and/or infection. This inflammation can spread to other areas of the intestine. Diverticulitis most often occurs in the sigmoid colon. Because the sigmoid colon is the segment with the smallest diameter, increased intraluminal pressure may predispose this area to more frequent herniation. Diverticulitis may be acute or chronic. In chronic diverticulitis, the bowel can become scarred, leading to narrowing of the lumen, and the patient may develop an intestinal obstruction. In a small number of patients with diverticulitis, it is difficult to distinguish from carcinoma because both may show

focal thickening of the bowel wall, or it may even resemble inflammatory bowel disease (IBD). Diverticulitis may lead to stricture formation that also has the appearance of cancer. Biopsy is required to make the differential diagnosis.

## Clinical Manifestations

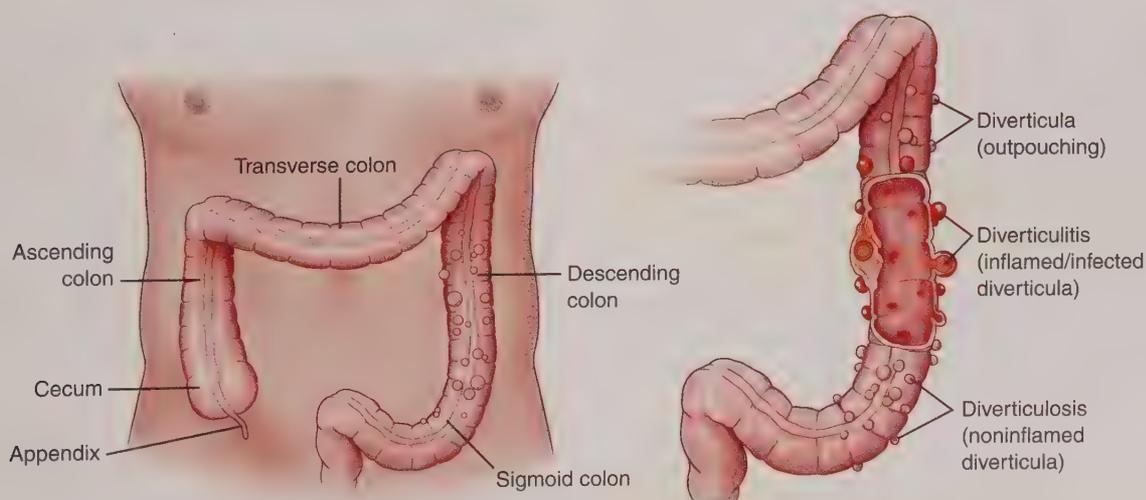

Patients with diverticulitis complain of abdominal pain over the area that is involved, usually the sigmoid colon. They may experience fever or leukocytosis, and often a palpable mass is felt over the involved area. The patient may complain of increased flatus, anorexia, abdominal bloating/distention, and diarrhea or constipation. Stools may contain mucus and blood. Bleeding occurs because of inflammation near areas of blood vessels and may range from minor to severe. Older adult patients, however, may present afebrile with a normal white blood cell (WBC) count and minimal abdominal tenderness. The first sign that may appear in the older adult patient is a change in mental status. Baseline temperature is often decreased from normal in the older adult. Therefore, one of the most common signs of infection may not be apparent in the older adult, and the patient may present with increased confusion, falling, and anorexia. If perforation has occurred, the patient may present with clinical manifestations of sepsis. If the pain is more generalized over the abdomen, peritonitis may have developed, and if peritonitis has occurred, the patient displays profound guarding with widespread rebound tenderness.

## Management

### Medical Management

#### Diagnosis

The most common diagnostic tests are plain flat-plate abdominal x-rays, but the diagnosis is usually confirmed with a CT scan. The CT scan also helps differentiate from other sources of abdominal pain and complicated cases of

**FIGURE 58.5** Diverticulitis. Diverticulitis is generally extraluminal, occurring on the outside of the colon, and is often referred to as an outpouching. Diverticulosis is the presence of diverticula that are noninflamed. Diverticulitis is an inflammation and/or infected diverticula.

diverticulitis. The white blood cells (WBCs) are monitored for elevations initially associated with inflammation and possible infection but should decrease with treatment. The urinalysis may show a few red blood cells (RBCs) if the ureter is near a perforated diverticulum. The patient with suspected diverticulitis should not have a barium enema because of the risk of rupturing the diverticula.

### Treatment

Uncomplicated diverticulitis may be treated on an outpatient basis with broad-spectrum antibiotics for 7-10 days but should be reassessed after 2-3 days of therapy. The patient is advised to consume a clear liquid diet until symptoms subside, and then the diet should then be advanced slowly as tolerated. Common antibiotics used to treat diverticulitis include: Ciprofloxacin and metronidazole, trimethoprim-sulfamethoxazole and metronidazole, amoxicillin-clavulanate, Augmentin or Moxifloxacin. The patient should be admitted to the hospital for fever higher than 102.5°F (39°C), microperforation (few air bubbles outside the colon or confined to the pelvis), immunosuppression, significant leukocytosis, severe abdominal pain or diffuse peritonitis, advanced age, significant comorbidities, intolerance of oral intake, noncompliance or failed outpatient treatment. There are no dietary restrictions in acute uncomplicated diverticulitis, although limiting to a clear liquid diet for 2 to 3 days is common, while advancing as tolerated.

If the patient is admitted to the hospital, IV fluids are started, and nothing is given by mouth (NPO) to allow the bowel to rest. The patient may have a nasogastric (NG) tube for bowel decompression and will receive parenteral antibiotics. Laxatives and enemas should be avoided because they increase intestinal motility. Pain medications may be given as needed, and opiates are frequently needed. Inpatients may be discharged as clinical manifestations resolve and should complete a course of 10 to 14 days of antibiotics, and then have a follow up examination. After clinical manifestations completely resolve, the patient is recommended to have a colonoscopy to assess the extent of the diverticular disease.

### Surgical Management

Failure of medical management may necessitate the need for surgical intervention. Indications for surgery may include perforation, obstruction, abscess formation which is not responding to antibiotic treatment, or fistula formation between the colon and another pelvic organ. If patients develop complications, they may require surgery to remove the diseased portion of the colon. They may have a temporary colostomy because re-anastomosis 3 to 6 months later is usually successful.

### Complications

Complications of diverticulitis include perforation, microperforation, abscess and fistula formation, bowel obstruction, and bleeding. Inflammation can also result in fistulas to other organs.

### Nursing Management

#### Assessment and Analysis

Fever often accompanies diverticulitis, ranging from a low-grade fever to 101°F (38.3°C) due to inflammation. Tachycardia often accompanies increased temperature. Pain accompanies diverticulitis, usually in the left lower quadrant or midabdomen depending on what area of the colon is involved. If abdominal pain is generalized, the diverticula may have ruptured, and peritonitis should be suspected. Altered bowel habits often accompany diverticulitis with constipation, diarrhea, or both. The patient may also complain of increased flatus and anorexia. Stools may contain mucus or blood. An elevated WBC is indicative of infection. However, it is not unusual for the patient with diverticulitis to initially present with a normal WBC.

#### Nursing Diagnoses

- **Acute pain** related to inflammation and distention of the colon
- **Knowledge deficit** related to the need to consume adequate fiber in the diet

#### Nursing Interventions

##### ■ Assessments

- **Vital signs**  
*Fever often accompanies diverticulitis, ranging from a low-grade fever to 101°F (38.3°C) because of inflammation. Tachycardia often accompanies increased temperature secondary to an increase in insensible fluid loss due to fever.*
- **Serum potassium levels**  
*If the patient has intermittent NG suction, potassium loss increases and requires monitoring and replacement if levels are below 3.5 mEq/L.*
- **Intake and output**  
*Fluid volume status may be impacted by NG suction and decreased intake. Important to monitor urine output to determine renal perfusion.*
- **Pain**  
*Pain accompanies diverticulitis, usually in the left lower quadrant or midabdomen depending on what area of the colon is involved. If abdominal pain is generalized, the diverticula may have ruptured, and peritonitis should be suspected. Opioid analgesics are frequently required but should be used with caution in older adults because of the mental status changes that may occur.*
- **Mental status in older adults**  
*Older adults do not always show classic signs of infection. The first changes observed may be changes in mental status.*

##### ■ Actions

- **Administer IV fluids**  
*Patients are often NPO during the acute phase to allow the bowel to rest, and fluid balance must be maintained.*
- **Administer ordered antibiotics**  
*Diverticulitis is a localized infection. Antibiotics are administered until pain, inflammation, infection, and fever subside.*

- Nasogastric tube to low intermittent suction  
*Gastric decompression decreases gastric motility and allows the bowel to rest until inflammation decreases.*
- Provide oral care  
*Oral cavity may be dry due to insensible fluid loss, as well as increased mouth breathing in the patient with an NG tube. Apply lip balm to dry, cracked lips.*

### Teaching

- Dietary recommendations  
*The nurse should teach patients about increasing fiber from raw fruits and vegetables in their diets. Without adequate fiber intake, more water is absorbed from the stool. This slows transit time and makes it more difficult for the stool to pass through the colon. This then causes increased intraluminal pressure from constipation and straining, which is thought to lead to the formation of diverticula. But it is also important to note that patients should not increase their fiber during acute phases, and the diverticulitis should be resolved.*
- Avoid straining, bending, and lifting.  
*These activities increase intra-abdominal pressure, which can lead to further outpouching of the diverticula.*
- Weight reduction  
*Obesity has been linked to increased intra-abdominal pressure, which is a risk factor for diverticulitis.*
- Complete antibiotic therapy as prescribed  
*Adherence to antibiotic therapy is crucial, and the nurse should stress to the patient who is being treated in the outpatient setting about the importance of taking all of the medication as prescribed. Rebound infection can occur when the prescribed dose of antibiotics is not taken.*

### Connection Check 58.4

A patient is admitted to the hospital for treatment for diverticulitis. The nurse recognizes which interventions appropriate for this patient?

- High-fiber diet, ambulate frequently, IV fluids, pain medications
- Antibiotics, IV fluids, NPO, NG tube, pain medications
- Laxatives, enemas, diet, pain medications
- Surgery with follow-up physical therapy

### Evaluating Care Outcomes

Uncomplicated diverticulitis may be managed on an outpatient basis. Frequently, however, the patient is admitted to the hospital for antibiotic therapy and bowel rest. The patient will be free of abdominal pain and fever prior to discharge from the hospital. Maintaining adequate fiber in the diet may decrease recurrence or the severity of bouts of diverticulitis.

## Appendicitis

### Epidemiology

Appendicitis is an acute inflammation of the vermiform appendix. Affecting males more than females, appendicitis is a common condition that occurs more frequently

in the 10- to 19-year-old age group. When it does occur in older adults, it usually ruptures and is much more serious, and mortality is higher in this age group. There are no particular risk factors or preventive measures.

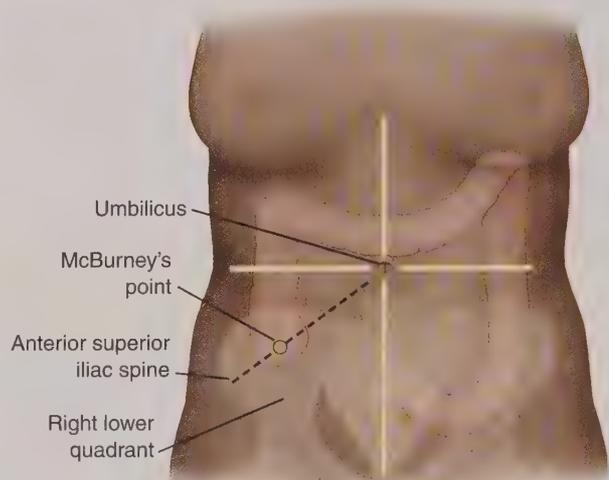

### Pathophysiology

The appendix is a small hollow appendage that extends off the cecum, and although it is made of lymphatic tissue, it has no known function. Appendicitis usually occurs as a result of a fecalith or other foreign body blocking the opening, leading to inflammation and subsequent infection. Other, less common causes may include malignant tumors, twisting and kinking of the appendix, edema of the bowel wall, adhesions, and other infections.

When the opening to the appendix becomes blocked, the mucosa begins to secrete fluid, leading to venous engorgement that increases intraluminal pressure and restricts blood flow. Subsequently, bacterial invasion occurs, and an abscess may develop if this process occurs slowly. Gangrene can occur in as little as 24 to 36 hours and is life threatening. Perforation can occur in as few as 24 hours, but the risk increases after 48 hours and can result in peritonitis, and this, too, is life threatening.

### Clinical Manifestations

The patient with appendicitis presents with periumbilical abdominal pain, often with complaints of anorexia, nausea, and vomiting. While the inflammatory process progresses, pain is shifted to the right lower quadrant of the abdomen and becomes more severe and steady in the area of **McBurney's point** (Fig. 58.6). When applying and releasing pressure to this area, if the patient notes increased pain when pressure is released, this is called *rebound tenderness* and is another indication of appendicitis. Another sign of appendicitis is **Rovsing's sign**, which presents when palpation of the left lower quadrant of the abdomen elicits pain in the right lower quadrant. The WBC may have a moderate

**FIGURE 58.6** McBurney's point. Located in right lower quadrant of the abdomen, pain increases at McBurney's point with appendicitis.

increase with acute appendicitis (10,000–18,000/mm<sup>3</sup>), and if the WBC is elevated to greater than 20,000/mm<sup>3</sup>, a perforated appendix should be suspected. In the event of perforation, the patient may exhibit signs of sepsis, including elevated temperature, tachycardia, and decreased blood pressure.

## Management

### Diagnosis

Appendicitis is commonly diagnosed based on clinical presentation and specific physical assessment findings. An ultrasound may reveal an enlarged appendix, but a CT scan is the most commonly used diagnostic test. Other diagnostic testing includes CBC and serum electrolytes.

### Surgical Management

There is no medical management for acute appendicitis. A surgical consult should be obtained as soon as possible, and the patient needs to be prepared for the operating room for removal of the appendix (appendectomy). Laxatives and enemas should be avoided because they can increase intra-abdominal pressure that may result in perforation of the appendix.

The surgeon may perform the appendectomy with laparoscopy, where several small incisions are made, and the laparoscope is placed. If the appendix is suspected of being ruptured and/or peritonitis is suspected, a laparotomy with a larger abdominal incision is made. If there are no complications after the appendectomy, the patient may be discharged from the postanesthesia care unit (PACU) or the following day. If complications develop after the appendectomy, such as peritonitis or abscesses, the patient is admitted to the hospital to receive parenteral antibiotics for several days depending on the severity of the infectious process.

## Complications

The major complications secondary to appendicitis are associated with rupture that results in contamination of the peritoneal cavity with intestinal matter. With rupture, the patient develops peritonitis that may deteriorate to sepsis and requires IV antibiotics to treat the infection.

## Nursing Management

### Assessment and Analysis

The patient may or may not initially present with an elevated temperature, but while the inflammatory process progresses, the patient will develop a fever. Tachycardia often results because of the fever, fluid loss, and pain. Clinical manifestations may begin with cramping periumbilical pain followed by anorexia, nausea, and vomiting. The patient may exhibit pain in the area of McBurney's point or Rovsing's sign. If the patient expresses increased pain with coughing and/or movement and indicates that pain is relieved with bending the right hip or knees, further assessment for

perforation and peritonitis is required. An abrupt change in the character of the pain and a change in blood pressure and/or pulse may also indicate perforation. The patient with appendicitis will likely have an elevated WBC count and a left shift in the differential (indication of increased number of immature white blood cells associated with inflammation and infection).

### Nursing Diagnoses

- **Acute pain** associated with inflammation of the appendix
- **Risk for deficient fluid volume** associated with increased fluid loss (fever and vomiting)
- **Knowledge deficit** associated with preoperative and postoperative care

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*A fever may not be present initially but will develop as inflammation increases. Tachycardia may also be present because of the fever.*
- **Intake and output**  
*Because of potential vomiting and fever, the patient is at risk for fluid volume deficit. During the surgical procedure, anesthesia depresses the nervous system and the ability to assess the patient's need to urinate. Urinary retention is more common with lower abdominal surgeries because of spasms and/or guarding related to pain. If the patient is being discharged from the PACU, it is imperative that the patient urinate before discharge.*
- **White blood cell count and differential**  
*The patient with appendicitis will likely have an elevated WBC count with a left shift in the differential.*
- **Pain**  
*The patient with appendicitis experiences pain, particularly in the right lower quadrant. Changes in pain, particularly if abrupt, may indicate perforation.*
- **Rebound tenderness**  
*When applying and releasing pressure to McBurney's point, the patient notes increased pain when pressure is released; this is an indication of appendicitis.*

#### ■ Actions

- **Make sure the patient is NPO**  
*Because surgical intervention is the definitive treatment for appendicitis, the patient must have nothing by mouth during the diagnostic work-up in the event the patient must emergently go to the operating room*
- **Administer prescribed IV fluids**  
*Because of an increase in fluid loss secondary to vomiting and fever, IV fluids are maintained preoperatively and postoperatively to maintain fluid balance.*
- **Prepare patient for operating room**  
*There is no medical treatment for appendicitis. The patient needs to be prepared for the operating room for removal of*

the appendix. Ensure that the surgical consent form is signed prior to the patient receiving any sedatives or narcotics.

- Provide comfort measures  
*While the patient is prepared for the operating room, ice may be applied to the right lower quadrant to impede blood flow to the area, which slows the inflammatory process. The nurse should never apply heat, however, because this increases blood flow and inflammation to the area and may cause the appendix to rupture. Analgesics may be prescribed preoperatively but are generally withheld until a diagnosis is made to prevent masking of clinical manifestations. Postoperatively, the patient requires opioid analgesics.*
- Position patient supine with head of bed elevated 30° to 45° with knees flexed or side-lying with knees flexed.  
*This position decreases the strain (pull) on the abdominal muscles and may decrease pain secondary to inflammation in the peritoneal cavity*
- Advance diet as tolerated after surgical procedure  
*Once bowel sounds have returned, begin diet with clear liquids, advancing as tolerated while assessing for nausea and/or vomiting*

### Teaching

- Turning, coughing, deep breathing, and incentive spirometer 10 times every hour while awake  
*Promotes lung expansion and prevents atelectasis and helps mobilize any secretions to be expectorated*
- Early ambulation  
*Promotes circulation and prevention of VTE and improves respiratory function*
- Take full course of antibiotics despite lack of fever or pain  
*The patient may have antibiotics prescribed, particularly if the appendix ruptured prior to surgery. Emphasize the importance of completing all antibiotics, even if having no symptoms.*
- Teach wound care if appropriate  
*If the appendix ruptured, the incision will be left open by the surgery to heal by secondary intention. Wound care usually involves a moist saline dressing two to three times a day. The patient/family should be taught to change the dressing before discharge. A home health referral should be included in the discharge planning to assist the patient and family at home with the dressing changes and assess for any complications that may arise.*

**Safety Alert** If the patient is suspected of having appendicitis, the nurse should never apply heat because this increases blood flow and inflammation to the area and may cause the appendix to rupture.

## Connection Check 58.5

The nurse is caring for a patient in the emergency department with abdominal pain, fever, nausea, and vomiting. The patient is suspected of having appendicitis. What intervention may the provider order to confirm diagnosis?

- Flat-plate x-ray of the abdomen, chemistry panel
- CT scan, complete blood count (CBC), abdominal assessment for rebound tenderness
- Administer a laxative to see if symptoms improve
- Colonoscopy, esophagogastroduodenoscopy (EGD), and endoscopic retrograde cholangiopancreatogram (ERCP)

### Evaluating Care Outcomes

The patient who has had surgery for appendicitis without rupture is usually discharged from the PACU on the first postoperative day. Most patients have an uneventful recovery, and can resume normal activities in 2 to 4 weeks. If the appendix has ruptured, the patient is admitted to the hospital and treated with antibiotics and wound care. The family is involved in wound care, and a home health nurse is ordered to monitor progress of healing and assist the family with wound care. Expected outcomes include stable vital signs, CBC within normal limits, and demonstrated understanding of postoperative and discharge teaching.

## COLORECTAL CANCER

### Epidemiology

Colorectal cancer involves cancer of the rectum and large intestine. It is the third most common form of cancer and second leading cause of death in the United States. In 2018, the American Cancer Society estimated that there would be 97,220 new cases of colon cancer and 43,030 new cases of rectal cancer, with a combined death of 50,630 in the United States. The incidence has steadily decreased in the United States, probably attributable to increased awareness and better screening techniques. Most colorectal cancers are found in the distal portion of the large intestine. The incidence has increased, however, in right-sided colon cancers, primarily in the cecum in the United States and internationally for reasons that are unclear. This could be associated with better screening for left-sided colon cancers and removal of polyps during colonoscopy. Death rates have been decreasing for more than 2 decades, also attributable to better screening methods and removal of polyps during colonoscopy before they can progress into cancer. Colorectal cancer affects men slightly more than women, with African Americans having the highest incidence and mortality with no clear reason. With early detection, it is now one of the most curable of all cancers. The United States has one of the highest survival rates from colorectal cancers.

Risk factors for developing colorectal cancer during one's lifetime include personal or family history of colorectal cancer (first-degree relative), history of adenomatous polyps, inflammatory bowel disease (IBD) for 10 years or more, familial adenomatous polyposis, hereditary non-polyposis colorectal cancer (HNPCC) or Lynch syndrome, physical inactivity, obesity (body mass index  $\geq 30$  kg/m<sup>2</sup>), high-fat diets and consumption of red meat ( $\geq$  seven servings a week) and processed meats, cigarette use, and alcohol intake ( $\geq$  four drinks per week). Another factor associated with increased risk is inadequate intake of fruits and vegetables, although it is unclear whether diets high in fiber seem to help. People with type 2 diabetes also have a 30% increased risk for development of colorectal cancer compared with people without diabetes. The risk of developing colorectal cancer increases with age, and the incidence is higher in industrialized countries. Risk factors are just that—risk factors. It does not necessarily mean the disease will develop, and many people with no known risk factors also get the disease. Most colorectal cancers are sporadic rather than familial (see Genetic Connections).

## Genetic Connections

### Hereditary Aspects of Colorectal Cancer

Heredity accounts for about 5% to 10% of all colorectal cancers. **Familial adenomatous polyposis (FAP)** is an autosomal dominant disorder that accounts for less than 1% of all colorectal cancers. Numerous colonic adenomas appear during childhood. Thousands of adenomas develop by late childhood or early adulthood. If left untreated, nearly 100% of these individuals will develop colon cancer by the age of 40 to 45. Treatment involves a total colectomy, usually in their late teens or early 20s. **Hereditary non-polyposis colorectal cancer (HNPCC)**, or **Lynch's syndrome**, is an autosomal dominant syndrome and accounts for 3% to 5% of all colonic adenocarcinomas. Lynch's syndrome is characterized by early age onset and predominance of right colon tumors. Patients with the gene for Lynch's syndrome are also at risk for developing extracolonic malignancies including carcinoma of the endometrium, ovary, stomach, small bowel, pancreas, upper renal tract, and hepatobiliary tract. They have a lifetime risk of colon cancer of approximately 80% to 100%, usually before age 45. Affected women also have a higher risk of developing endometrial cancer. Once Lynch's syndrome or FAP is diagnosed, genetic testing is performed on all offspring so close surveillance can be implemented with early intervention in order to prevent colorectal cancers from developing.

There have been several studies associated with what are known as protective factors for colorectal cancers. There is some evidence that diets high in fruits and vegetables, regular physical activity, regular use of aspirin or other NSAIDs, and hormone replacement therapy in postmenopausal women may have protective properties for colorectal cancer. Research continues on the effectiveness of the administration of folic acid, vitamin B<sub>6</sub>, calcium, magnesium, garlic, fish consumption, and statin medications, but there is no clear evidence to support either at this time.

## Pathophysiology

Most colorectal cancers are adenocarcinomas, which are a type of cancer that originates in glandular cells of internal organs. **Metastasis** (spread of the cancer) can occur by direct extension to adjacent organs, through the lymphatic system or the bloodstream. The most common area of metastasis is to the liver, but colorectal cancer can also metastasize to the lungs, brain, bones, and adrenal glands. Seeding may also occur during resection when the cancer cells break off from the tumor into the peritoneal cavity. A surgeon experienced in resection of colon cancer uses special techniques to prevent this from occurring. Box 58.2 illustrates common diagnostic tests for colorectal cancer.

## Clinical Manifestations

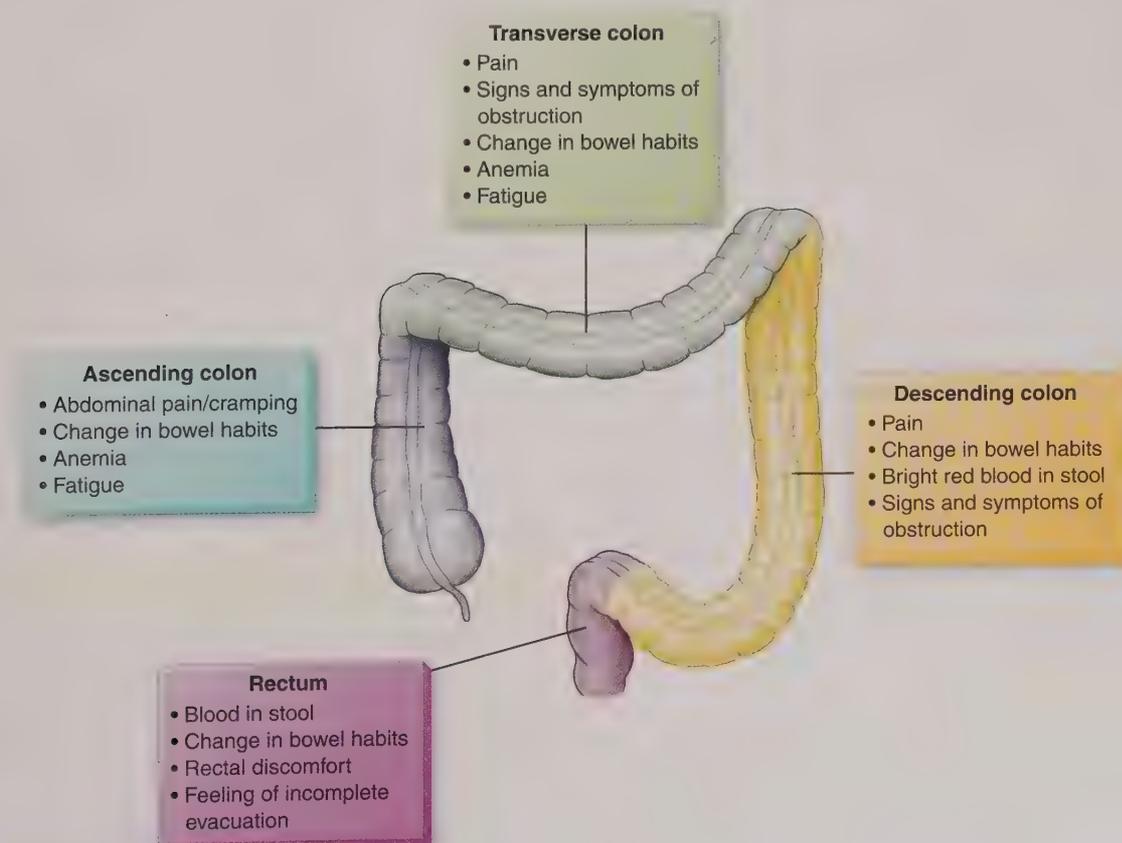

In the very early stages of colorectal cancer, the symptoms are insidious and may be ignored by the patient until the disease is advanced. Clinical manifestations vary according to where the cancer is located in the intestine. **Unexplained weight loss and fatigue** may be the first signs for any location of the cancer. Other clinical manifestations may include a change in bowel regularity and/or the appearance of stool, blood in the stool (red or black depending on location), abdominal pain and/or distention, and a sensation of pressure as with incomplete evacuation after a bowel movement, along with clinical manifestations of anemia. The patient's presentation progresses to clinical manifestations of intestinal obstruction as the cancer increases in size. Specific to the area in which the primary tumor is located, clinical manifestations include (Fig. 58.7):

- **Ascending colon:** vague abdominal pain and/or cramping, change in bowel habits, anemia, and fatigue
- **Transverse colon:** pain, clinical manifestations of obstruction, change in bowel habits, anemia, and fatigue
- **Descending colon:** pain, change in bowel habits, bright red blood in stool, and clinical manifestations of intestinal obstruction
- **Rectum:** blood in stool, change in bowel habits, rectal discomfort, and feeling of incomplete evacuation

## Box 58.2 Diagnostic Studies for Colorectal Cancer

- Fecal occult blood test (FOBT) or fecal immunochemical test (FIT) and digital rectal examination (DRE)—stool sample is collected and placed on a special slide and tested for hidden blood. A DRE is performed by the provider.
- Lower GI series—a tube is inserted into the rectum, and the large intestine is filled with barium. The patient is asked to change positions several times in order to evenly distribute the barium. X-ray pictures and/or video are taken. The barium is constipating, so care should be taken to advise the patient to take appropriate measures to prevent constipation.
- Double-contrast barium enema—takes place after the patient has expelled most of the barium from the intestine. The remaining barium clings to the intestinal wall. The intestine is then inflated with air, and additional x-ray images are taken.
- Sigmoidoscopy—a flexible tube with a light and camera at the end is inserted into the rectum and colon up to the transverse colon. The camera transmits images to a computer screen. Biopsies can be taken from the rectum and sigmoid colon for further examination.
- Colonoscopy—a long, flexible tube with a light and camera on the end is inserted into the full length of the colon. The provider has the ability to view the entire colon as well as to remove polyps and take biopsies as deemed necessary. The patient receives sedation for the procedure.
- Virtual colonoscopy—performed in either the computed tomography (CT) scanning department or magnetic resonance imaging (MRI) (most commonly CT scanning). A tube is inserted into the rectum. For CT, carbon dioxide is administered to enlarge the colon for better viewing. For MRI, a contrast medium is given through the rectum to expand the large intestine. Cross-sectional images are produced and processed to create three-dimensional, computer-generated images of the large intestine. Sedation is not required for the procedure.
- Fecal DNA testing—colorectal cancers contain abnormal DNA that is shed in the stool. If this test is positive, it should be followed with a colonoscopy.
- Wireless capsule endoscopy—known as the pill camera, - is a pill approximately the size of a vitamin. The patient swallows the pill with the camera within the pill, and the camera captures video throughout the GI tract. It takes approximately 8 hours to pass through the GI tract while images are recorded on a portable device. The images are transferred from the portable device to a computer. This technique is most useful with cancers of the small bowel that are difficult to detect through traditional endoscopy.

DNA, Deoxyribonucleic acid; GI, gastrointestinal.

**FIGURE 58.7** Colorectal cancer tumor clinical manifestations based on anatomical location of the tumors.

## Management

### Medical Management

#### Diagnosis

Colonoscopy is the gold standard for colorectal cancer screening. With the use of colonoscopy, biopsies can be taken, and polyps removed during the procedure. There are studies that demonstrate that colonoscopy is overutilized in some populations and underutilized in others. Individuals have different risk factors for colorectal cancer, and the recommendation for colonoscopy is based on the patient's risk factors, rather than age alone. Colonoscopy is far more expensive than some of the other screening methods as well as more invasive. Recommendations for screening for colorectal cancers are included in Box 58.3. For more specific guidelines related to age, race and other comorbidities, refer to Chapter 55 Evidence-Based Practice: Preferred Colorectal Cancer Screening Recommendations.

Other diagnostic studies that may be evaluated with suspected colorectal cancer include a serum carcinoembryonic antigen (CEA), CBC, CT, MRI, and abdominal x-rays. An elevated CEA indicates overexpression of an oncofetal glycoprotein that is normally expressed by mucosal cells, the CBC results may demonstrate anemia due to blood loss and elevated WBC secondary to inflammation or infection, and CT, MRI, or abdominal x-rays may provide information about abdominal obstruction.

The most common method of staging colorectal cancer is with the TNM (tumor-node-metastasis) classification system, which is further classified into stages I through IV. Prognosis worsens with larger size and depth of the tumor, lymph node involvement, and metastasis. Table 58.5 demonstrates the TNM classification system and staging system. Table 58.6 demonstrates survival rates for colorectal cancer.

#### Treatment

##### Chemotherapy

Chemotherapy is used as an adjunct to improve survival rates for patients whose tumors cannot be completely removed. Adjuvant chemotherapy is recommended for patients with stage II or stage III disease. Chemotherapy interrupts the DNA production of cells. These medications cannot distinguish between healthy cells and cancer cells. Intra-arterial chemotherapy may be given into the liver if metastasis (spread of the cancer to one or more sites within the body, usually by the blood or lymphatic system) has occurred. Common side effects of chemotherapy include diarrhea, mucositis, leukopenia, mouth ulcers, alopecia, and peripheral neuropathies. Commonly used chemotherapy medications used to treat colorectal cancer are listed in Table 58.7.

##### Radiation Therapy

Radiation therapy can be used preoperatively to reduce the size of the tumor, making it easier to remove all or most of the tumor. For colon cancer, preoperative or postoperative radiation has not proven to be effective in overall survival rates, but it can be effective in providing regional or local control of the disease. Radiation can also be used as a

## Box 58.3 Screening Recommendations for Colorectal Cancers

### People With Average Risk

#### Age 45–75

Stool-based tests (options)

- High-sensitivity fecal occult blood test (FOBT) annually
  - Highly sensitive guaiac-based fecal occult blood test (gFOBT) every year
  - Multi-targeted stool DNA test (MT-sDNA) every 3 years
- Visual (structural) exams of the colon or rectum (options)
- Flexible sigmoidoscopy (FSIG) every 5 years
  - Virtual colonoscopy every 5 years
  - Colonoscopy every 10 years

#### Age 76–85

Do not screen routinely\* The decision would be made based on patient's overall health and prior screening history

#### Age older than 85

Do not screen\*

People with risk factors such as inflammatory bowel disease, Familial adenomatous polyposis (FAP), and Lynch's syndrome should follow their provider's recommendations.

### People at Increased or High Risk

Screening might need to begin before age 45 and be screened more often and/or get specific tests for these individuals

- Strong family history of colorectal cancer or certain types of polyps
- Personal history of colorectal cancer or certain types of polyps
- A personal history of inflammatory bowel disease
- Known family history of hereditary colorectal cancer
- Personal history of radiation to the abdomen or pelvic area to treat a prior cancer

\*Complications seen with screening often outweigh the benefits for persons aged 76 to 85.

palliative measure to control pain, hemorrhage, bowel obstruction, or metastasis to the lung in advanced disease. Radiation is effective for rectal cancer and may be used preoperatively, intraoperatively, or postoperatively.

### Surgical Management

Treatment of colorectal cancers usually involves surgery to remove the affected portion of the colon. The type and extent of surgery depends on the size of the tumor, its location, and its stage. The goal of surgery is to remove the tumor and affected portion of the colon with proximal and distal margins of the normal bowel. Adjacent lymph nodes are also removed. Depending on the location of the tumor, a temporary or permanent colostomy may be performed. Often a temporary colostomy is performed, and at a later time after healing has taken place, an **anastomosis** (attachment of one end to the other) is performed to reconnect the

**Table 58.5 American Joint Committee on Cancer's Tumor-Node-Metastasis Classification of Colorectal Cancer**

<b>T</b>	<b>Primary Tumor</b>
<b>T<sub>x</sub></b>	Primary tumor cannot be evaluated because of incomplete information
<b>T<sub>is</sub></b>	Carcinoma in situ; cancer is in the earliest stage and has spread; involves only the mucosa
<b>T<sub>1</sub></b>	Tumor has grown beyond the mucosa into the submucosa
<b>T<sub>2</sub></b>	Tumor has grown through the submucosa into the muscularis propria (outer muscle layer)
<b>T<sub>3</sub></b>	Tumor has grown through the muscularis propria into the outer layers but not into neighboring organs or tissues
<b>T<sub>4a</sub></b>	Tumor has spread completely through the serosa (visceral peritoneum), the outermost layer of the intestine
<b>T<sub>4b</sub></b>	Tumor has spread completely through the serosa (visceral peritoneum), the outermost layer of the intestine, and into nearby tissues or organs
<b>N</b>	<b>Lymph Node Involvement</b>
<b>N<sub>x</sub></b>	Lymph nodes cannot be assessed because of incomplete information
<b>N<sub>0</sub></b>	No lymph node involvement is found
<b>N<sub>1a</sub></b>	Cancer is found in one nearby lymph node
<b>N<sub>1b</sub></b>	Cancer is found in 2–3 nearby lymph nodes
<b>N<sub>1c</sub></b>	Cancer is found in fat near lymph nodes but not in the lymph nodes themselves
<b>N<sub>2a</sub></b>	Cancer is found in 4–6 nearby lymph nodes
<b>N<sub>2b</sub></b>	Cancer is found in 7 or more nearby lymph nodes
<b>M</b>	<b>Metastasis</b>
<b>M<sub>0</sub></b>	No distant metastasis is seen
<b>M<sub>1a</sub></b>	Cancer has spread to 1 distant organ or set of distant lymph nodes
<b>M<sub>1b</sub></b>	Cancer has spread to more than 1 distant organ or set of lymph nodes, or it is in parts of the abdominal cavity
	<b>Stage Grouping</b>
<b>0</b>	T <sub>is</sub> , N <sub>0</sub> , M <sub>0</sub> : The cancer is in its earliest stage; known as carcinoma in situ or intramucosal carcinoma
<b>I</b>	T <sub>1–2</sub> , N <sub>0</sub> , M <sub>0</sub> : Cancer has grown into submucosa or muscularis propria, but it has not spread to nearby lymph nodes or distant sites
<b>IIA</b>	T <sub>3</sub> , N <sub>0</sub> , M <sub>0</sub> : The cancer has grown into the outermost layers but has not gone through them and has not spread to lymph nodes or distant sites
<b>IIB</b>	T <sub>4a</sub> , N <sub>0</sub> , M <sub>0</sub> : Cancer has grown through the wall of the colon or rectum but has not grown into other tissues or organs; it has not spread to lymph nodes or distant sites
<b>IIC</b>	T <sub>4b</sub> , N <sub>0</sub> , M <sub>0</sub> : Cancer has grown through the wall of the colon or rectum and grown to nearby tissues or organs; it has not spread to lymph nodes or distant sites
<b>IIIA</b>	T <sub>1–2</sub> , N <sub>1</sub> , M <sub>0</sub> : The cancer has grown through the submucosa and may have grown into the muscularis propria; it has spread to 1–3 nearby lymph nodes or into areas of fat near the lymph nodes; it has not spread to distant sites
	or
	T <sub>1</sub> , N <sub>2a</sub> , M <sub>0</sub> : The cancer has grown into the submucosa and has spread to 4–6 nearby lymph nodes; it has not spread to distant sites
<b>IIIB</b>	T <sub>3–4</sub> , N <sub>1</sub> , M <sub>0</sub> : The cancer has grown into the outermost layers of the colon or rectum or through the visceral peritoneum; it has spread to 1–3 lymph nodes or areas of fat near lymph nodes; it is not in distant organs
	or
	T <sub>2–3</sub> , N <sub>2a</sub> , M <sub>0</sub> : The cancer has grown into the muscularis propria or into the outermost layer of the colon or rectum; it has spread to 4–6 nearby lymph nodes but not to distant sites
	or
	T <sub>1–2</sub> , N <sub>2b</sub> , M <sub>0</sub> : The cancer has grown into the submucosa or into the muscularis propria and spread to 7 or more lymph nodes; it has not spread to distant sites

<b>IIA</b>	67%	65%
<b>IIB</b>	59%	52%
<b>IIC</b>	37%	32%
<b>IIIA</b>	73%	74%
<b>IIIB</b>	46%	45%
<b>IIIC</b>	28%	33%
<b>IV</b>	6%	6%

\*Survival rates were better for some stage III cancers than some stage II cancers, but the reasons are unclear.

colon to the rectum to allow for normal defecation. It may be possible to preserve sphincter function in some rectal cancers. Common surgical procedures are:

- **Colectomy**—excision of part of or all of the colon
- **Hemicolectomy**—excision of half or less of the colon (may be right or left)
- **Abdominoperineal resection**—the affected colon and affected rectum are removed, and the anus is closed. The colon is removed through an abdominal incision, and the rectum is removed through a perineal incision. The ileostomy is permanent.

### Complications

Based on the timing of diagnosis, location of the cancer, as well as the treatment, the patient may develop complications related to colorectal surgery. For patients undergoing

**Table 58.7 Commonly Used Chemotherapy Medications for Colorectal Cancer**

Medication	Action
<b>5-Fluorouracil (5-FU) with leucovorin (LV)</b>	Cell-cycle-specific, interfering with the synthesis of DNA and RNA, causing their death
<b>Capecitabine (Xeloda)</b>	Converted in tissue to 5-FU, which inhibits DNA and RNA synthesis by preventing thymidine production, causing death of rapidly replicating cells
<b>Oxaliplatin (Eloxatin)</b>	A platinum-based antineoplastic agent; binds to DNA and RNA mis-coding information and/or inhibiting DNA replication, and cells die
<b>Bevacizumab (Avastin)</b>	An antiangiogenesis medication that reduces blood flow to the tumor cells, depriving them of nutrients needed for replication
<b>Irinotecan (Camptosar)</b>	Inhibits the enzyme topoisomerase I required for DNA replication, causing cell death by damaging DNA produced during the S phase of cell synthesis
<b>Cetuximab (Erbix)</b>	Cetuximab (Erbix)—a monoclonal antibody that binds to protein to slow cell growth

chemotherapy, complications include fatigue, increased risk of infection, and anemia. Radiation enteritis may develop and lead to diarrhea, blood in the stool, and weight loss. Postoperative complications include blood loss, anastomoses, infection, and incisional dehiscence. Metastasis

is also a potential complication for colorectal cancer, particularly when the cancer is more advanced when diagnosed.

## Nursing Management

### Preoperative Patient

The patient with colorectal cancer undergoes a variety of emotions, and it is important to include family members whenever possible with assessment and teaching. Nursing management includes teaching, preparation for treatments, and emotional support.

### Assessment and Analysis

Assess the patient's current knowledge of the disease and treatment. A comprehensive understanding of the location, type, severity, and classification of the cancer is key to providing holistic nursing care. It is also important to correlate the clinical manifestations and diagnostic study results with the definitive diagnosis. The clinical presentation is closely associated with the location of the tumor, and includes unexplained weight loss, fatigue, blood in the stool, and clinical manifestations of anemia. Assess any support systems the patient has because the patient will need this support from family and friends through surgery and afterwards at home.

### Nursing Diagnoses

- **Knowledge deficit** related to surgery for colorectal cancer
- **Fear** related to the potential outcome of surgery for colorectal cancer

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Vital signs measure physiological function and provide a baseline for after surgery.*
- **Serum electrolytes and CBC values**  
*It is important that the patient's serum electrolytes are within normal limits prior surgery. The CBC provides baseline data about hemoglobin and hematocrit, as well as the WBC that may be elevated due to inflammation or infection*
- **Current knowledge of disease and pre-/postoperative care**  
*The nurse should reinforce any teachings given by the surgeon, such as the incision and any drains that may be present after surgery. The knowledge of what to expect postoperatively helps to alleviate concerns and fears associated with the surgery.*

#### ■ Actions

- **Bowel prep (if ordered)**  
*The patient will likely receive a thorough "bowel prep" prior to surgery to minimize bacterial growth and prevent contamination with feces during surgery. The most common method of bowel prep or cleansing is polyethylene glycol solution (e.g., GoLYTELY). An antibiotic may also*

*be given prior to the incision, also to reduce the risk of infection (see Evidence-Based Practice: Mechanical Bowel Preparation).*

- **Establish a therapeutic relationship**  
*A therapeutic relationship enhances the trust of the patient and decreases anxiety and fears,*
  - **Ensure the surgical consent form is signed and witnessed**  
*This is a legal requirement for all invasive procedures. The consent form must be signed prior to the patient receiving any type of sedative, hypnotic, narcotic, or anesthetic agent*
- #### ■ Teaching
- **Preoperative teaching related to ostomy care (Box 58.4)**  
*With adequate preoperative teaching, it is more likely the patient will be compliant with the treatment regimens, and to have less anxiety and fear of what to expect. If the patient has adequate preoperative teaching related to ostomy care, the patient demonstrates better adjustment postoperatively. If the patient is expected to have an ostomy performed during surgery, a preoperative consultation is necessary with the wound ostomy continence nurse (WOCN).*
  - **Pain**  
*Teach the patient about methods of pain management postoperatively, such as patient-controlled analgesia (PCA), epidural anesthesia with the progression to oral pain medication. Knowledge of how pain will be managed postoperatively decreases anxiety and fears.*

## Evidence-Based Practice

### Mechanical Bowel Preparation

There is growing evidence that bowel surgery can safely be performed without mechanical bowel preparations. Because of the time required, as well as the side effects of bowel preparations, including fluid and electrolyte loss and patient issues with tolerating the ordered medications, there is evidence the bowel can be adequately prepared immediately before the surgical procedure.

- Bhat, A. H., Parray, F. Q., Chowdri, N. A., Wani, R. A., Thakur, N., Nazki, S. & Wani, I. (2016) Mechanical bowel preparation versus no preparation in elective colorectal surgery: A prospective randomized study. *International Journal of Surgery Open 2* (2016) 26-30. <http://dx.doi.org/10.1016/j.ijso.2016.02.010>
- Rollins, K. E., Javanmard-Emamghissi, H. & Lobo, D. N. (2018). Impact of mechanical bowel preparation in elective colorectal surgery: A meta-analysis. *World Journal of Gastroenterology*, 24 (4), 519-536. <http://dx.doi.org/10.3748/wjg.v24.i4.519>

### Postoperative Patient

Nursing management of the patient undergoing surgery for colorectal surgery is similar to that for other general abdominal surgeries.

## Box 58.4 Ostomy Care

A colostomy is a surgically created opening on the abdomen in which the large intestine is connected for the elimination of fecal matter into an appliance specifically designed for this purpose. If the entire colon is removed, the opening is connected to the ileum of the small intestine and is called an ileostomy. If the patient has an ostomy (colostomy or ileostomy), the color and integrity need to be assessed frequently. The stoma should be reddish pink and moist. There is usually some edema initially, which subsides with time. Common locations of stomas according to ostomy location are demonstrated in Figure 58.8. The appliance is secured in place to minimize skin exposure to the stool. Slight bleeding from the stoma is not initially unusual. If the stoma begins to show signs of ischemia (dark red, purplish, or black color) or unusual bleeding, the provider should be notified immediately. The skin around the ostomy site should be inspected frequently and assessed for leakage. Leakage around the appliance into the surgical incision is a risk for infection. The ostomy will begin to function within 2 to 4 days postoperatively. It is important to note any gas being expelled from the appliance, as well as stool. The appliance needs to be emptied when there is gas or if it is one-third to one-half full of stool to decrease the risk of the appliance detaching from the skin. Stool appearance is initially liquid.

The final consistency of the stool is dependent on the location of the ostomy (Fig. 58.9). The closer the ostomy is to the small intestine, the more liquid the stool. The patient with an ileostomy needs to be monitored more closely for fluid and electrolyte balance depending on the amount of drainage noted. The ostomy is described according to location and can be placed in any section of the colon or at the ileum. Stool consistency is generally described as:

- Ileostomy—liquid to semiliquid
- Ascending colostomy—semiliquid
- Transverse colostomy—semiliquid to semiformal
- Descending colostomy—semiformed
- Sigmoid colostomy—formed

Self-care of the ostomy by the patient is far more successful if initial teaching is implemented before the surgery, if possible. Occasionally, a patient undergoes surgery under emergent conditions, and therefore, preoperative teaching is not possible. If the surgery is planned, the patient should have a consult with the wound ostomy continence nurse (WOCN) prior to surgery, who will discuss fears and concerns associated with having an ostomy. The WOCN provides educational materials that patients can review prior to having surgery and answer any questions. The WOCN marks the abdomen for the best possible placement of the ostomy based on the contour of the abdomen in lying, sitting, and standing positions. The WOCN also assesses the presence of any skin folds, creases, bony prominences, and scars, as this allows for optimal placement and best fitting of an appliance after surgery.

### Assessment and Analysis

Vital signs measure physiological functions and should be within the range of preoperative levels. After anesthesia, it is important to note the patient's ability to arouse and orientation to surroundings. Change in level of consciousness is often the first sign of other complications. The patient is better able to participate in activities to prevent postoperative complications if pain is adequately treated. Postoperatively, pain in the surgical area is expected. The bowel sounds will be severely diminished or absent, which is expected postoperatively due to surgical manipulation. The CBC may demonstrate mild anemia, and the WBC is elevated due to inflammation, and is monitored for infection. In the case of an ostomy, assessment of the stoma is important to ensure that there is adequate perfusion to the stoma.

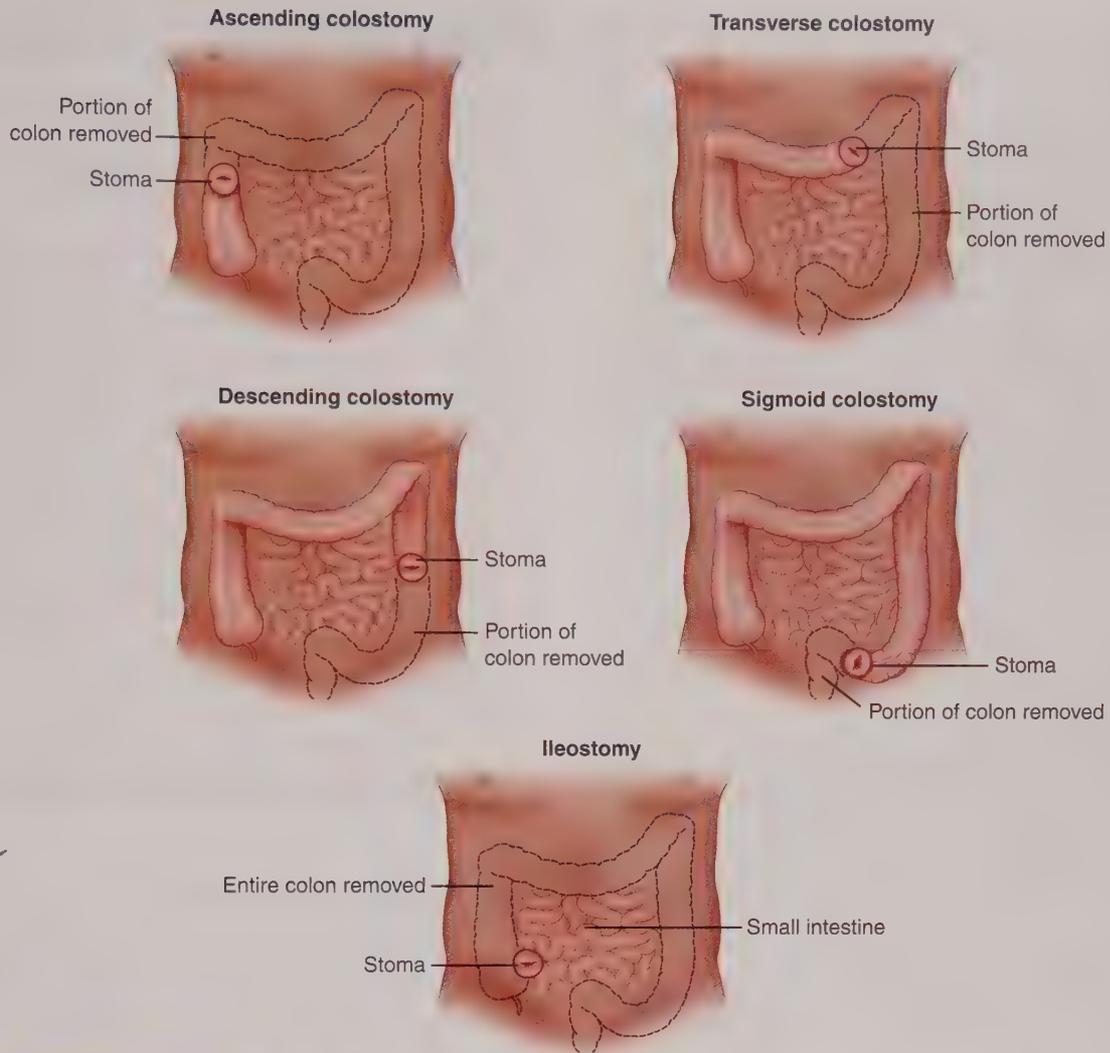

### Nursing Diagnoses

- **Acute pain** associated with the surgical incision
- **Potential for infection** associated with interruption of primary defenses (skin) and indwelling tubes and drains
- **Risk for imbalanced fluid volume** associated with the response to abdominal surgery
- **Knowledge deficit** associated with postoperative care
- **Disturbed body image** associated with the ostomy

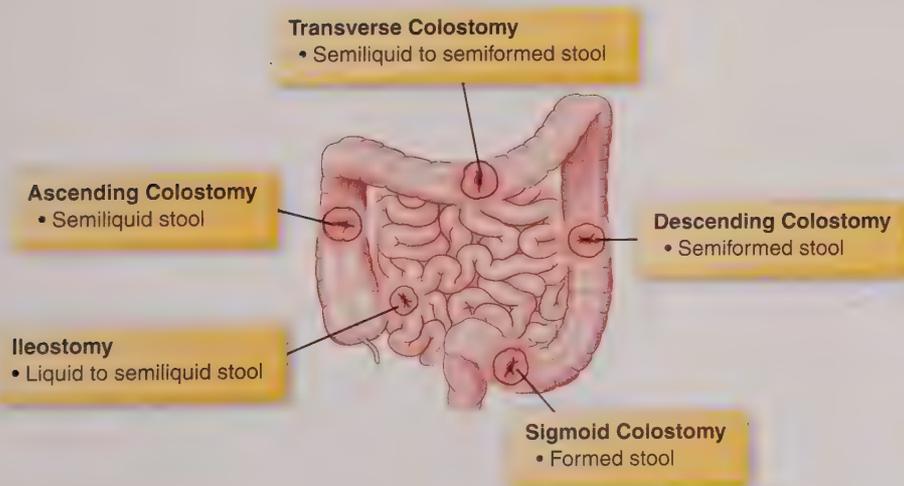

### Nursing Interventions

#### ■ Assessments

- **Vital signs at least every 4 hours**  
*A mild elevation in temperature may be expected in the first 48 hours because of the inflammatory response to surgery. A marked elevation in the first 48 hours is usually related to atelectasis. After the first 48 hours, the patient should continue to be assessed for infection. Elevations in heart rate and decrease in blood pressure are indicative of decreased fluid volume status.*
- **Hemoglobin and hematocrit**  
*Monitor hemoglobin and hematocrit daily while patient is hospitalized because this may indicate bleeding and/or nutritional deficits. It is important to compare preoperative levels to postoperative levels while noting the estimated blood loss in surgery.*
- **White blood cells**  
*WBC is monitored every day for the first few days. A mild elevation can be expected in the first 48 hours because of the inflammatory response. Later an elevation may indicate infection or other complication*
- **Nausea and vomiting**  
*Anesthesia and manipulation of the bowel decrease peristalsis, and bowel sounds may be absent for 1 to 3 days after surgery. The patient will not have anything to eat or drink after surgery (NPO), with IV fluids and electrolyte replacements given as needed. The patient may have an NG tube for stomach decompression postoperatively, and it must be frequently assessed for patency. The NG tube remains in place until bowel function returns.*

**FIGURE 58.8** Common locations of stomas.

**FIGURE 58.9** Stool consistency based on the location of the ostomy.

The patient then begins with a clear liquid diet, advancing the diet as tolerated.

- Intake and output  
Fluid losses from surgery result in decreased renal perfusion, leading to fluid retention. The lower output is caused by increased aldosterone and antidiuretic hormone secretion because of the surgery and associated stress associated. The patient should maintain 30 mL/hr of urine output. The patient may have an indwelling urinary (Foley) catheter in place after the surgery, with standard measures taken to prevent urinary tract infection. Low urine output compared with intake in the first 24 hours is normal as long as 30 mL/hr is maintained. By the third postoperative day, urine output normalizes
- **Stoma** (opening of the ostomy), if applicable  
Determines the health of the stoma. The stoma should be reddish pink and moist. There may be some edema noted initially, which will subside in a few days. There may also be slight bleeding or serosanguineous drainage. Any discolorations could be a sign of necrosis and should be reported to the healthcare provider.
- Ostomy drainage  
The type, amount, appearance, and consistency of drainage will differ as to where the ostomy is placed. The closer to the small intestine the ostomy is placed, the more liquid the stool. For the patient with an ileostomy, it is important to monitor fluid and electrolyte balance due to potential losses of potassium (see Evidence-Based Practice: Passive Drains).
- Abdominal/perineal dressing/incision  
Incisions and dressings should not have excessive drainage noted because this could indicate complications such as bleeding.
- Pain  
Adequate pain management is necessary for the patient to return to an optimal level of functioning and to prevent postoperative complications.

#### ■ Actions

- Administer IV fluids  
IV fluids are maintained postoperatively to replace fluid losses in surgery and to assist in maintaining proper fluid balance.
- Maintain NPO/Advance diet as tolerated  
Prevention of nausea and vomiting until bowel function returns. Return of bowel sounds is required prior to advancing the diet to minimize nausea and vomiting.
- Nasogastric tube care  
The patient may have an NG tube for stomach decompression, and measurement of this output is also necessary. Nasogastric tubes that allow for gastric decompression remain in place until bowel function returns, preventing nausea and vomiting from occurring. It is important to ensure that there is consistent drainage, as lack of output from the drain may indicate an obstruction. Without adequate decompression and drainage, there may be pressure on the surgical site.

- Implement pain management strategies  
Adequate pain management is important in the postoperative period. The patient may have a PCA pump or epidural analgesia for the first few days postoperatively. If pain is adequately controlled, the patient will return to an optimal level of activity sooner and prevent postoperative complications.
- Drain management  
The placement of drains prevents fluid accumulation near the site of surgery. There may be drains placed within the perineal and/or abdominal incision such as a Penrose drain, Jackson-Pratt, or Hemovac. The nurse notes the appearance and amount of drainage frequently, and drainage is usually serosanguineous. Drains are monitored for decreasing amount of drainage and are usually left in place approximately 3 to 5 days. When the dressing of a Penrose drain is changed, care must be taken to make sure it is not accidentally dislodged. Make a note of the amount, color, and odor of the drainage.
- Turning, coughing, deep breathing, and incentive spirometer 10 times every hour while awake  
Promotes lung expansion, prevents atelectasis, and helps mobilize secretions to be expectorated
- Implement early ambulation  
Promotes circulation and prevention of postoperative complications such as venous thromboembolism (VTE). The patient may also be receiving anticoagulation therapy with heparin or Lovenox for VTE prophylaxis.
- Perianal care  
For the patient who has undergone an abdominoperineal resection, it is important to note that the perineal incision is much more sensitive and a greater source of pain for the patient than the abdominal incision. The patient often complains of phantom rectal sensation due to the fact that sympathetic nerves responsible for rectal control are not severed during surgery. The area should be inspected frequently for drainage and abscess (localized collection of pus) formation. Sitz baths may be ordered for comfort and gentle cleansing of the perineal area.
- Make appropriate referrals
  - Social worker/case manager
  - Home health agency
  - Ostomy support group
 With appropriate referrals in place prior to discharge, patients can be assured that they will continue to have their needs met after discharge, which will decrease fears and anxiety.

#### ■ Teaching

- Methods to prevent postoperative complications  
Teaching methods to prevent postoperative complications are more successful if the teaching takes place preoperatively.
- Ostomy teaching: assist the WOCN with ongoing teaching related to the care of the ostomy  
If the patient has adequate preoperative teaching related to ostomy care, the patient demonstrates better adjustment postoperatively. If the patient is expected to have an ostomy performed during surgery, a preoperative consultation is necessary with the WOCN.

## Evidence-Based Practice

### Passive Drains

Surgeons often use a type of drain in the patient near the site of incision to prevent fluid collection, which may cause an infection. Drains may be active or passive. Examples of passive drains include Penrose drains, Foley catheter, Word catheter, and Malecot catheter. They are called *passive* because they rely on gravity to drain. Active drains may be further subdivided into open or closed systems. An example of an open system is a Salem sump, which is connected to suction into a canister at the bedside. The Jackson-Pratt drain is referred to as a closed system and works by negative pressure. A disadvantage of the open system is the potential for bacterial contamination. Most surgeons prefer closed systems with negative pressure, such as the Jackson-Pratt drain.

Numata, M., Godai, T., Shirai, J., Watanabe, K., Ingaki, D., Hasegawa, S., Masuda, M. (2014). A prospective randomized controlled trial of subcutaneous passive drainage for the prevention of superficial surgical site infections in open and laparoscopic colorectal surgery. *International Journal of Colorectal Disease*, 29(3), 353–358.

### Evaluating Care Outcomes

There is a direct relationship between outcomes and how well the patient was prepared for the surgery and/or treatment related to colorectal cancer. The outcomes for the patient with colorectal cancer depends on the extent of the disease and treatment regimen. At discharge the patient demonstrates stable vital signs, adequate hematocrit and hemoglobin, no signs of infection, positive bowel sounds, ability to care for surgical incision site and ostomy (as required), and pain management strategies. The patient requires follow-up care for return of normal bowel function, as well as adaptation to the diagnosis and treatment.

**Safety Alert** If the stoma begins to show signs of ischemia (dark red, purplish, or black color) or unusual bleeding, the provider should be notified immediately. This is a sign that there is little or no blood flow to the stoma.

### Connection Check 58.6

The nurse is caring for a patient with colorectal cancer who just had a total colectomy with placement of a permanent ileostomy. Which nursing diagnosis is a priority for the immediate postoperative period?

- Disturbed body image
- Acute pain
- Potential for infection
- Knowledge deficit

## ABDOMINAL TRAUMA

### Epidemiology

Abdominal trauma may result from blunt trauma in which there is no penetrating injury or from a penetrating injury caused by a stabbing or a gunshot wound. The most common cause of blunt trauma is motor vehicle crashes, with motor vehicle crashes and pedestrian versus automobile accidents accounting for more than 75% of all cases of blunt abdominal trauma. Any abdominal organ may be injured, but the spleen & liver are the most common organs.

With abdominal stab wounds, the liver is the most often injured organ. Although stab wounds are approximately three times more prevalent than gunshot wounds, morbidity and mortality are less. Abdominal trauma from gunshot wounds is associated with approximately 90% of mortalities from penetrating abdominal injuries.

### Pathophysiology

Abdominal trauma may be the result of blunt trauma or penetrating injury between the diaphragm and the pelvis. Blunt trauma may occur as a result of a motor vehicle accident, falls, assaults, or contact sports. Although injury may not be immediately obvious, there may be significant internal organ damage. Blunt trauma involves concussive and compression forces that result in tears and hematomas of solid organs, as well as deceleration forces that can lead to organ rupture secondary to intraluminal pressure changes. Bleeding and organ damage may also develop secondary to stretching and tears along ligaments that support organs secondary to these deceleration injuries.

Penetrating trauma may be caused by gunshot wounds or stabbing wounds. Any organ within the abdominal cavity has the potential for injury as a result of either injury, but the liver is the most commonly injured organ. The foreign object penetrates the abdominal cavity and may result in profuse bleeding that may deteriorate to hemorrhagic shock.

Hypovolemic shock can occur rapidly. Trauma to solid organs, such as the liver and spleen, causes hemorrhage when injured. Hollow organs, such as the stomach, urinary bladder, and intestines, may cause peritonitis when their contents (undigested food, urine, or feces) spill into the abdominal cavity.

### Clinical Manifestations

Once the trauma patient's airway, breathing, and circulation have been thoroughly assessed, then the patient needs to be evaluated for signs of hemorrhage, shock, and peritonitis. The clinical manifestations vary widely according to the organ of injury, and assessment includes the presence, location, and quality of any pain experienced by the patient. Often with abdominal trauma, there are obvious injuries, including bruising, penetrating injuries, abrasions, lacerations, discolorations, and asymmetry. **Ecchymosis** (bruising) around the umbilicus (**Cullen's sign**) or the flank areas

(**Turner's sign** or **Grey Turner's sign**) may indicate intra-abdominal and/or retroperitoneal hemorrhage and should be reported to the provider immediately. With the loss of bowel sounds, peritonitis should be suspected. Auscultation of bruits over the abdomen may indicate renal artery, arterial, or aortic damage. Abdominal trauma is often associated with other injuries, such as bone fractures and head injuries.

## Management

### Medical Management

#### Diagnosis

Laboratory tests include baseline serum chemistries, CBC, and urinalysis. The hemoglobin and hematocrit may or may not be abnormal initially as fluids are being lost along with the red blood cells. Once fluid resuscitation has begun, a change will then be noted in the hemoglobin and hematocrit if the patient is bleeding internally, as the remaining RBCs will be diluted. Urinalysis is assessed for the presence of blood in the urine. The patient should also be typed and cross matched for the possibility of a blood transfusion. Based on the stability of the patient, x-rays and CT or MRI scans may be completed to fully determine the severity of the trauma. If the patient is able to travel to radiology, a CT scan is performed to identify specific areas of injury. Healthcare providers must be attentive to potential spinal cord injuries when transferring to radiology and patients should be accompanied by a provider familiar with the care of the trauma patient.

Diagnostic peritoneal lavage (DPL) may be used to diagnose intra-abdominal bleeding. The provider inserts a catheter into the abdominal cavity. Fluid is allowed to enter the abdominal cavity and is then allowed to drain. If the fluid that drains out of the abdomen appears bloody, the patient is prepared for emergency surgery. Another diagnostic tool used to evaluate trauma patients is the focused abdominal sonography for trauma (FAST), which can be used to scan the abdomen in 3 to 5 minutes, noting any free fluid in the abdominal cavity. The FAST scan is recommended versus DPL if ultrasound is available.

#### Treatment

Medical management is totally dependent on the nature of the injury or injuries. Large-bore IV lines are inserted, and fluid resuscitation is initiated for volume expansion. A nasogastric tube may be inserted for gastric decompression. The trauma patient's condition can change rapidly and requires vigilant observation. An indwelling urinary catheter may be inserted to observe for hematuria as well as to closely monitor urinary output in the immediate postoperative period.

### Surgical Management

The patient may be transported emergently to the operating room for an exploratory laparotomy to determine and treat the injuries. With bowel perforation or laceration, the injury is surgically explored and repaired, and the patient is started on antibiotics due to increased risk of peritonitis.

### Complications

Complications of abdominal trauma are directly related to the injury to internal organs. Hemorrhagic shock may develop, particularly secondary to penetrating trauma. Peritonitis, potentially leading to septic shock, may develop with intestinal damage that allows fecal material to enter the peritoneal cavity. Ischemic bowel and paralytic ileus may also occur secondary to the traumatic event. With significant blood loss, accompanied with sepsis, the patient may develop adult respiratory distress syndrome and disseminated intravascular coagulopathy.

### Nursing Management

Nursing care of the abdominal trauma patient is based on protocols from Advanced Trauma Life Support that follows the ABCDE pattern: Airway, Breathing, Circulation, Disability (Neurological status), and Exposure.

### Assessment and Analysis

Airway management is the priority to ensure a patent airway, as chest injuries are often associated with abdominal trauma. The abdominal trauma patient's vital signs can change very quickly based on the amount of fluid loss, and the nurse should be trained in emergency management. Clinical manifestations of abdominal trauma are based on type (blunt or penetrating) of trauma, as well as organs and structures involved. Based on the severity of the trauma, clinical presentation of abdominal trauma may include:

- Tachycardia
- Tachypnea
- Pain
- Bruising
- Abrasions
- Lacerations
- Discoloration
- Cullen's sign
- Turner's sign
- Absence of bowel sounds

The patient can deteriorate quickly with large blood and fluid losses, and hypovolemic shock and death can occur rapidly.

### Nursing Diagnoses

- **Risk for ineffective airway clearance** associated with trauma
- **Risk for deficient fluid volume** associated with blood loss
- **Acute pain** associated with tissue damage caused by abdominal trauma

### Nursing Interventions

#### Assessments

- **Airway**  
*It is important to assess airway clearance because the patient may have blood and/or vomitus in the oral cavity.*

*Establishment of a patent airway is the priority because other injuries are likely with abdominal trauma and require adequate oxygenation and perfusion of vital organs.*

- Vital signs including oxygen saturation  
*Vital signs can change very quickly with abdominal trauma. Respiratory rate and effort may increase with airway obstruction. Heart rate increases and blood pressure decreases with significant blood loss. Pulse may increase with pain.*
- Level of consciousness using the Glásgow Coma Scale  
*Determines patient's level of consciousness because there may be associated head injury with motor vehicle accidents. The level of consciousness may also decrease with profound hypovolemia associated with blunt trauma to the abdominal cavity.*
- Clinical manifestations of hypovolemic shock  
*Hypovolemic shock and death can occur rapidly and are manifested by decreased blood pressure, increased pulse, diminished peripheral pulses, decreased skin temperature, and decreased urinary output.*
- CBC and urinalysis  
*The hemoglobin and hematocrit need to be monitored because values may decrease as fluid resuscitation is started in patients with blood loss. Low values also are indicative of the degree of blood loss from the injury.*
- Serum electrolytes  
*Baseline serum electrolytes are particularly important in patients who may require nasogastric decompression because potassium loss occurs with NG suctioning.*
- Urinalysis  
*Urinalysis is assessed for the presence of blood in the urine.*
- Bowel sounds  
*With damage to the abdominal organs, there may be a decrease or complete absence of bowel sounds.*
- Area of injury  
*Observe for signs of internal bleeding (Cullen's and Turner's signs) with blunt abdominal trauma. Assess for entry and exit wounds with gunshot wounds. Observe area of stabbing, and if the instrument is still in the patient's body, do not remove and allow the physician to manage the weapon.*

#### ■ Actions

- Administer supplemental oxygen  
*With trauma, particularly with the risk of hypovolemia, supplemental oxygen increases oxygen delivery to maximize organ perfusion*
- Insert large-bore IV and administer IV fluids  
*Administration of IV fluids rapidly may prevent the patient from hypovolemic shock.*
- Do not remove object protruding from wound  
*Removing objects may increase the risk of bleeding.*
- Control bleeding  
*Promotes hemodynamic stability*

- Administer antibiotics  
*Prophylactic antibiotics are typically initiated with abdominal trauma secondary to the risk of internal damage that may lead to peritonitis*
- Consult with primary provider regarding need for Type and Cross match  
*With the increased chance of bleeding with abdominal trauma, it is important to have blood ready for transfusion as the patient's condition warrants.*

#### ■ Teaching

- Explain to the patient and family all procedures regardless  
*The patient has many fears and is generally unfamiliar with hospital and trauma protocols. Patient confidence and cooperation is enhanced by understanding of what is happening in the ED, OR, PACU, and inpatient unit.*
- Keep family informed about the patient's condition  
*Families are often subject to being overlooked in the trauma setting and should be kept informed of the patient's condition.*
- Nutrition and diet  
*Based on the type of injury, the patient may require dietary modifications. With significant damage to the gastrointestinal tract, the patient may require long-term total parenteral (TPN) or enteral nutrition.*
- Wound care  
*Based on the extent of the surgical procedure, the patient may have tubes, drains, or an ostomy. Patient teaching encourages independence in postoperative care.*
- Clinical manifestations of infection  
*Due to the increased risk of peritoneal contamination with abdominal trauma, the patient needs to acknowledge the signs and symptoms of infection and to report immediately to their provider.*

#### Evaluating Care Outcomes

The outcome is largely dependent on the nature and extent of the injuries. The priorities are physiological stability as evidenced by stable vital signs, hematocrit and hemoglobin within acceptable parameters, no clinical manifestations of infection, adequate pain management, and stable weight. The patient is independent in care requirements for the postoperative wound, and any associated equipment (for example, ostomy).

**Safety Alert** Clinical manifestations of hypovolemic shock are restlessness, anxiety, cool clammy skin, confusion, weakness, pale color, tachypnea, tachycardia, and hypotension. If the patient experiences abdominal trauma and displays these clinical manifestations, the nurse should keep the patient calm and warm, elevate lower extremities (unless contraindicated by other injuries), maintain a patent airway, and maintain IV access.

### Connection Check 58.7

A patient has just been brought to the emergency department by emergency medical services after a motor vehicle accident. What is the first thing the nurse should do?

- Ask the patient if he or she is in pain
- Mental status examination and vital signs
- Ask the patient to move all extremities
- Order laboratory tests

## Making Connections

### CASE STUDY: WRAP-UP

A colonoscopy shows that Jack has multiple ulcerative lesions in the descending colon. His upper gastrointestinal endoscopy is negative. The wireless capsule endoscopy is negative. His vital signs are: temperature is 100.5°F (38°C); pulse is 133; respiratory rate is 24; blood pressure is 122/75 mm Hg; pain score is 7/10 (0–10 pain scale). His weight is 62 kg (136.4 lb), and his height is 165.5 cm (65.2 in.). His hemoglobin is 7.6 g/dL, and his hematocrit is 21.2%. Jack's diagnosis is ulcerative colitis.

Jack Conner undergoes surgery for his ulcerative colitis. He had the first of two surgeries: colectomy, mucosal proctectomy, and ileal pouch-anal canal anastomosis. Jack has a temporary ileostomy. He will return to the hospital in 2 to 3 months to have the ileostomy reversed.

#### Case Study Questions

- What clinical manifestations does Jack display that are consistent with a diagnosis of ulcerative colitis? (*Select all that apply.*)
  - Bloody stools
  - Constipation
  - Belching
  - Chest pain
  - Dysphagia
- What diagnostic tests does the nurse expect to be ordered for Jack on the basis of these symptoms?
  - CBC, MRI, electrolytes, stool analysis
  - CT scan, MRI, chemistry panel, ERCP
  - Colonoscopy, CBC, wireless capsule endoscopy, upper GI endoscopy
  - BUN, creatinine, ultrasound, chest x-ray
- What other priority information may the nurse assess in order to care for Jack?
  - Psychosocial history, family history, vital signs, previous bowel history
  - Vaccine history, medication history, heart rate
  - Orientation status, ability to participate in sports, blood pressure
  - Cranial nerves, sensation, skin assessment

- Which information does the nurse include in the teaching to Jack related to his diagnosis of ulcerative colitis?
  - “Decrease fluid intake to decrease diarrhea.”
  - “Spread out your meals to six times per day.”
  - “Avoid foods high in potassium.”
  - “Increase your intake of simple sugars for energy.”
- On the basis of the above information, what will the nurse consider a priority to notify the provider?
  - Height and weight
  - Temperature
  - Blood pressure
  - Hemoglobin and hematocrit

## CHAPTER SUMMARY

Hernias typically occur because of weakened abdominal muscles accompanied by increased abdominal pressure. Types of hernias include inguinal, femoral, umbilical, and ventral. Inguinal hernias occur most often in males, whereas femoral hernias occur most often in females. Indirect inguinal hernias are the most common and occur only in males. They are commonly repaired with surgery that may include using a mesh material to minimize reoccurrence of the hernia. A hernia is usually self-limiting and surgical repair is an elective procedure unless the hernia becomes strangulated, causing blood supply to be compromised.

Hemorrhoids may be internal or external. If conservative treatment fails, there are several surgical options. Conservative treatments include sitz baths, oral analgesics, and hemorrhoid ointments and creams. Hemorrhoids can become quite painful, requiring analgesic usage, but are usually self-limiting, although surgery may be necessary with perforations or excessive bleeding.

Irritable bowel syndrome (IBS) is a complex illness in which there is no pathologic cause, which is characterized by abdominal pain and changes in bowel habits and characteristics of the stool. There are three types: diarrhea dominant (IBS-D), constipation dominant (IBS-C), and mixed (IBS-M). There are many psychosocial issues surrounding the patient with IBS. Social isolation is a common problem with IBS-D because of the frequency of needing to locate restrooms while in public. Treatments vary according to the severity of the syndrome and the type of syndrome the patient experiences.

Inflammatory bowel disease is a term used for ulcerative colitis and Crohn's disease. Although there are many similarities, there are many differences as well. Surgery for either type depends on the severity of the disease and failure to maintain remission with medication. Surgery for Crohn's disease often causes a flare at the site of anastomosis and is reserved for severe cases in which medical management fails. Surgery for ulcerative colitis can result in cure of the disease itself but does not cure the extraintestinal

complications that often coincide with the disease. Inflammatory bowel disease requires an interprofessional team because there are many physical, as well as psychosocial factors impacting the disease. A dietitian should be utilized because he or she can manage the many nutritional deficits resulting from frequent gastrointestinal losses.

Celiac disease is a genetic autoimmune disorder associated with gluten sensitivity. Patients with this disorder typically present with diarrhea, flatulence, abdominal bloating, weakness, fatigue, and weight loss. Treatment is based on lifelong adherence to gluten-free diet, and support groups and networks are available to support the patient and family in this goal.

Diverticulitis is a term used to describe inflammation of diverticula. Diverticula are small pouchlike herniations in the colon. If stool is trapped in the diverticula, inflammation can result. Treatments are based on severity and may include outpatient antibiotics or inpatient care requiring gastric decompression as well as IV antibiotics.

Appendicitis is a common disorder that affects 5% to 12% of the population. It occurs more often in adolescents and young adults, affecting males more than females. The only treatment is surgical removal of the appendix.

Colorectal cancer rates and deaths are decreasing in the United States because of improvements in diagnosis and treatment. Compared with other cancers, colorectal cancers have improved significantly in survival rates as a result of increased public awareness and early interventions. Treatment of colorectal cancer includes surgical procedures, including colectomy and ileostomy, often with chemotherapy and/or radiation therapy.

Abdominal trauma is divided into two groups: blunt trauma (caused by things such as vehicle accidents and sports injuries) and penetrating trauma (caused by things such as gunshot wounds and stabbings). Surgical intervention is typically required for abdominal trauma, and based on the area of injury the patient is at risk for hemorrhage and infection.

## Coordinating Care for Patients With Hepatic Disorders

*Sandy Swoboda*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of hepatic disorders.
2. Correlating clinical manifestations with pathophysiological processes of:
  - a. Hepatitis
  - b. Cirrhosis
  - c. Liver cancer
  - d. Liver trauma
3. Describing the diagnostic results used to confirm the diagnoses of hepatic disorders
4. Discussing the medical management of:
  - a. Hepatitis
  - b. Cirrhosis
  - c. Liver cancer
  - d. Liver trauma
5. Developing a comprehensive plan of nursing care for patients with hepatic disorders
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with hepatic disorders

### CONCEPTS

- Assessment
- Clotting
- Fluid and Electrolyte Balance
- Infection
- Inflammation
- Medication

### ESSENTIAL TERMS

Alpha-fetoprotein  
Ascites  
Asterixis  
Cholangiography  
Cholangitis  
Cholestasis  
Cirrhosis  
Disseminated intravascular coagulation (DIC)  
Ecchymosis  
Esophageal varices  
Epistaxis  
Hemochromatosis  
Hepatic encephalopathy  
Hepatitis  
Hepatocytes  
Hepatomegaly  
Hepatosplenomegaly  
Hepatorenal syndrome (HRS)  
Icterus

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Harold Green, a 56-year-old unemployed male, presents to the clinic with anorexia, generalized weakness, malaise, and weight loss. He has type 2 diabetes mellitus, treated with metformin XR 1,500 mg once per day. His medical history includes IV drug use, and currently he describes drinking two to three beers per day with his friends while looking for work...

## INTRODUCTION

The liver is located under the diaphragm in the right upper quadrant (RUQ) of the abdominal cavity and receives approximately 25% of the cardiac output via the hepatic portal vein and the hepatic artery. The portal vein carries deoxygenated nutrient-rich blood from the small intestines, and the hepatic artery delivers oxygen-rich blood from the general circulation. The liver serves several functions including blood storage, blood filtration, production of bile, synthesis of clotting factors (prothrombin and factors II, VII, IX, and X), removal of clotting factors to prevent clotting, and metabolism of carbohydrates, fats, and protein. The liver also serves to detoxify the blood and is a storage area for vitamins A, D, E, and K and iron. Hepatic dysfunction occurs when the liver is no longer able to perform its usual functions. Several conditions such as **hepatitis** (inflammation of the liver), **cirrhosis** (chronic liver disease characterized by inflammation and irreversible scarring), liver trauma, and liver cancer all impair the ability of the liver to perform its routine functions (Box 59.1).

### Box 59.1 Healthy People 2020

*Healthy People 2020* initiatives for liver disorders focus on health promotion and prevention, healthy lifestyles, education, and vaccination. Specific goals of *Healthy People 2020* for patients with hepatitis and cirrhosis include interventions to reduce hepatitis A, hepatitis B, and new hepatitis C infections; increased education to the population about hepatitis and knowledge about infection; and efforts to reduce the number of deaths associated with cirrhosis.

## HEPATITIS

### Epidemiology

The incidence and prevalence of hepatitis is worldwide, and the risk for developing hepatitis is generally associated with individual behavior and exposure. There are several viruses that cause hepatitis, and transmission is either through fecal-oral contamination or directly through blood and body fluid exposures. Other risk factors for hepatitis include alcohol abuse, exposure to some prescription and over-the-counter (OTC) medications, toxins, or autoimmune diseases (Box 59.2). In autoimmune hepatitis, an immune system response causes inflammation of the liver, which can be classified as type 1 or type 2. Type 1 autoimmune hepatitis occurs most frequently in females during adolescence, and these patients usually have other autoimmune disorders such as type 1 diabetes, Graves' disease (hyperthyroidism), ulcerative colitis, or proliferative glomerulonephritis. Type 2 autoimmune hepatitis is less common and affects girls between the ages of 2 and 14.

### Connection Check 59.1

The nurse recognizes which patient is at greatest risk for type 1 autoimmune hepatitis?

- A 45-year-old postmenopausal female
- A 30-year-old female with a history of hyperthyroidism
- A 16-year-old female with type 1 diabetes mellitus
- A 12-year-old female with autism

Approximately two billion people worldwide have been infected with the hepatitis virus, and almost 350 million people live with a chronic infection. Twenty-five percent of adults with chronic hepatitis will develop cirrhosis or liver cancer because of chronic infection with the virus (cirrhosis is discussed later in the chapter). The introduction of

### Box 59.2 Risk Factors for Hepatitis

#### Medications

- Statins
- Anabolic steroid
- Azathioprine
- Methotrexate
- Isoniazid
- Valproic acid
- Tetracyclines
- Phenytoin
- Acetaminophen

#### Toxins

- Industrial chemicals
- Carbon tetrachloride
- Phosphorus
- Mushrooms

vaccines for hepatitis A and hepatitis B has greatly decreased the incidence of these types of viral hepatitis.

## Pathophysiology

Hepatitis is inflammation of liver cells most commonly caused by a virus that impairs its ability to function normally. This inflammation limits the ability of the liver to detoxify substances, limits the production of proteins and clotting factors, and alters the ability to store vitamins, fats, and sugars. Modes of transmission of viral hepatitis include contact with blood, blood products, semen, saliva, and mucous membranes; direct contact with infected fluids or objects; or through the fecal-oral route with contaminated water or food such as shellfish. Patients with hepatitis may experience a mild or severe illness that can be acute or chronic.

The viruses of hepatitis are classified according to letters ranging from A to G, each of which differs in its incubation period, mode of transmission, and other characteristics. The most common hepatitis viruses are hepatitis A, B, and C. The major viral types of hepatitis and routes of transmission are found in Table 59.1. Diagnosis of type is made by using a specific serological profile.

## Clinical Manifestations

Clinical manifestations of hepatitis include abdominal pain, irritability, **pruritus** (itching of the skin), malaise, fever, nausea, vomiting, **jaundice** (yellowish skin color), and laboratory abnormalities such as elevated liver enzymes

(aspartate aminotransferase- [AST] and alanine transaminase [ALT]), elevated bilirubin (total and direct), elevated serum ammonia, and decreased albumin. Pruritus is excessive itching on the body, especially in the hands and feet, caused by accumulation of bile salts under the skin that cannot be processed by the liver

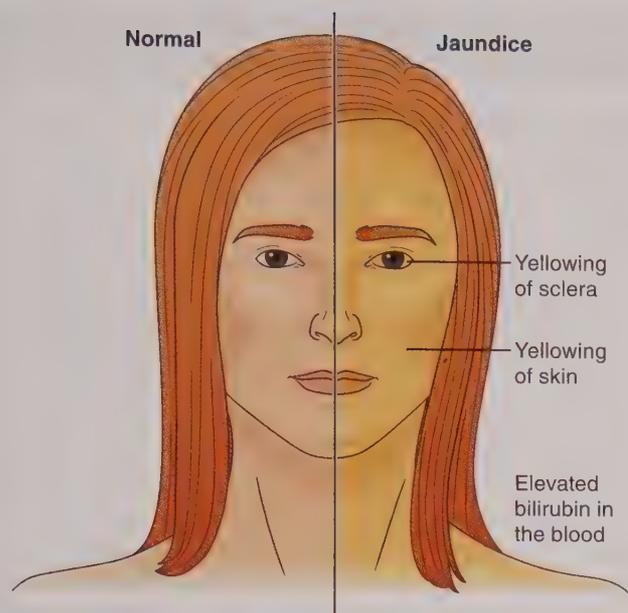

Patients can also exhibit jaundice (**icterus**) or yellowing of the skin or sclera (Fig. 59.1). Jaundice occurs secondary to the liver's inability to metabolize and excrete bilirubin (hepatocellular jaundice), resulting in elevated bilirubin levels in plasma. Bilirubin is a by-product of the breakdown of red blood cells that is filtered through the liver and stored with bile. Bile acids normally secreted by the liver make stool its brown color. With an obstruction in the liver, these bile acids are not excreted in the stool, resulting in clay-colored stools. This also leads to increased excretion of conjugated bilirubin in the urine producing a dark amber color. Obstructive jaundice may be caused by scarring, edema, stone formation, and any obstruction that interferes with the normal process of bile flow through the bile ducts.

In general, symptoms of hepatitis can be mild or severe and vary from patient to patient according to the degree of liver involvement. Patients may present with common flulike symptoms.

Fulminant viral hepatitis is a severe, rapidly progressive, life-threatening form of acute liver failure that includes neurological decline (encephalopathy, insomnia, somnolence, and impaired mentation), gastrointestinal (GI) bleeding, coagulation disorders, **thrombocytopenia** (low platelet

**Table 59.1** Types of Hepatitis

count of less than  $150,000 \text{ mm}^3$ ), fever, oliguria, edema, and **ascites** (accumulation of fluid in the peritoneal cavity secondary to low serum albumin levels). (Ascites is discussed in more detail in the section on Cirrhosis).

**Hepatic encephalopathy** presents with impaired mentation, altered levels of consciousness, confusion, somnolence, and insomnia due to the accumulation of toxins in the bloodstream that are normally cleared by a healthy liver. In severe hepatic failure, the liver is unable to metabolize waste secondary to severe inflammation, and because the **hepatocytes** (liver cells) are not functioning properly. Additionally, due to scarring of the liver, blood bypasses the liver and is not detoxified. As a result, waste products accumulate, specifically ammonia, causing changes in mental status. Additional complications of liver failure include the inability of the liver to produce clotting factors, resulting in coagulation disorders and thrombocytopenia.

## Types of Hepatitis

### Viral Hepatitis

**Hepatitis A** is the most common type of hepatitis and is primarily spread through the oral route from food, water, or shellfish that has been infected with the virus. It can also be spread through close contact with infected persons such as in households and day care centers, with an increased incidence in the presence of unsanitary conditions. Hepatitis A is an acute infection lasting as long as 8 weeks and has several phases. The first phase can last for about a week and presents with abrupt onset of fever with anorexia, nausea, vomiting, malaise, abdominal pain, myalgia, diarrhea, **urticaria** (pale red, raised bumps on the skin), cough, and

**hepatosplenomegaly** (enlarged liver [**Hepatomegaly**] and/or spleen [**Splenomegaly**]). Clinical manifestations of later phases include clay-colored stools and a rise in serum bilirubin levels, and jaundice may occur 4 to 30 days after onset of infection. Clinical manifestations in patients with hepatitis A are usually mild, and some patients are completely asymptomatic. The most definitive diagnosis of hepatitis A is through a blood test for the presence of anti-hepatitis A immunoglobulin M (IgM anti-HAV), which can be elevated for as long as 6 months.

**Hepatitis B** is spread by blood and body fluids or secretions such as semen. The virus can be spread through mucous membranes, contact with infected fluids, during childbirth, or through skin puncture with contaminated needles or other instruments. Patients infected with hepatitis B can have acute or chronic infections and are considered infectious as long as antigens are present in the bloodstream. There is a vaccine for hepatitis B that is required for all healthcare personnel. This vaccine is a multiseried injection given at specified intervals, with several vaccines currently available. Recommendations for intervals for children and adults are available from the CDC (Centers for Disease Control and Prevention), WHO (World Health Organization) and local state and governing bodies. The dose given is dependent on the specific vaccine and age of the individual. In the United States, local laws and requirements vary, however, hepatitis A and B vaccines may be required for entry into day-care, elementary, and middle schools.

Chronic hepatitis B infection is present in more than 350 million people globally and accounts for one-third of the cases of liver cirrhosis and one-half of all cases of hepatocellular carcinoma (HCC). Risk factors for hepatitis B include sexual contact with infected persons, multiple sex partners, male homosexual sex, injection drug use, hemodialysis, blood transfusions, and occupational exposure. Acute hepatitis B occurs after an incubation period of 4 to 10 weeks, and chronic hepatitis B is diagnosed by detectable serum HBV (hepatitis B virus) DNA levels and persistent elevation of ALT and AST levels. High-risk patients with hepatitis B should be screened every 6 to 12 months for HCC. Screening includes an ultrasound and a serum **alpha-fetoprotein** (protein produced by the liver) level as a marker for liver cancer. Because patients with a chronic hepatitis B infection can still spread the virus to others, it is important to educate patients about screening and vaccination of close family members and sexual partners to prevent the spread of infection.

**Hepatitis C** (previously known as non-A non-B) is spread through blood or body fluids and from mother to child during childbirth. A significant number of cases of hepatitis C occur from sharing of contaminated needles by IV drug users and unintended needlesticks in the healthcare environment. Other risk settings include tattoo and body piercing establishments because of the chance of contact with blood. Infection with hepatitis C can be acute or chronic, and approximately 85% of acute cases develop chronic infection, with cirrhosis developing within 20 to 30 years of diagnosis. Studies examining the spread of hepatitis C and

specific genotypes indicate that Baby Boomers, those born in the United States between 1940 and 1965, may also be at increased risk for hepatitis C as a result of medical interventions in which glass and metal syringes were re-used. Medical management of hepatitis C is available with established cure rates, but treatment is costly. There is currently no vaccine for hepatitis, but there is ongoing research. Hepatitis C is the most common indication for liver transplantation.

## Evidence-Based Practice

### Hepatitis C: Implications to Public Health

Hepatitis C, a global public health issue, is a leading cause of liver cirrhosis and hepatocellular cancer. Several studies on vaccine development, including peptides, recombinant protein, DNA, and viral vectors have been conducted. The search for vaccine for this disease is ongoing.

Ghasemi, F., Rostami, S., & Meshkat, Z. (2015). Progress in the development of vaccines for hepatitis C virus infection. *World Journal of Gastroenterology*, 21(42), 11984.

*Hepatitis D* infection is not common in the United States and occurs only in people who are infected with the hepatitis B virus because it requires the hepatitis B antigen to replicate. It is spread through contact with infectious blood and is most commonly found in patients who are IV drug users, receiving hemodialysis, and have received multiple blood transfusions. There is no vaccine for hepatitis D.

*Hepatitis E* is caused by the hepatitis E virus that is transmitted via the fecal-oral route primarily through water that is contaminated in areas of poor sanitation. This is rare in the United States, and there is currently no vaccine for hepatitis E. Patients with this type of hepatitis exhibit clinical manifestations similar to those of hepatitis A; the disease has a rapid onset and is self-limited. Almost all patients with hepatitis E develop jaundice.

*Hepatitis G* was discovered in 1996 and is known to be transmitted by infected blood or blood products, making patients with hemophilia and those who require blood transfusions at greatest risk. Patients who are infected with hepatitis B or C virus can often be infected with hepatitis G. Little is known about the frequency of hepatitis G, and currently there is no vaccine.

### Nonviral Forms of Hepatitis

Nonviral forms of hepatitis are caused by ingested, inhaled, or injected toxins or medications. Patients with nonviral forms of hepatitis have clinical presentations similar to those of viral hepatitis such as anorexia, nausea and vomiting, jaundice, and **hepatomegaly** (an enlarged liver). Diagnosis includes a detailed history and physical examination and a history of exposure to potential toxins. If it is determined that the patient has been exposed to a liver toxin and the toxin is removed, recovery can be rapid. However, if there is a prolonged time period between exposure to the toxin and the

development of clinical manifestations, recovery can be prolonged or not at all possible if the toxin is not identified.

### Acute Versus Chronic Hepatitis

Hepatitis can be acute or chronic and is differentiated by the length of time a patient is infected with the virus. An acute hepatitis infection usually lasts less than 6 months, with most patients shedding the virus in this time frame and recovering from all of their clinical manifestations. Chronic hepatitis is an infection that lasts longer than 6 months and can span the patient's lifetime. Having the virus for a prolonged period of time increases the patient's chance for developing complications such as cirrhosis, liver failure, or liver cancer.

Patients who contract hepatitis B and C can develop chronic hepatitis that leads to progressive liver damage and causes approximately 80% of all primary liver cancers. Management of clinical manifestations and routine monitoring of the disease and medical care help prevent the progression to liver cancer. In patients with chronic hepatitis C, the risk for liver cancer is decreased for patients on antiviral therapy because this therapy prevents the virus from reproducing, thus slowing the progression of liver damage. The treatment course and antiviral medication choice are based on the age of the patient, severity of illness, adverse reactions, medication tolerance, viral load, ALT level, and the patient's compliance with the medication regimen.

## Management

### Medical Management

#### Diagnosis

Laboratory and diagnostic testing include assessments that determine the extent of liver damage and guide diagnosis. Diagnostic test results and a thorough physical examination are important in the determination of the cause of the patient's clinical manifestations. Most of these tests are collected as routine blood samples and require no specific preparation. Table 59.2 provides an overview of some of the most important laboratory tests used to evaluate liver function.

Monitoring AST and ALT levels along with the clinical presentation of the patient provides information about whether these elevations are associated with the liver solely or with another major organ. (Often abnormalities in a liver panel may not be associated specifically with the liver). An AST level that is extremely high (usually 10 times the normal range) indicates acute hepatitis most often caused by a virus but can also be associated with exposure to medications or other hepatotoxins. These levels usually remain elevated for 1 to 2 months but can take as long as 3 to 6 months to return to normal. Liver enzymes are measured serially over time to monitor recovery or worsening of the disease. Ratios of AST to ALT can help determine whether the liver disease is viral in origin or associated with a toxin or alcohol exposure.

Two laboratory values that indicate abnormalities of bile flow are the GGT (gamma glutamyl transferase) and alkaline phosphatase. Specifically, GGT is a protein that

**Table 59.2 Diagnostic Testing for Liver Disorders**

Test	Normal Results
ALT Alanine transaminase	Males: 13–40 units/L Females: 24–36 units/L
AST Aspartate transaminase	Males: 20–40 units/L Females: 15–35 units/L
Alkaline phosphatase (Total)	Males: 35–142 units/L Females: 25–125 units/L
Alkaline phosphatase (Liver Fraction)	0–93 units/L
GGT Gamma glutamyl transferase	Males: 0–30 units/L Females: 0–24 units/L
LDH Lactate dehydrogenase	90–176 units/L
Bilirubin, total	0.3–1 mg/dL
Bilirubin, indirect	0.2–0.8 mg/dL
Bilirubin, direct	0.1–0.3 mg/dL
Albumin	3.4–5.1 g/dL
Ammonia	15–60 mcg/dL
Coagulation tests	
● Prothrombin time	10–13 seconds
● Activated partial thromboplastin time (aPTT)	25–35 seconds
Platelets	150,000–450,000 mm <sup>3</sup>

is found in the liver and bile ducts, and high levels of this enzyme can indicate inflammation, injury, or blockage of the bile ducts, more commonly known as **cholestasis**. Alkaline phosphatase is an enzyme found in the bone, intestines, liver, and bile ducts and when elevated indicates a blockage of bile flow that can be caused by gallstones or scarring in the biliary tree.

Serum albumin measures the amount of protein that is made by the liver. A low serum albumin may be an indicator of liver damage and malnutrition. Bilirubin is a by-product of the breakdown of red blood cells that is filtered through the liver. There are two measurements of bilirubin, direct and indirect. Indirect bilirubin, or unconjugated bilirubin, measures the serum level of bilirubin before it gets to the liver. Once it is in the liver, it is changed (conjugated) to direct bilirubin while it binds to certain sugars. The direct bilirubin is then released into the bile and stored in the gallbladder. When the liver is unable to conjugate the bilirubin because of dysfunction, levels are elevated, and patients develop jaundice.

Lactate dehydrogenase (LDH) is a test for an enzyme that is produced by many organs in the blood as the result of tissue damage. It is not used solely to help determine liver disease but is a test used in conjunction with those listed previously to determine the presence and severity of liver dysfunction.

## Medications

Approved therapeutic agents for use in patients with hepatitis include oral antiviral agents for viral suppression. Postexposure prophylaxis for hepatitis A exposure should be considered if the source of exposure was serologically confirmed or the source of exposure had infectious hepatitis A. Use of immune globulin is recommended if exposure to the source of hepatitis A was less than 2 weeks. The hepatitis A vaccine is also recommended.

Pegylated interferon injections also work toward viral suppression. Vaccination for hepatitis B is recommended for all children as well as adults in high-risk categories. Table 59.3 lists these medications with mechanism of action, side effects, and treatment response. Most oral agents used to treat hepatitis B are given daily for as long as 1 year or longer to slow or stop the growth of the virus. Injections of the interferons can be weekly or multiple times a week for 6 to 12 months. Patients undergoing medical treatment are followed serially over time to monitor liver function tests (LFTs) and treatment response.

Table 59.4 provides an overview of vaccines available for hepatitis A and B; there are no vaccines for the other types of hepatitis.

## Diet and Activity

Diet recommendations for patients with hepatitis are similar to a healthy diet, low in fat and high in fruits, vegetables, and whole grains. Adequate oral intake is also important to ensure the hydration. Eating a low-fat diet decreases indigestion due to the liver's inability to process bile, which emulsifies dietary fat. If liver tissue is damaged, it is unable to store large amounts of glycogen for energy, and eating small, frequent meals helps the liver restore glycogen reserves. Small, frequent meals also provide nutrition in the anorexic patient with hepatitis who does not feel like eating. Patients should avoid alcohol and any medication that is toxic to the liver such as acetaminophen. Vitamin supplements of A, D, E, and K are also beneficial.

There is no recommended exercise program for patients with hepatitis and no specific exercise is restricted. Activities such as walking and resistance training, as well as low-impact aerobics help maintain strength and minimize fatigue. It is important for patients to maintain a good balance of proper rest and exercise. The patient should alternate periods of rest with low-level exercise, and as fatigue resolves, activity can be increased.

## Connection Check 59.2

In reviewing diagnostic results of a patient with suspected hepatitis, the nurse correlates which result as consistent with hepatitis A?

- Prolonged prothrombin time (PT)
- Decreased white blood cell count
- Presence of IgM anti-HAV
- Detectable serum HBV DNA

Table 59.3 Approved Agents for Use in Patients With Hepatitis

	Approved Agent	Mechanism of Action	Side Effects	Treatment Response
<b>Hepatitis A</b>	None			
<b>Hepatitis B</b>	Oral agents: tenofovir, entecavir, lamivudine, telbivudine. All oral agents are given once a day for 1 year or longer.	Viral suppression and remission	Oral agents: limited side effects	Based on serial monitoring of liver enzymes
	Injections: Interferon-alpha: injection several times a week (6–12 months) Pegylated interferon: weekly injection (6–12 months)	Viral suppression	Injections: flulike symptoms, depression, headaches, fatigue, thyroid problems	
<b>Hepatitis C</b>	Pegylated interferons Ribavirin Combination therapy ● peginterferon with ribavirin ● interferon with ribavirin Interferon therapy lasts 12–8 months. Ribavirin therapy lasts 48 weeks	Viral suppression	Pegylated interferons: flu-like symptoms, depression, headaches, fatigue, thyroid problems	Serum test for presence of hepatitis C
	Harvoni (sofosbuvir + ledipasvir) is a polymerase inhibitor 8–12 weeks of treatment	Direct acting antiviral	Severe form of anemia Fatigue, headache, nausea, diarrhea, insomnia, weakness	

Table 59.4 Vaccines for Hepatitis

Hepatitis Vaccine	Description
<b>Hepatitis A vaccine</b>	Recommended for healthcare workers, restaurant workers, food handlers, persons traveling to areas with endemic hepatitis A, children and workers in child care, and those with risky behavior such as illegal injected drug users and persons with chronic liver disease. One injection followed by a booster dose 6–12 months later. Vaccine is considered effective for 15–20 years. Protection from the vaccine usually occurs 2–4 weeks after vaccination.
<b>Hepatitis B vaccine</b>	Recommended for everyone including newborns. Vaccine is given as a series of three injections over 6 to 12 months. Vaccine is considered effective for 15 years or longer.

## Surgical Management

### Liver Transplantation

Hepatitis C–related cirrhosis is the most common reason for liver transplantation. Currently, liver transplantation occurs primarily from a cadaver donor through a procedure known as an *orthotopic liver transplant*. In this procedure, the native diseased liver is removed, and a cadaver donor liver is transplanted in its place. A living donor liver transplant can occur, in which a lobe of the liver, usually the right lobe, is removed from a donor and transplanted to the recipient after the recipient's diseased liver has been removed. Patients undergoing these procedures require intense patient education, support, and long-term medical management.

The major complications after liver transplant are organ rejection and infection. Organ rejection typically presents between days 4 and 10 postoperatively and is characterized by fever, RUQ pain, tachycardia, changes in bile, and jaundice. To reduce the risk of rejection after liver transplantation, the patient is placed on immunosuppression medications such as cyclosporine and tacrolimus. These medications also increase the patient's risk of infection. In the first postoperative year, approximately 80% of patients develop at least one postoperative infection, and

these infections are the primary reason for critical illness and death in patients after liver transplantation.

## Nursing Management

### Assessment and Analysis

Many of the clinical manifestations observed in the patient with hepatitis are directly associated with the inability of the liver to perform its normal functions because of inflammation. Common findings include:

- Elevated temperature associated with inflammation
- Elevated LFTs
- Jaundice
- Fatigue
- Decreased appetite

### Nursing Diagnoses

- **Activity intolerance** associated with fatigue, fever, flu-like symptoms
- **Acute pain** associated with edema of liver
- **Altered nutrition (less than body requirements)** associated with decreased liver metabolic function secondary to loss of appetite, nausea, and vomiting
- **Altered thought processes** associated with elevated serum ammonia levels secondary to liver dysfunction
- **Knowledge deficit** associated with the disease process

### Nursing Interventions

#### ■ Assessments

- **Vital signs**  
*Elevation in temperature and pulse associated with infectious process*
- **Serum liver enzymes**  
*Elevated levels of liver enzymes indicate that liver injury is present and liver enzymes have entered the bloodstream.*
- **Serum bilirubin**  
*Bilirubin is a by-product of red blood cell breakdown, and the liver is responsible for removing bilirubin in the blood. Total bilirubin and direct, or conjugated, bilirubin levels are elevated because of inflammation and obstruction of the liver by hepatitis.*
- **Color of skin, sclera**  
*Yellow pigmentation of the eyes and skin occurs because of increased levels of bilirubin in the blood. Deep jaundice may result in a greenish tint to the skin due to by-products of bilirubin conversion.*
- **Nutritional intake**  
*Loss of appetite occurs because of abdominal fullness or the lack of desire to eat foods the patient previously enjoyed as a result of indigestion. This occurs frequently with fatty foods and alcohol.*
- **Daily weight**  
*Monitors nutritional intake and evaluates weight loss associated with decreased nutritional intake. Anorexia may develop secondary to abdominal distention and obstruction. An increase in body weight may be secondary to ascites.*
- **Intake and output**  
*Fluid volume status, either overload or depletion, may occur. Fluid overload is often associated with ascites that develops*

*secondary to damage to liver by the inflammatory and infectious processes seen with hepatitis.*

- **Signs of organ rejection in the patient after liver transplantation**

*In patients who undergo transplantation for cirrhosis, organ rejection may occur within the first 10 days after the procedure and may include RUQ pain, changes in bile drainage, fever, tachycardia, and jaundice.*

#### ■ Actions

- **Administer medications as ordered (see Table 59.3)**  
*Administer medications as ordered for management of specific hepatitis type if indicated.*
- **Provide small, frequent meals and supplements (as needed)**  
*Because of decreased appetite and feelings of fullness, small, frequent meals and nutritional supplements are encouraged to promote adequate nutrition.*
- **Administer antiemetics**  
*Antiemetics decrease symptoms of nausea and vomiting associated with the virus, which may occur for a prolonged time. Use caution; some antiemetics (phenothiazines) are metabolized by the liver and should not be used.*
- **Promote balance between physical activity and rest**  
*Rest decreases metabolic demands on the liver*
- **Encourage rest periods between walking and physical activity**  
*Maintains strength and conditioning*

#### ■ Teaching

- **Nutritional teaching**  
*Importance of balanced nutrition to promote energy and small, frequent meals to increase nutritional intake while minimizing the negative effects of eating. Patients with clinical manifestations of hepatitis such as nausea and vomiting tend to limit food intake. It is important to stress calorie intake and proteins in moderate doses because the liver processes protein; vitamins and minerals with a balanced diet or supplements; limit fat intake because the liver may not be able to make enough bile to process fats. Small, frequent meals are indicated because the liver cannot store glycogen for energy because of inflammation. Hydration is important to manage symptoms including dizziness, fatigue, skin and mucous membrane dryness and side effects of any medications. Alcohol and caffeine should be avoided as they may cause dehydration.*
- **Good hand hygiene before and after meals and use of the bathroom to decrease transmission from fecal-oral route**  
*Practice good hand hygiene before and after eating and after using the toilet to decrease transmission from the fecal-oral route*
- **Avoid behaviors (needle sharing, unprotected sex) that contribute to transmission**  
*Avoiding behaviors that expose patients to the virus decreases transmission. Mode of transmission of the diagnosed form of hepatitis must be included in the discharge teaching.*

- Importance of vaccinations to prevent hepatitis A and hepatitis B

*The hepatitis A vaccine can prevent hepatitis A. It is recommended for healthcare workers, food handlers, child-care workers, and travellers to endemic hepatitis A areas. It is a series of two injections (initial injection and booster 6–12 months later). The vaccine is effective for as long as 20 years. The hepatitis B vaccine can prevent hepatitis B and the serious consequences of HBV infection, including liver cancer and cirrhosis. The hepatitis B vaccine is usually given as a series of several injections. This vaccine series gives long-term protection from HBV infection. It is recommended for everyone.*

- Safe public water supply, sewage

*Consider the water source and whether the public water supply is safe from sewage. Infected fecal matter can transmit hepatitis A.*

### Evaluating Care Outcomes

Hepatitis is a manageable disease process when patients have a clear understanding of the disease and are compliant with interventions and therapies. Expected outcomes include stable vital signs, stable weight, and comprehensive understanding of the risk factors, transmission, and treatment of hepatitis. Additional outcomes include decrease in liver function test values while the infection is resolving. Lifestyle activities that contribute to liver disease should be altered or eliminated to slow the progression of the disease. Knowledge of diet, nutritional intake, activity tolerance, and compliance with medical interventions are necessary. Patients require serial follow-up and monitoring of symptoms and should take a proactive role in their self-care.

## CIRRHOSIS

### Epidemiology

Cirrhosis, the end result of most chronic liver diseases, accounts for approximately 35,000 deaths annually in the United States and is the ninth leading cause of death. Between 1999 and 2016, annual deaths from cirrhosis increased by 65%, with the largest increases associated with alcoholic cirrhosis among people between the ages of 25 to 34. Most patients with cirrhosis die in their 50s and 60s because the liver has had many years of exposure to viruses, toxins, or medical conditions that have led to cirrhosis. Hepatitis C is the leading cause of chronic hepatitis and cirrhosis, followed by alcoholic liver disease.

Risk factors that predispose a patient to develop cirrhosis include chronic infection with hepatitis A, B, or C, followed by chronic alcoholism, biliary disease, accumulation of fat in the liver, and some autoimmune diseases. Improving health habits and refraining from risky behaviors such as needle sharing and unprotected sex, refraining from consumption of alcohol, and receiving vaccination for hepatitis are steps that can be taken to help prevent cirrhosis.

Cirrhosis of the liver is caused by several different factors including viruses, alcohol, biliary disease, accumulation of fat in the liver cells, genetic and autoimmune diseases, and other causes. The most common causes are chronic infections with hepatitis B and C viruses and alcohol use. Alcohol-induced cirrhosis (also known as **Laënnec's cirrhosis**) is now the second most common form of cirrhosis in the United States and results from chronic alcoholism and malnutrition. In this type of cirrhosis, fibrosis occurs around the central veins and portal areas. Patients may develop vascular or arterial spider angiomas on the abdomen. These numerous small vessels look like spider legs and are common with alcoholic cirrhosis. Some patients develop reddened palms known as *palmar edema* or liver palms.

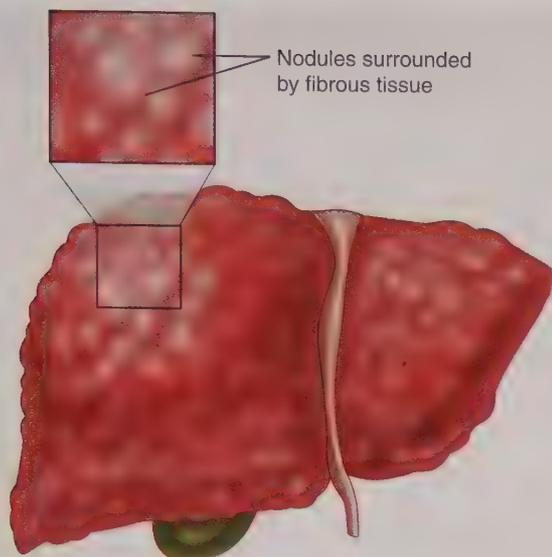

Another cause of cirrhosis is postnecrotic or micronodular cirrhosis, which involves bands of scar tissue in the liver due to previous acute viral hepatitis or exposure to hepatotoxins. Biliary cirrhosis is defined by scarring of the liver tissue around the bile ducts and lobes of the liver because of chronic biliary obstruction and infection or **cholangitis** (inflammation of the common bile duct). Patients with biliary cirrhosis commonly develop severe itching, or pruritus, because of retention of bile salts. Other causes of cirrhosis include nonalcoholic steatohepatitis (NASH), which is commonly found in obese patients. This is caused by the accumulation of fat in the liver cells, which leads to inflammation of the liver cells and over time results in cirrhosis. Nonalcoholic steatohepatitis can be diagnosed by a liver biopsy.

Genetic causes of cirrhosis include Wilson's disease and **hemochromatosis** (iron overload). In Wilson's disease, there is an abnormality of a protein that causes excessive accumulation of copper in the liver leading to chronic inflammation. Similarly, in patients with hemochromatosis, there is an abnormally high accumulation of iron, which leads to chronic liver inflammation and cirrhosis. Treatment of these patients is aimed at decreasing levels of copper and iron, respectively.

An autoimmune diagnosis of cirrhosis is more common in women, caused by an abnormal immune system that causes progressive inflammation and dysfunction of the liver. Other causes of cirrhosis can be associated with exposure to hepatotoxins, medications, parasites, and cardiac dysfunction. Some patients with severe long-term right-sided heart failure develop what is known as *cardiac cirrhosis*, which causes decreased oxygenation of the liver cells, leading to liver cell death.

### Pathophysiology

Cirrhosis of the liver (Fig. 59.2) is a chronic disease that causes cell destruction and fibrosis or scarring of hepatic tissues. Functional liver cells die, and damaged liver cells regenerate into nodules of liver cells that are surrounded by fibrous tissue. The blood supply to this area is abnormal and occurs through a thick capillary network surrounding

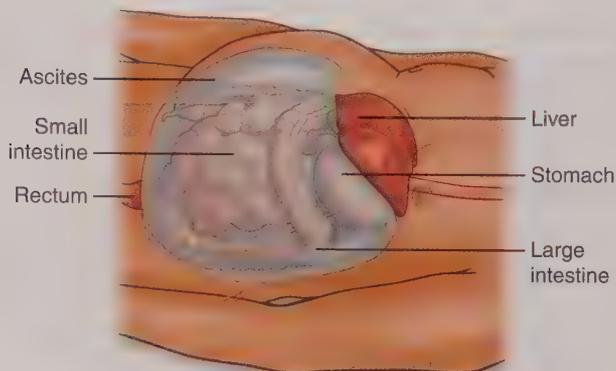

**FIGURE 59.2** Cirrhosis. Cirrhosis causes cell destruction and fibrosis or scarring of hepatic tissues. Functional liver cells die, and damaged liver cells regenerate into nodules of liver cells that are surrounded by fibrous tissue.

these nodules. In a normal healthy liver, approximately 85% of blood flow occurs through the portal vein in contrast to a cirrhotic liver, where blood flow is dependent on the hepatic artery. This irreversible chronic injury to functional liver cells results in liver cell necrosis, altered liver structure and function, and leads to alterations in blood and lymph flow, resulting in hepatic insufficiency and hypertension in the portal vein.

Alteration of blood flow to the liver results in **portal hypertension** (an increase in the pressure in the veins that carry blood through the liver) and shunting of blood around the liver, bypassing the liver cells. While the blood reaches the liver from the stomach, intestines, spleen, and pancreas, it travels through the portal vein branching into the liver. Because these vessels are blocked by the scarring of the liver, blood cannot flow freely and blood backs up, causing an increase in pressure that leads to the enlargement of the veins in the esophagus, skin of the abdomen, and veins in the rectum and anus (hemorrhoids). This shunting of blood around the liver causes increased pressure in the surrounding vessels resulting in **esophageal varices** and gastric varices (abnormally dilated and weak veins), which may result in upper GI bleeding.

Other pathophysiologic changes that develop secondary to altered blood flow include ascites, coagulopathy, and hepatic encephalopathy. Ascites is the accumulation of protein-rich fluid in the abdominal cavity (Fig. 59.3) and is associated with a poor quality of life, increased risk of infection, and a poor long-term outcome. Some patients with ascites develop pleural effusions because of the exchange of fluid across the diaphragm to the pleural space surrounding the lungs. Because the liver synthesizes most of the coagulation cascade factors and fibrinolytic proteins, liver disease impacts the synthesis of clotting factors and coagulation mechanisms, leading to prolonged or excessive bleeding. Patients with

**FIGURE 59.3** Ascites. Ascites is the accumulation of protein-rich fluid in the abdominal cavity, and if the accumulation of ascitic fluid is greater than 500 mL, the patient develops an increase in abdominal girth, abdominal pain, and bloating.

significant liver disease are thrombocytopenic and have a prolonged PT. Some patients may exhibit significant bleeding, leading to **disseminated intravascular coagulation (DIC)**. In DIC, small blood clots form inside blood vessels, which in turn disrupt blood flow to organs and disrupt normal coagulation leading to excessive bleeding from the GI tract, pulmonary system, wounds, and any skin puncture sites such as IV sites.

Hepatic encephalopathy is characterized by numerous disturbances in the central nervous system, including changes in motor function, to changes in levels of consciousness ranging from restlessness and confusion to seizures and coma. Patients with hepatic encephalopathy can be staged (Table 59.5) based on the severity of their clinical presentation. The main cause of hepatic encephalopathy is the accumulation of ammonia and toxins in the blood that are normally detoxified by the liver. These accumulated toxins lead to altered neurological status. Other causes of encephalopathy include dehydration, excessive diuresis, infection, surgery, fever, and exposure to sedatives or antianxiety

**Table 59.5 Stages of Hepatic Encephalopathy**

Stage	Clinical Manifestations
1	Patients have slurred speech, tremors, lethargy and euphoria, reversal of day and night sleep patterns Asterixis, impaired writing, impaired decision making, poor coordination
2	Increased drowsiness, disorientation, inappropriate behavior, mood swings, agitation Asterixis, fetor hepaticus (sweet fecal smell of the breath)
3	Severe confusion, difficult to awaken, slurred speech Asterixis, increased deep tendon reflexes, rigid extremities
4	Coma, nonresponsive to painful stimulus

medications. Cirrhosis is generally irreversible once it develops, and treatment generally focuses on preventing progression and complications. In advanced stages of cirrhosis, the only option is a liver transplant.

### Clinical Manifestations

Based on the degree of liver involvement, the clinical manifestations may vary and get progressively more pronounced as the liver dysfunction worsens. The clinical presentation of cirrhosis (Fig. 59.4) typically includes the following manifestations:

- Shortness of breath
- Jaundice
- Increased abdominal girth
- Abdominal pain and bloating
- Enlarged spleen
- Elevated liver enzymes
- Increased risk of bleeding
- Thrombocytopenia
- Prolonged PT
- Hemorrhoids
- Elevated serum ammonia levels
- Changes in level of consciousness
- Changes in motor function
- Hyponatremia
- **Asterixis** (flapping tremor of the hand when wrist extended)

### CASE STUDY: EPISODE 2

Several hours after Mr. Green attended a cookout with family members, he became confused and started saying things that did not make sense. His confusion worsened the following day, and he complained of shortness of breath and had an episode of upper GI bleeding. He was admitted to the hospital for a work-up, which revealed high serum ammonia levels and esophageal varices...

### Management

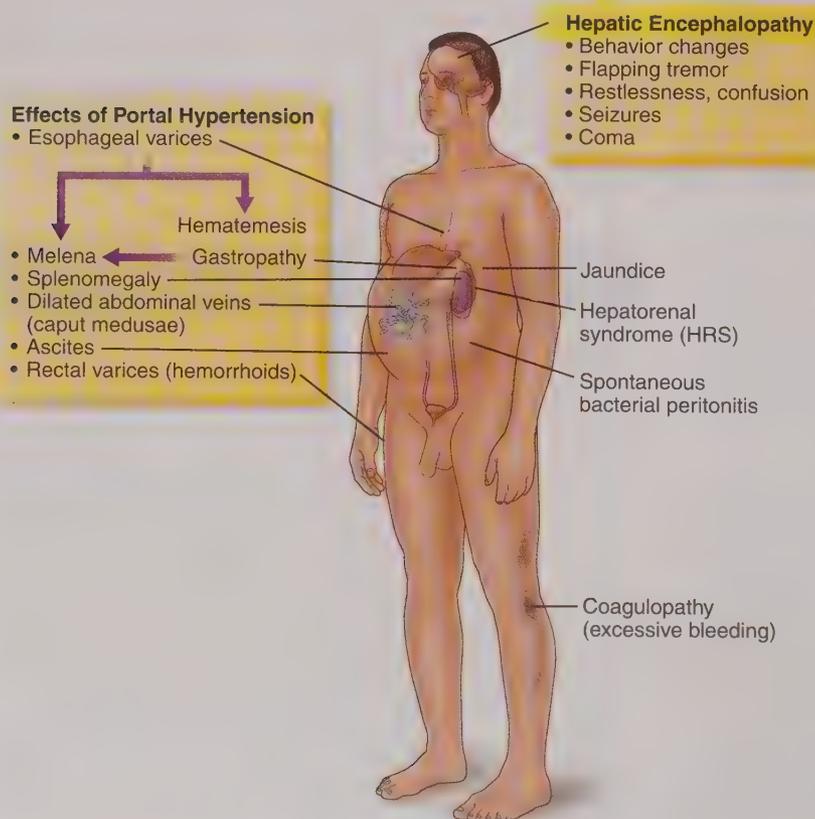

#### Medical Management

#### Diagnosis

Laboratory and diagnostic testing includes assessments that determine the extent of liver damage to guide diagnosis (Table 59.6). Diagnostic test results and a comprehensive physical examination are important to determine interventions.

There are several diagnostic studies that are performed to determine the severity of liver failure.

- *Diagnostic ultrasound and computed tomography (CT)* scans are noninvasive tests to determine abnormalities of the liver.

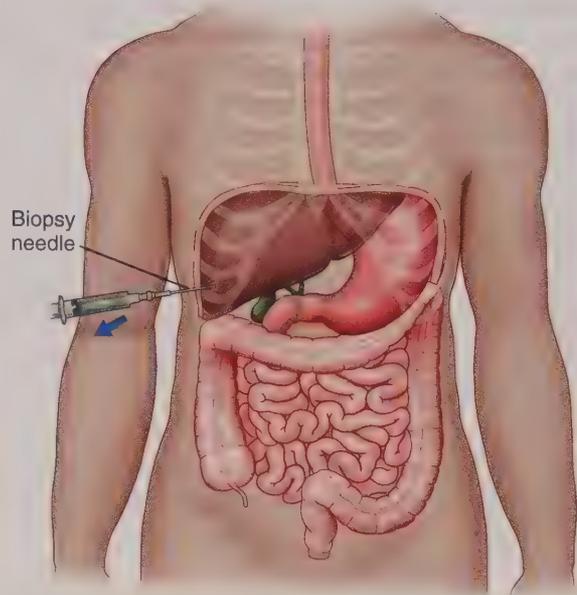

**FIGURE 59.4** Clinical presentation of cirrhosis.

**Table 59.6** Abnormal Laboratory Values With Liver Disease

Test		Result
ALT	Males: 13–40 units/L	Elevated
	Females: 24–36 units/L	
AST	Males: 20–40 units/L	Elevated
	Females: 15–35 units/L	
Alkaline phosphatase (Total)	Males: 35–142 units/L	Elevated
	Females: 25–125 units/L	
Alkaline phosphatase (Liver Fraction)	0–93 units/L	Elevated
Bilirubin, total	0.3–1 mg/dL	Elevated
Bilirubin, direct	0.1–0.3 mg/dL	Elevated
Albumin	3.4–5.1 g/dL	Decreased
Ammonia		Elevated
Coagulation tests		
● Prothrombin time	10–13 seconds	Prolonged
● Activated partial thromboplastin time (aPTT)	25–35 seconds	Prolonged
Platelets	150,000–450,000 mm <sup>3</sup>	Decreased

ALT, Alanine transaminase; AST, aspartate transaminase.

- *Esophagogastroduodenoscopy (EGD)* is a minimally invasive procedure that uses an endoscope to visualize the GI tract from the esophagus to the duodenum to evaluate for esophageal varices or bleeding.
- *Percutaneous transhepatic portal angiography* is used to visualize the portal venous system and liver biopsy. Endoscopic retrograde cholangiopancreatography (ERCP) is a technique that combines endoscopy and fluoroscopy to visualize the biliary system to diagnose and treat causes of obstruction in the biliary tree.
- *Percutaneous transhepatic cholangiography* is a radiological test that uses a contrast medium injected into the bile duct of the liver to visualize the biliary tract and identify obstruction that, if identified, can be treated with the insertion of drains or stents.
- *Liver biopsy* is an invasive procedure done to collect a sample of liver tissue to determine the severity of liver disease (Fig. 59.5). This can be done percutaneously, transvenously, or directly in the operating room

**FIGURE 59.5** Liver biopsy. Liver biopsy is an invasive procedure done to collect a sample of liver tissue to determine the severity of liver disease.

through the abdomen. Patients who undergo liver biopsy are usually maintained on bedrest for several hours postprocedure, sometimes with a 5- to 10-lb sandbag over the biopsy site. Careful monitoring is required after the procedure associated with the risk of hypotension and bleeding (see Safety Alert).

**Safety Alert** A change in the patient's level of consciousness or a decrease in blood pressure and increase in heart rate after a liver biopsy may indicate severe bleeding associated with the procedure, and the nurse should immediately notify the healthcare provider.

### Treatment

Ascites requires restriction of sodium intake to less than 2 g per day and administration of diuretics to increase salt and water excretion. Patients receive a combination of diuretics such as spironolactone and furosemide. In patients with end-stage liver disease, often secondary to cirrhosis, it is necessary to perform routine and frequent paracentesis for ascites that requires removal of several liters of fluid to relieve patient's clinical manifestations of abdominal bloating and pain and shortness of breath. With removal of fluid, the patient may develop hypotension requiring close monitoring.

Treatment of portal hypertension involves symptom management and controlling complications of bleeding. Patients may undergo endoscopic procedures such as banding or **sclerotherapy** (a procedure used to shrink veins). Banding involves placing bands around the varices to block the bleeding, and sclerotherapy involves the injection of a solution into the bleeding varices to make them shrink to

stop bleeding. Some patients may also be given beta blockers to lower systemic blood pressure. Historically, patients with uncontrolled esophageal variceal bleeding were treated with a **Sengstaken-Blakemore tube** (Fig. 59.6), which is inserted into the GI tract through the nose to provide compression and traction in the esophagus and stomach to stop hemorrhage. This modality of treatment is rarely used (see Safety Alert).

### **Safety Alert** Sengstaken-Blakemore Tube

A Sengstaken-Blakemore tube is a temporary measure and should not be left in place longer than 24 hours. It can cause mucosal ulcerations, and the tube can migrate up out of the stomach and cause airway obstruction. Scissors should be kept at the bedside for emergency use.

Management of patients with hepatic encephalopathy includes avoiding protein overload, decreasing bacterial production of ammonia, and correcting fluid and electrolyte imbalances. Patients should eat small, frequent meals to prevent protein loading. To reduce the bacterial production of ammonia, patients usually receive neomycin and lactulose. Neomycin is a broad-spectrum antibiotic that destroys bacteria normally present in the GI tract, decreasing protein breakdown and production of ammonia. Lactulose promotes the excretion of ammonia in the stool and can be given

orally or via rectal enemas. These treatments can cause diarrhea and altered fluid and electrolytes; therefore, it is important to monitor fluid volume status and electrolyte values. Patients also receive vitamins A, B complex, C, and K, as well as folic acid to correct abnormalities.

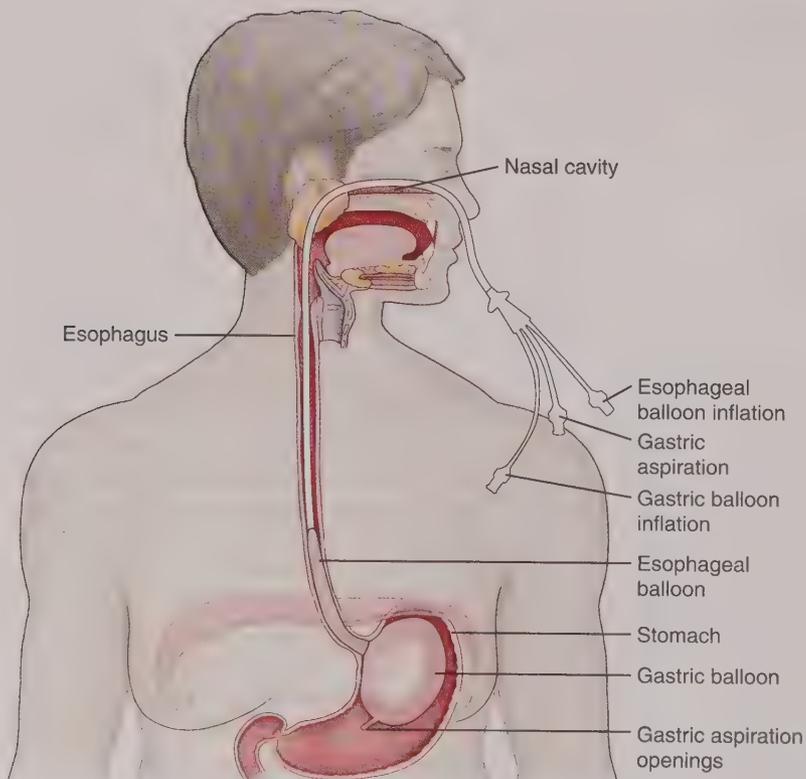

### **Surgical Management**

In some cases of cirrhosis, patients with ascites require surgical intervention that includes the placement of a shunt between the portal venous system and the systemic venous system to reduce portal pressure to reduce fluid accumulation. This type of shunt is known as a **transjugular intrahepatic portosystemic shunt (TIPS)** (Fig. 59.7). Cirrhosis is also an indication for liver transplantation (see Liver Transplantation).

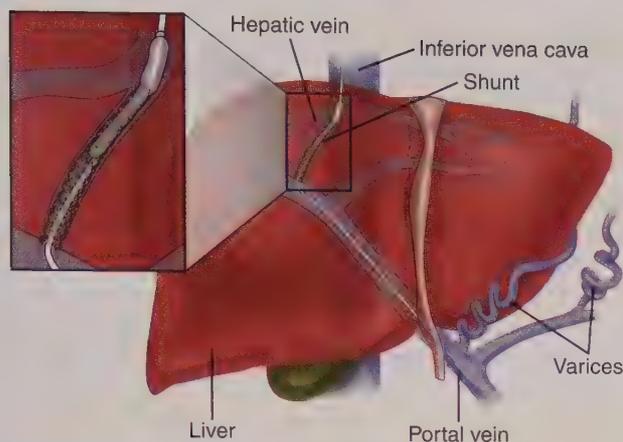

### **Complications**

In addition to complications associated with ascites, portal hypertension, coagulopathies, and hepatic encephalopathy, patients with cirrhosis are also at risk for hyponatremia, hepatorenal syndrome, and spontaneous bacterial peritonitis. The significant changes in liver function secondary to the pathophysiologic changes of cirrhosis often results in liver failure.

Hyponatremia (low serum sodium) is often seen in patients with advanced cirrhosis. This complication is associated with an impairment in the kidneys' ability to excrete free water, resulting in retention of water that is disproportionate to retention of sodium. On review of laboratory results, these

**FIGURE 59.6** Sengstaken-Blakemore tube. A Sengstaken-Blakemore tube is inserted into the gastrointestinal tract through the nose to provide compression and traction in the esophagus and stomach to stop hemorrhage.

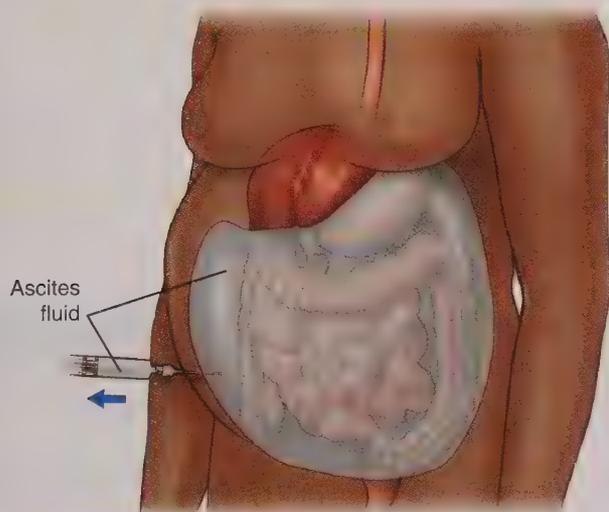

**FIGURE 59.7** Transjugular intrahepatic portosystemic shunt (TIPS). The transjugular intrahepatic portosystemic shunt involves the placement of a shunt between the portal venous system and the systemic venous system to reduce ascites accumulation by decreasing portal pressure.

patients demonstrate hyponatremia and decreased serum osmolality.

Some patients with cirrhosis develop **hepatorenal syndrome (HRS)** which is characterized as rapid deterioration of kidney function as a result of altered blood flow to the kidneys. The mortality associated with HRS is high, and the only long-term treatment is liver transplantation. Patients with HRS may have normal urine output or oliguria, and the diagnosis is usually based on abnormal laboratory values such as elevated serum creatinine and blood urea nitrogen (BUN) levels.

**Spontaneous bacterial peritonitis (SBP)** is the development of peritonitis in the abdomen that can occur in patients with chronic cirrhosis, and clinical manifestations include fever, abdominal pain, encephalopathy, or acute hemodynamic decompensation. Diagnosis of SBP is confirmed with a diagnostic paracentesis (Fig. 59.8) and culture

**FIGURE 59.8** Paracentesis. Paracentesis is an invasive procedure done to remove fluid from the abdominal cavity to ease patient symptoms, as well as to collect samples for laboratory analysis.

of the ascitic fluid. Patients with SBP usually have cultures positive for *Escherichia coli* (43%), *Streptococcus* species (23%), or *Klebsiella pneumoniae* (11%). Patients are generally treated with a short course of antibiotic therapy; however, some patients are treated for prolonged periods of time prophylactically.

### Nursing Management

#### Assessment and Analysis

Many of the clinical manifestations observed in the patient with cirrhosis are directly associated with the inability of the liver to perform its normal functions. Common findings include:

- Shortness of breath
- Decreased blood pressure
- Petechiae, bruising, and bleeding
- Altered mental status
- Asterixis
- Elevated liver enzymes
- Jaundice
- Dark amber urine
- Increased abdominal girth and bloating
- Decreased serum albumin levels
- Spider angiomas
- Palmar erythema
- Pruritus (secondary to accumulation of bile salts)

Other clinical manifestations associated with cirrhosis include acid-base disorders including respiratory alkalosis and metabolic alkalosis. Elevated serum ammonia levels, hyperventilation, and hypoxemia due to ascites or bacterial infection contribute to respiratory alkalosis while the patient exhales more carbon dioxide. Metabolic alkalosis can occur because of vomiting, fluid loss, diarrhea, and the use of diuretics.

#### Nursing Diagnoses

- **Fluid volume excess** associated with water and sodium retention secondary to decreased plasma protein (albumin)
- **Fluid volume deficit** associated with third spacing of peritoneal fluid (ascites), coagulation abnormalities, variceal bleed
- **Altered nutrition, less than body requirements**, associated with altered liver metabolism of nutrients, impaired absorption of fat-soluble vitamins, B vitamins, insufficient intake
- **Impaired skin integrity** associated with compromised nutrition, edema, decreased immune status, and accumulation of bile salts
- **Risk for injury: Bleeding** associated with coagulopathy

#### Nursing Interventions

##### ■ Assessments

- Respiratory status, shortness of breath  
*Adventitious breath sounds, decreased breath sounds, and increased respiration rate may indicate pulmonary fluid overload or inability to lower the diaphragm because of ascites.*

- Vital signs

*Blood pressure may be elevated because of fluid volume excess, but blood pressure may be low because of fluid shift out of the vascular space secondary to decreased oncotic pressure due to low serum albumin.*

- Peripheral edema secondary to fluid retention (see Evidence-Based Practice: Outpatient Treatment of Fluid Retention in Patients with Cirrhosis)

*Fluid shift into tissues associated with retention of sodium and water, decreased albumin*

- Abdominal girth

*Increased girth due to accumulation of fluid (ascites) in the peritoneal cavity secondary to fluid shifts caused by loss of intravascular plasma proteins*

- Bleeding gums, ecchymosis (bruising), epistaxis (nosebleed), and petechiae (small, round spots on the skin as a result of bleeding)

*Complications of decreased clotting factors and vitamin K deficiency*

- Skin, sclera, urine, and stool color;

*Signs of jaundice (yellowish skin and sclera) along with dark urine and clay-colored stools are associated with increased bilirubin levels due to the inability of the liver to produce bile or because bile flow is blocked.*

- Mental status

*Signs of anxiety, behavioral or personality changes, lethargy, stupor, asterixis indicate hepatic encephalopathy secondary to elevated ammonia levels*

- Intake and output

*Fluid status requires vigilant monitoring due to risk of fluid retention secondary to ascites, diarrhea, and potential blood loss.*

- Daily weight

*Increased weight indicates fluid retention.*

- Acid-base disorders

*Elevated serum ammonia levels, hyperventilation, and hypoxemia contribute to respiratory alkalosis. Metabolic alkalosis can occur because of vomiting and fluid loss, diarrhea, and the use of diuretics.*

- Signs of organ rejection

*In patients who undergo transplantation for cirrhosis, organ rejection may occur within the first 10 days after the procedure and may include RUQ pain, changes in bile drainage, fever, tachycardia, and jaundice.*

### ■ Actions

- Administer diuretics

*Diuretics help decrease fluid overload and edema.*

- Administer electrolyte replacements such as potassium

*Maintain electrolytes within normal range. Potassium levels may be low associated with vomiting, diarrhea secondary to treatment for elevated ammonia levels, the use of diuretics, or low dietary intake of potassium-rich foods.*

- Administer magnesium as needed

*Hypomagnesemia in patients with a history of alcohol abuse is a result of poor nutrition and diarrhea.*

- Administer phosphate as needed

*Hypophosphatemia, or low phosphate levels, due to alcohol abuse, poor nutrition, use of diuretics*

- Restrict sodium and fluid intake as ordered

*Prevents fluid accumulation and edema*

- Restrict protein intake

*Elevated amounts of protein in the diet can raise ammonia levels and lead to hepatic encephalopathy.*

- Head of bed elevation and leg elevation

*Helps respiratory status by decreasing pressure on the diaphragm secondary to ascites and minimizes dependent edema*

- Administer vitamin K, blood products, and fresh frozen plasma as ordered

*Corrects coagulation disorders secondary to liver's inability to synthesize clotting factors*

- Promote rest periods between activities; sit down while bathing, dressing

*Decreases metabolic demand on liver, decreases oxygen demand, and prevents fatigue*

### ■ Teaching

- Overview of disease process and dietary restrictions (protein, sodium, fluid)

*Promotes knowledge of signs and symptoms of disease and promotes understanding of the importance of following dietary guidelines to prevent progression of the disease process*

- Lifestyle changes:

- No alcohol intake

*If alcohol is the cause of cirrhosis, remove alcohol from diet and refer to support groups*

- Educate about medications that are metabolized in the liver such as acetaminophen (Tylenol) and over-the-counter herbs and supplements

*These medications can cause further liver damage.*

- Seek routine care for liver disease

*Encourage patient to be proactive in disease process and to monitor laboratory values and progression of disease.*

- Consume adequate calories to minimize weight loss, eating a well-balanced diet with plenty of fruits, vegetables, and whole grains

*Helps prevent malnutrition and provides body with adequate energy*

- Need for care with hygiene, soft toothbrushes, careful flossing, electric razors

*Minimize risk of bleeding*

## Evidence-Based Practice

### Outpatient Treatment of Fluid Retention in Patients With Cirrhosis

Patients with cirrhosis often require hospitalizations due to exacerbations of fluid retention. Treatment for severe fluid retention in patients with cirrhosis is more cost-effective when performed in an outpatient setting, and it decreases

preventable rehospitalizations. This literature review examined outpatient evidence-based interventions used in patients with cirrhosis with fluid retention and included 17 manuscripts (nine randomized controlled trials with a total of 1,694 patients, one meta-analysis that included five randomized controlled trials with 330 patients, and three cohort studies with 86 patients). There were also 2,115 articles from a systematic review and another 110 articles from a literature review. Six primary interventions that can be safely implemented in an outpatient setting were identified and include daily weights, sodium restrictions, diuretics, albumin infusions and paracentesis, placement of transjugular intrahepatic portosystemic shunt (TIPS), and telephone management. Because cirrhosis is a chronic disease, managing exacerbations of fluid retention in an outpatient setting decreases rehospitalizations and is more cost-effective than admission to an acute care facility.

White, A. (2014). Outpatient interventions for hepatology patients with fluid retention: A review and synthesis of the literature. *Gastroenterology Nursing, 37*(3), 236–244.

### Evaluating Care Outcomes

Cirrhosis is a manageable disease process when patients have a good understanding of the disease and are compliant with interventions and therapies (see Evidence-Based Practice: Outpatient Treatment of Fluid Retention in Patients With Cirrhosis). Expected outcomes include stable vital signs, stable weight, decreased abdominal girth, and absence of bleeding tendencies. Lifestyle activities that contribute to liver disease need to be altered or eliminated to slow progression of the disease. Knowledge of diet, nutritional intake, activity tolerance, and compliance with medical interventions are necessary. Patients require routine follow-up and monitoring of symptoms and should take a proactive role in their self-care. If the disease progresses to end-stage symptoms and patients require hospitalization at the end of life, education and interventions associated with the need for intensive care unit (ICU) management, potential transplantation, and/or palliative care can be explored.

### Connection Check 59.3

Elevated ammonia levels can lead to hepatic encephalopathy. Which provider order best reduces this risk in patients with cirrhosis?

- Administer furosemide and spironolactone
- Administer antibiotics
- Restrict protein intake
- Restrict caloric intake

### Connection Check 59.4

In a patient with cirrhosis, the nursing diagnosis “Risk for injury and bleeding associated with prolonged clotting factors” is most appropriate associated with which disorder?

- Pruritus
- Vitamin K deficiency
- Hyponatremia
- Ascites

## LIVER CANCER

### Epidemiology

Worldwide, more than 700,000 people are diagnosed with liver cancer annually. Liver cancer is more common in sub-Saharan African countries and in Southeast Asia. In 2018, in the United States, it was estimated that more than 42,000 men and women will be diagnosed with liver and intrahepatic bile duct cancer, with more than 30,000 deaths. Patients may also develop liver cancer secondary to metastasis from other areas. The incidence of hepatocellular carcinoma (HCC) more than doubled between 1995 and 2015, with the increase among African Americans even higher. The mortality rate also increased to approximately 4.7 per 100,000 between 2010 and 2015.

### Pathophysiology

Hepatocellular carcinoma is the most prevalent type of primary liver cancer, accounting for 85% to 90% of cases. Secondary liver cancer most often metastasizes from the colon, with more than half of patients diagnosed with colorectal cancer developing liver cancer. Risk factors for primary liver cancer include diseases that cause long-term inflammation of the liver including chronic infection with hepatitis B or C, or a several-year history of heavy alcohol drinking (defined as more than two alcoholic drinks a day for several years). Because of the inflammation, necrosis, fibrosis, and ongoing liver regeneration associated with chronic disease, cirrhotic changes occur and increase the risk of HCC development. Other risk factors include autoimmune disorders, hemochromatosis, obesity, a history of diabetes, or as a by-product of mold found in certain foods. Hemochromatosis is the excess build-up of iron in the body and can be a genetic disorder or a result of massive transfusions, chronic alcohol use, or hemolytic anemia. Obese patients tend to accumulate fat in the liver, which leads to chronic liver damage, inflammation, and nonalcoholic steatohepatitis (NASH). A by-product of the mold *Aspergillus flavus* found in peanuts, soy, rice, corn, and wheat stored in hot and humid environments can cause genetic mutations in the liver and has been associated with liver cancer in China and Africa. Liver cancer is usually fatal within 6 to 12 months of diagnosis, and for some patients the only cure is a liver transplant.

## Clinical Manifestations

Liver cancer is often asymptomatic until the liver becomes enlarged or the patient demonstrates clinical manifestations of liver dysfunction. Because the tumor typically impairs normal functions of the liver, patients exhibit abdominal pain, weight loss, anorexia, weakness, fatigue, jaundice, and ascites. The prognosis for patients with primary liver cancer is poor because patients are usually asymptomatic and are not diagnosed until late in the disease process. If diagnosed early, aggressive surgery can be successful if the tumor is small and slow growing and the liver is otherwise healthy. However, in many patients, liver tumors may be undetected on physical examination because of the location of the liver in the abdomen.

## Management

### Medical Management

#### Diagnosis

Routine screening for liver cancer is indicated in high-risk patients, including those with cirrhosis, viral hepatitis, hemochromatosis, alpha-1-antitrypsin deficiency, and a history of chronic alcohol use. Cross-sectional imaging studies every 6 to 12 months are recommended in patients with cirrhosis, along with assessment of alpha-fetoprotein measurements. This aggressive screening has resulted in 30% to 50% increases in diagnosis of HCC as compared with those patients who are not screened. In patients with suspected metastasis to the liver, ultrasound and contrast CT scans of the liver are useful in identifying tumor growth. Full body scans may also be indicated if the site of the original cancer has not been determined. A liver biopsy may also be performed to determine the type and stage of the cancer.

#### Treatment

Some patients may undergo a combination of chemotherapy and radiation, but radiation alone is ineffective at slowing tumor growth. Selective internal radiation therapy is considered for patients with liver cancer that cannot be treated surgically and includes delivering radiation directly into the liver via a catheter placed in the hepatic artery by an interventional radiologist. Systemic chemotherapy may be used for liver cancer but is generally ineffective. Hepatic arterial infusion allows for a more direct, targeted approach to delivery of chemotherapeutic agents to the liver. This procedure involves placement of a catheter into the hepatic artery by an interventional radiologist. An advantage to this approach is fewer side effects as compared with systemic administration of chemotherapy. Transcatheter arterial chemoembolization is another treatment for liver cancer that involves cannulation by an interventional radiologist of the feeding artery of the tumor. High doses of chemotherapy are administered via the catheter, and then the artery is occluded with gel foam or coils to prevent systemic toxicity. Ablation procedures are also used with

liver tumors, including radiofrequency ablation that uses energy waves to heat and kill tumor cells. Liver cancer is also treated with cryotherapy, which uses liquid nitrogen to freeze and kill tumor cells.

### Surgical Management

Surgical options for treatment of cancer are dependent on the degree of normal liver function and whether it is a primary or secondary cancer; surgical options for metastatic disease are typically palliative for symptom relief of pain and distention. In patients with small, single liver tumors with normal liver function, a partial hepatectomy may be performed to remove the tumor. Liver transplantation may also be an option in patients with small, single primary liver cancer.

## Connection Check 59.5

The nurse assesses for which clinical manifestations in the patient diagnosed with liver cancer? (Select all that apply.)

- A. Periumbilical pain
- B. Anorexia
- C. Hemoptysis
- D. Fatigue
- E. Jaundice

## Nursing Management

### Assessment and Analysis

The clinical manifestations in patients with liver cancer are directly associated with the degree of liver dysfunction and include:

- Pain in the RUQ with extension to the back or shoulder
- Fluid accumulation in the peritoneal cavity (ascites)
- Anorexia
- Weakness
- Shortness of breath
- Jaundice of skin, sclera
- Elevated serum liver enzymes, bilirubin

### Nursing Diagnoses

- **Pain** associated with pressure caused by the presence of the tumor
- **Activity intolerance** associated with fatigue and weakness
- **Risk for ineffective coping** associated with changes in health status and chronic disease

### Nursing Interventions

#### ■ Assessments

- Shortness of breath

*Fluid accumulation in the peritoneal cavity pushes up on the diaphragm and causes shortness of breath. Patients can experience hypoxia from intrapulmonary arteriovenous shunting and commonly develop pleural effusions.*

- **Vital signs**

*Increased respiratory rate and shortness of breath due to increased pressure on the diaphragm; elevated fever usually associated with infection*

- **Pain**

*Pain in the upper abdomen on the right side that may extend to the back or shoulder is associated with tumor size and location.*

- **Abdominal swelling and bloating**

*Ascites or protein-rich fluid accumulation in the peritoneal cavity occurs because of impaired sodium and water retention due to inflammation of the liver resulting in decreased production of plasma proteins (albumin) and to the presence of the tumor.*

- **Weakness and feelings of extreme tiredness**

*Associated with poor nutritional intake secondary to abdominal fullness and lack of appetite*

- **Weight loss**

*Decreased appetite causes poor nutritional intake.*

- **Appetite and feelings of fullness, nausea, and vomiting**

*Gastrointestinal symptoms can be associated with size of the tumor, accumulation of ascites, and compression on the stomach, leading to feelings of early satiety and decreased appetite*

- **Skin color and eyes**

*Jaundice develops, causing yellowish skin and scleral yellowing secondary to elevated bilirubin levels due to tumor obstructing bile ducts.*

- **Urine color**

*Increased serum bilirubin levels being filtered by the kidneys leads to dark, amber urine*

- **Abdominal girth measurements daily**

*Measure and document abdominal girth daily at the level of the umbilicus (standardized location) to determine fluid accumulation*

- **Liver enzymes and look for trends in laboratory values**

*All liver enzymes can be elevated because of abnormal functioning of the liver.*

- **Actions**

- **Administer pain medications such as NSAIDs, narcotics via oral route, IV, subcutaneous, topical patches, or narcotic-coated lollipops**

*Provides symptomatic relief. The use of pain therapy is patient specific; some patients respond to nonsteroidal anti-inflammatory medications, whereas others require topical patches. Combinations of therapies may be indicated depending on the severity of the patient's symptoms.*

- **Nerve blocks**

*Nerve blocks may be used and are injected locally directly into the nerves of the abdomen to provide relief of pain.*

- **Administer antibiotics and antipyretics**

*Antibiotics may be used if the patient has an infection. Antipyretics are used to treat temperature elevations.*

- **Apply elastic wraps/bandages or support stockings to lower extremities and elevate the legs**

*These actions help prevent edema and promote venous return. Leg elevation increases venous return and prevents peripheral edema.*

- **Restrict fluid intake; sodium restriction and protein restriction**

*Fluid restriction helps prevent edema, sodium restriction prevents accumulation of salts, and sodium retention and protein restriction may prevent symptoms of encephalopathy.*

- **Teaching**

- **Provide education on the importance of eating and maintaining an exercise regimen.**

*Proper diet and exercise teaching helps to maintain nutrition and strength and range of motion and conditioning. Importance of limited salt intake is particularly important.*

- **Provide patient education about procedures, diagnostic tests, interventions, or treatments (see Box 59.3)**

*Describe different treatment regimens to patients once ordered to help them understand the procedures.*

- **Teach patient about therapies used to control pain, alleviate symptoms for palliative therapy**

*Controls and relieves symptoms of pain and discomfort and improves quality of life*

## Evaluating Care Outcomes

The prognosis for patients with liver cancer depends on the age of the patient, the stage of the cancer, and whether or not it is primary or secondary liver cancer. Once a patient has been diagnosed, the course of treatment is determined for either cure if diagnosed early in the disease or treatment of symptoms. Surgical options may be curative or palliative to control pain due to tumors. Preventing complications of fluid retention and decreased nutritional intake are important care outcomes for these patients and their families.

## Evidence-Based Practice

### Liver Cancer

Studies of patients taking metformin for diabetes have shown a decreased risk of certain cancers. The impact of these studies has been scrutinized based on treatment duration, and patient factors. However, in 2018, results from a review of a national Veteran Health Administration database found a decreased incidence of liver cancer in patients receiving metformin compared with other solid tumors. Future clinical studies examining the possible protective effects of metformin should be conducted.

Murff, H.J., Roumie, C.L., Greevy, R.A., Hackstadt, A.J., McGowan, L.E.D., Hung, A.M., Grijalva, C.G. & Griffin, M.R. (2018). Metformin use and incidence cancer risk: evidence for a selective protective effect against liver cancer. *Cancer Causes & Control*, 29(8), 823–832.

## Box 59.3 Complementary Therapy for Patients With Liver Cancer

**Relaxation techniques:** Listening to soft music, learning breathing techniques to breathe more slowly, or massage may help patients relax.

**Acupuncture or acupressure:** Based on traditional Chinese medicine, acupuncture involves the use of fine needles to specific points on the body to aid in healing and decrease pain. Acupressure uses touch pressure in the same manner without the use of needles.

## LIVER TRAUMA

### Epidemiology

The liver is the most vulnerable organ to trauma in the abdominal cavity because of its size, vascular structure, and location near the ribs. The right lobe of the liver is more susceptible to injury than the left lobe because of the proximity of the ribs. In trauma, injuries to the liver can include lacerations, contusions, hematomas, bile leaks, and bleeding.

In the United States, liver trauma is more common in males and accounts for approximately 15% to 20% of blunt abdominal injuries. The primary causes are associated with motor vehicle accidents or injuries associated with occupation, sports, or fighting. Blunt trauma accounts for approximately 70% of injuries and is usually associated with motor vehicle accidents. The steering column of a car can cause trauma to an entire lobe of the liver, the seat belt can cause liver trauma, and mountain bike accidents can cause severe hematomas. Other blunt injuries can be attributed to crush injuries, blast injuries, and direct-force blunt injury from a blow to the abdomen by a hard object such as a baseball bat. Penetrating injuries such as gunshot wounds, shrapnel, and stab wounds also cause trauma to the liver and are more prevalent in urban areas. Hemorrhage is the most common cause of death in patients with liver trauma.

One caveat about liver trauma is that the patient may have other injuries in addition to a liver injury. These include abdominal and retroperitoneal injuries (60%), thoracic injuries (18%), extremity injuries (12%), and head injuries (10%). Pelvic fractures, long bone fractures, and soft tissue injuries are also common. The mortality rate associated with concomitant injuries of the liver, abdomen, and head is approximately 70%.

### Pathophysiology

The outcome of patients with liver injury is dependent on the mechanism of injury, the presentation of the patient on admission to the hospital, the patient's age, the severity of the injury, concomitant injuries, and shock state. Because

of the vascularity of the liver, any type of trauma increases the risk of hemorrhage. Additionally, damage to the hepatocytes may lead to signs of liver dysfunction seen with other liver disorders.

### Clinical Manifestations

Whether the patient sustains blunt or penetrating liver trauma, significant blood loss may occur, leading to severe hypotension despite fluid resuscitation. Clinical manifestations of shock may develop, including decreased blood pressure, tachycardia, tachypnea, decreased level of consciousness, pallor, and cool skin. Urine output may be decreased, and with associated trauma to the kidney or bladder, there may be frank blood in the urine. Patients may complain of RUQ pain and guarding and rebound tenderness of the abdomen may be observed. While blood and fluid accumulate in the abdominal cavity, there is dullness to percussion accompanied by abdominal distention and peritoneal irritation. Bowel sounds are most likely diminished, and the lack of sounds does not necessarily correlate with hemorrhage. If bowel sounds are heard in the chest cavity, this may indicate a diaphragmatic tear, and special attention is made to breathing patterns.

### Management

#### Diagnosis

Historically, most liver injuries were treated surgically. However, evidence shows that almost 86% of liver injuries have stopped bleeding by the time surgical exploration is performed, and 67% of operations performed for blunt abdominal trauma are nontherapeutic. In general, as part of an abdominal trauma work-up, patients undergo an abdominal CT scan. This diagnostic intervention has reduced the incidence of exploratory surgery. In trauma situations, abdominal, chest, and cervical x-rays are also performed to rule out other injuries. Approximately 80% of adults and 97% of children are treated conservatively by using careful follow-up imaging studies. Other diagnostic tests indicated for patients with liver trauma include a complete blood count (CBC) to monitor for both blood loss and infection, coagulation profile, serum electrolytes, LFTs, and drug and alcohol screens. Because of the risk of hemorrhage, the patient is also typed and crossmatched for blood products.

#### Medical Management

Patients who present with a potential liver injury require fluid resuscitation, frequent monitoring of vital signs and complete blood count, and blood transfusions depending on the severity of bleeding. Conservative, nonsurgical management includes hemodynamic monitoring for shock, close observation for changes in the abdominal examination, increased pain, serial hemoglobin and hematocrit testing, and CT scans. Patients are initially on bed rest and then have activity restrictions for as long as 6 weeks with no strenuous activity and no contact sports. Liver function tests

(LFTs) are monitored over time and can be elevated initially in response to trauma to the liver.

### Surgical Management

Operative management is used to control excessive bleeding or bile leaks. Operative procedures include suturing, cautery, removal of a damaged portion of the liver (hepatic resection) or packing around the liver. If packing is used to control bleeding, the patient may have to return to the operating room several times for packing removal and re-exploration of the wound.

### Complications

Immediately after the injury, the risk of hemorrhagic or hypovolemic shock is high. Because patients with liver trauma often have concomitant injuries to the abdomen or other body systems, they are also at risk for other complications including atelectasis, pneumonia, abscess, fistulas, transfusion-related acute lung injury, peritonitis, and sepsis. Because of damage to the liver, the patients often have issues with albumin synthesis, blood coagulation, resistance to infection, and nutritional deficits. In rare cases, liver transplantation is utilized as salvage therapy with massive tissue destruction.

### Nursing Management

#### Assessment and Analysis

Clinical manifestations observed in the patient with liver trauma are associated with the severity of the injury and blood loss. Common findings include:

- Increased respiratory rate
- Tachycardia
- Low blood pressure
- Abdominal pain and guarding due to the injury
- Low hematocrit and hemoglobin
- Tense, firm abdomen due to bleeding into the peritoneal cavity
- Elevated liver enzymes

Early assessment and intervention in patients with abdominal trauma lead to appropriate management and facilitate positive patient outcomes.

#### Nursing Diagnoses

- **Risk for fluid volume deficit** due to bleeding
- **Ineffective breathing pattern** associated with abdominal pain
- **Risk for infection** associated with products of liver metabolism entering the abdominal cavity leading to peritonitis

### Nursing Interventions

#### Assessments

- Monitor vital signs (VS) and clinical manifestations of shock  
*Frequent measurement of VS determines hemodynamic status. Elevated pulse rate and decreased blood pressure may indicate bleeding or shock state because of the highly vascular*

*nature of the liver. Respirations may be elevated or altered because of pain.*

- **Abdominal guarding/tenderness and RUQ**  
*The RUQ is a common site of pain for trauma to the liver; worsening pain may indicate peritonitis. Peritonitis or inflammation can occur from tissue trauma and leakage of bile or blood into the abdominal cavity from trauma.*
- **Serial hemoglobin or hematocrit (H&H)**  
*Measures the extent of bleeding and blood loss and determines the need for fluid or blood replacement. Trending changes in H & H may indicate continuing internal hemorrhage*
- **Serum LFTs**  
*Alterations in LFTs may indicate the inability of the liver to function normally.*
- **Nausea and vomiting**  
*The nausea and vomiting occurs because of inflammation of the peritoneal cavity and may be an early, subtle sign of peritonitis.*
- **Abdominal girth**  
*Abdominal enlargement may be due to bleeding in the abdominal cavity.*
- **Urine output**  
*Decreased perfusion to the kidneys associated with hypovolemia results in decreased production and is a sign of decreased renal perfusion.*

#### Actions

- **Fluid resuscitation as ordered**  
*Maintains hemodynamic stability and promotes organ perfusion*
- **Administer blood products as ordered**  
*Transfusion maintains adequate hemoglobin concentration. In the absence of typed and crossmatched blood, blood type O negative may be administered.*
- **Administer antibiotics as ordered**  
*Injuries to the liver may result in infectious processes in the peritoneal cavity (penetrating knife injuries or associated intestinal injury), and antibiotics are used to destroy the organisms.*
- **Activity restrictions**  
*Patients should have no strenuous activity for 6 weeks after injury, including no contact sports and no heavy lifting or straining to allow for healing.*

#### Teaching

- **Educate patient about diagnostic studies such as CT scan**  
*Computed tomography scans identify the location of an injury, fluid collections, and bleeding; although CT is the preferred diagnostic test, some institutions may use ultrasound.*
- **Take prescribed vitamins and iron supplements**  
*Because the liver is a storage area for vitamins A, D, E, and K and iron, the patient with liver trauma requires supplementation with these vitamins and iron. Additionally, iron is needed for synthesis of hemoglobin.*

- Importance of activity restrictions  
*Recovery from liver trauma may take 6 to 8 weeks and strenuous activity should be avoided to allow the liver to heal.*
- Patient education about abdominal signs and symptoms of increased pain, tenderness  
*Some patients with liver trauma may develop future complications such as liver abscesses because of undiagnosed injury or a delay in the healing process.*

### Evaluating Care Outcomes

Liver trauma is a result of an injury to the liver via either blunt or penetrating trauma. It is important to serially monitor a patient with trauma to the abdomen for liver damage, which may not occur immediately after the traumatic event. Therefore, close abdominal assessments, serial hematocrit and hemoglobin levels, and frequent hemodynamic monitoring are important. The outcome of patients with liver injury is dependent on the mechanism and severity of injury, the presentation of the patient on admission to the hospital, age, and other injuries sustained at the time of the liver injury. Patients can recover well from injury with prompt intervention. It is important to monitor for concomitant complications such as atelectasis, pneumonia, and abscess formation.

### Connection Check 59.6

Which statement by a patient diagnosed with liver trauma indicates understanding of the prescribed plan of care?

- “I will need a liver transplant.”
- “I will need a blood transfusion.”
- “I am at increased risk for infection.”
- “I will never be able to drink alcohol again.”

## Making Connections

### CASE STUDY: WRAP-UP

Mr. Green is admitted to the unit for further follow-up. On physical examination, he is responsive to questions and is oriented to person and time but not place and is mildly confused. His blood pressure is 91/43 mm Hg, and his heart rate is 100 bpm. He complains of slight shortness of breath with a respiratory rate of 24. His oxygen saturation is 94% on 2-L nasal cannula. He is afebrile. His abdomen is very large and distended, and the nurse notes the presence of veins throughout the abdomen. He complains that his clothes are too tight and that it is hard to lie flat on his back; he has to sit in a semi-upright position. His arms and legs are covered with scarring from his former

IV drug use. His pupils are reactive and equal, and his sclera are slightly yellow as is his skin. He states that his urine is very dark.

Diagnostic tests reveal:

- Chest x-ray indicates small bilateral pleural effusions
- Electrocardiogram reveals sinus tachycardia
- LFTs elevated greater than 4 times the normal range (AST = 220 IU/L; ALT = 185 IU/L)
- Bilirubin levels are twice the normal range (total bilirubin = 2.8 mg/dL; direct bilirubin = 1.0 mg/dL)
- Prolonged INR (international normalized ratio)
- Elevated serum ammonia levels
- Low albumin levels 3 g/dL

Mr. Green is diagnosed with liver failure.

### Case Study Questions

1. What clinical manifestation does Mr. Green display that is consistent with a diagnosis of liver failure?
  - A. Yellow sclera
  - B. Arm and leg scars from IV drug abuse
  - C. Tachycardia
  - D. High blood pressure
2. Which clinical manifestation experienced by Mr. Green will be relieved by paracentesis?
  - A. Jaundice
  - B. Dyspnea
  - C. Diarrhea
  - D. Decreased urine output
3. Which order will the nurse anticipate for Mr. Green?
  - A. Increase iron intake
  - B. Strict bedrest
  - C. Placement of an indwelling urinary catheter
  - D. Restrict sodium to 2 g per day
4. Which information does the nurse include in teaching Mr. Green about his diagnosis of liver failure?
  - A. “Avoid foods high in fat”
  - B. “Avoid foods high in protein”
  - C. “Need for oxygen when he is discharged”
  - D. “Need for antihypertensive medications”
5. Based on Mr. Green’s most recent clinical presentation, which finding is the priority that the nurse needs to communicate to the healthcare provider?
  - A. Temperature
  - B. Worsening mental status
  - C. Inability to lie flat
  - D. Blood pressure

## CHAPTER SUMMARY

The liver serves several functions including blood storage, blood filtration, production of bile, synthesis of clotting factors (prothrombin and factors II, VII, IX, and X), and metabolism of carbohydrates, fat, and protein. The liver also serves to detoxify the blood and is a storage area for vitamins A, D, E, and K and iron. Hepatic dysfunction occurs when the liver is no longer able to perform its usual functions. Several conditions such as hepatitis, cirrhosis, liver trauma, and liver cancer all impair the ability of the liver to perform its routine functions.

Hepatitis is inflammation of liver cells most commonly caused by a virus that limits the ability of the liver to detoxify substances, limits the production of proteins and clotting factors, and alters the ability to store vitamins, fats, and sugars. Modes of transmission of viral hepatitis include contact with blood, blood products, semen, saliva, and mucous membranes; direct contact with infected fluids or objects; or through the fecal-oral route with contaminated water or food.

Patients with hepatitis can have a mild or severe illness, which can be acute or chronic. The viruses of hepatitis are classified according to letters ranging from A to G, each of which differs in its incubation period, mode of transmission, and other characteristics. The most common hepatitis viruses are hepatitis A, B, and C.

Cirrhosis of the liver is a chronic disease that causes cell destruction and fibrosis or scarring of hepatic tissues. Functional liver cells die, and damaged liver cells regenerate into nodules of liver cells, which are surrounded by fibrous tissue. This irreversible chronic injury to functional liver cells results in liver cell necrosis and altered liver structure and function, leading to alterations in blood and lymph flow, resulting in hepatic insufficiency and hypertension in the portal vein. Alteration of blood flow to the liver results in portal hypertension and shunting of blood around the

liver that leads to increased pressure in the surrounding vessels and esophageal and gastric varices, which may result in upper GI bleeding. Cirrhosis is generally irreversible, and treatment generally focuses on preventing progression and complications. In advanced stages of cirrhosis, the only option is a liver transplant.

Liver cancer is classified as either primary or secondary. Primary liver cancer (hepatocellular carcinoma) originates from the liver, and secondary liver cancer originates from other areas of the body and metastasizes to the liver. Risk factors for primary liver cancer include diseases that cause long-term inflammation of the liver, including chronic infection with hepatitis B or C or a several-year history of heavy drinking (defined as more than two alcoholic drinks a day for several years). Other risk factors include autoimmune disorders, hemochromatosis, obesity, and a history of diabetes or as a by-product of mold found in certain foods. The prognosis for patients with liver cancer depends on the age of the patient, the stage of the cancer, and whether or not it is primary or secondary liver cancer. Once a patient has been diagnosed, the course of treatment is determined for either cure if diagnosed early in the disease or treatment of the symptoms if more advanced and considered incurable.

Liver trauma is a result of an injury to the liver via either blunt or penetrating trauma. The right lobe of the liver is more susceptible to injury than the left lobe because of its proximity to the ribs. In trauma, injuries to the liver can include lacerations, contusions, hematomas, bile leaks, and bleeding, and it is important to serially monitor a patient with trauma to the abdomen for liver damage, which may not occur immediately after the traumatic event. Close abdominal assessments, serial hemoglobin and hematocrit values, and frequent hemodynamic monitoring are important. Patients can recover well from injury with prompt intervention. It is important to monitor for concomitant complications such as atelectasis, pneumonia, and abscess formation.

# Chapter 60

## Coordinating Care for Patients With Biliary and Pancreatic Disorders

*Sandy Swoboda*

### LEARNING OUTCOMES

Content in this chapter is designed to support the learner in:

1. Describing the epidemiology of biliary and pancreatic disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Cholecystitis
  - b. Acute pancreatitis
  - c. Chronic pancreatitis
  - d. Pancreatic cancer
3. Describing the diagnostic results used to confirm the diagnoses of biliary and pancreatic disorders
4. Discussing the medical management of:
  - a. Cholecystitis
  - b. Acute pancreatitis
  - c. Chronic pancreatitis
  - d. Pancreatic cancer
5. Developing a comprehensive plan of nursing care for patients with biliary and pancreatic disorders
6. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with biliary and pancreatic disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Inflammation
- Medication
- Nutrition
- Safety

### ESSENTIAL TERMS

Acalculous  
Amylase  
Autodigestion  
Bile  
Biliary  
Calculous  
Cholangiogram  
Cholecystitis  
Cholecystokinin  
Choledocholithiasis  
Cholelithiasis  
Common bile duct  
Cullen's sign  
Endoscopic retrograde  
cholangiopancreatography  
(ERCP)  
Gallstones  
Gastrojejunostomy  
Grey Turner's sign  
Hepaticojejunostomy  
Hepatobiliary iminodiacetic acid  
(HIDA) scan  
Lipase  
Lithotripsy  
Murphy's sign  
Necrosectomy  
Pancreaticoduodenectomy  
Pancreaticojejunostomy  
Pleural effusion  
Pseudocyst  
Ranson's criteria  
Sphincter of Oddi  
Sphincterotomy  
Steatorrhea  
Trypsin  
Vagotomy  
Whipple procedure

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Tony Edwards presents to the emergency department with severe, acute epigastric pain and nausea and vomiting. He describes the pain as sudden and radiating to the back. His heart rate is 110 bpm, blood pressure is 108/65 mm Hg, respiratory rate (RR) is 18, and temperature is 100.2°F (37.9°C). His abdomen is tender. Laboratory values include white blood cell count (WBC)  $10.7 \times 10^3/\text{mm}^3$ , blood urea nitrogen (BUN) 23 mg/dL, creatinine (Cr) 1.2 mg/dL, serum lipase level 250 U/L, amylase 3,500 U/L, alanine transaminase (ALT) 190 U/L, aspartate aminotransferase (AST) 150 U/L, total bilirubin 0.4 mg/dL, and albumin 3.3 g/dL. His sclerae are slightly yellow...

## INTRODUCTION

The **biliary** system includes the gallbladder and bile ducts. The cystic duct (from the gallbladder) and the hepatic duct (from the liver) join to form the **common bile duct**. The primary purpose of the biliary system is to transport bile from the liver, where it is produced, to the gallbladder, where it is stored, and then to the duodenum, where it aids in the digestion of fats. **Bile** is a digestive enzyme that helps break down fats. Biliary disease occurs when the gallbladder or ducts become inflamed, infected, or cancerous, impairing the ability of the gallbladder to function normally. Several disorders, such as cholecystitis, pancreatitis, and pancreatic cancer, impair routine biliary functions.

## CHOLECYSTITIS

### Epidemiology

**Cholecystitis** is the inflammation of the gallbladder caused by an obstruction of bile flow and is classified as either **calculous** cholecystitis (presence of gallstones) or **acalculous** cholecystitis (without stones). **Gallstones** are hard deposits formed from bile contents that often cause obstruction of ducts in and around the gallbladder. Approximately 20 million people in the United States have gallstones, also known as **cholelithiasis**, and more than 500,000 cholecystectomies (removal of the gallbladder) are done annually. The incidence of gallstones and cholecystitis increases with age, and gallstones are more common in women than men and also more common in people of European descent than in people of African American descent. One approach to remembering signs and symptoms associated with gallstones is the five Fs (fair, fat, female, fertile, and over forty years of age). Risk factors for gallstones include obesity or rapid

weight loss, weight-loss surgery, eating large amounts of foods with saturated fats, pregnancy (because of elevated progesterone levels), genetics (members of the Pima and Chippewa tribes may have increased risk), and some medications (estrogen, octreotide, and cholesterol-lowering medications).

### Pathophysiology

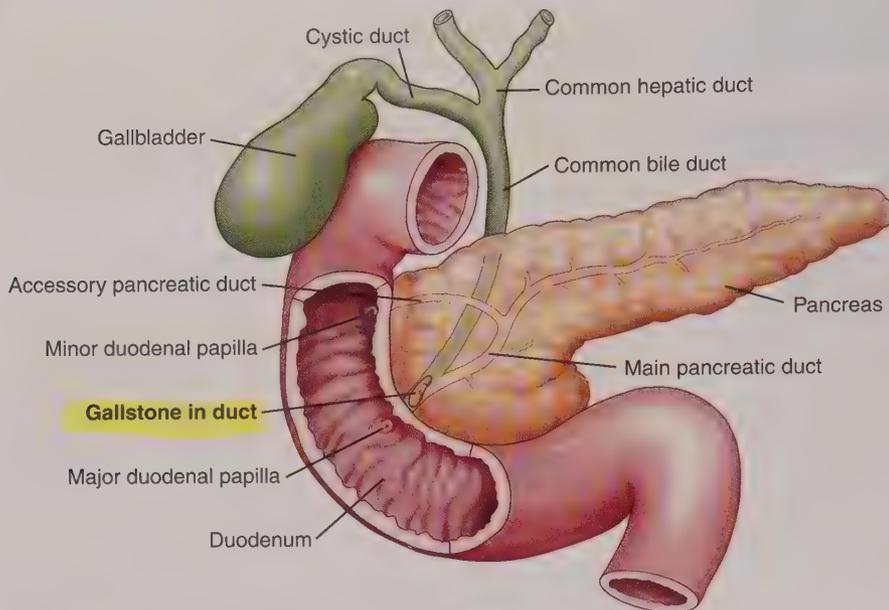

Gallstones are hard deposits that form in the gallbladder and are generally classified into three categories: cholesterol stones (the most common type), pigmented (formed from excess bilirubin), and mixed stones (combination of both types). Gallstones vary in size and can be very small like a pea or as large as a softball. Patients can have multiple stones or a single stone, and gallstones are most commonly found blocking the cystic duct or the common bile duct (Fig. 60.1). The medical term for gallstones in this location is **choledocholithiasis**.

Acalculous cholecystitis is associated with biliary stasis, where there is a slowing or stopping of the flow of bile either from decreased contractility of the gallbladder or spasms in the **sphincter of Oddi**. Because this sphincter controls the release of digestive enzymes into the duodenum, opening only in response to oral intake, when not working properly, it contributes to biliary stasis. The exact mechanism of acalculous cholecystitis is not well understood. Some believe the presence of endotoxin in sepsis can cause necrosis, hemorrhage, and ischemia to the gallbladder or that it inhibits the release of **cholecystokinin**, a peptide hormone activated when eating that causes the gallbladder to contract and release bile, leading to biliary stasis. Several causes of acalculous cholecystitis are found in Box 60.1.

Patients with noncomplicated cholecystitis related to gallstones recover within 1 to 4 days after onset of clinical manifestations, and the disease has only a 4% mortality rate. However, approximately 25% of patients with cholecystitis develop a complication, some requiring emergent surgery (12% of cases). Complications such as perforation or gangrene can lead to a critical illness and carry a mortality rate of up to 60%, usually due to sepsis.

### Clinical Manifestations

The clinical presentation of acute cholecystitis ranges from no physical findings to pain and tenderness in the right upper quadrant (RUQ), sometimes with rebound tenderness or guarding, fever, and tachycardia. The pain associated with cholecystitis is due to the release of cholecystokinin, which causes the gallbladder to contract. Pain can be described as **colicky pain**, which is intermittent and radiating to the back, and this is related to the movement of the gallstones through the bile ducts as the bile flows. There are several small valves in the ducts, and the colicky pain is due to the movement of stones through these areas. Radiation to the back is related to the innervations of the gallbladder. Forty percent of patients have a palpable fullness in the RUQ, and

**FIGURE 60.1** Gallstone in the common bile duct. Gallstones are most commonly found blocking the cystic duct or the common bile duct.

### Box 60.1 Causes of Acalculous Cholecystitis

- Abdominal surgery
- Severe trauma
- Long-term IV nutrition (> 1 month)
- Prolonged fasting
- Sickle cell disease
- Diabetes mellitus
- Endotoxin
- AIDS
- *Salmonella* infection
- Cytomegalovirus

some patients exhibit a positive **Murphy's sign**, which is pain on palpation of the RUQ upon deep inspiration. To test for the presence of a positive Murphy's sign, the examiner's fingers are placed on the RUQ of the abdomen, and then the examiner gently presses down while asking the patient to take a deep breath. The test is positive if the patient has pain upon deep inspiration. Some patients with gallstones may be jaundiced because of the impaired bile flow. Sometimes, cholecystitis is difficult to diagnose because not all patients exhibit specific localized clinical manifestations, and the pain can be general. It is common for older adults and patients with diabetes to present with vague symptoms.

### Management

#### Medical Management

#### Diagnosis

There are several different tests that are utilized to determine the presence of gallstones. It is also important for the nurse to be aware of patient allergies to iodine or radiopaque

substances because these may be used for some of the procedures. This includes monitoring for allergic reaction to any diagnostic agent used. Diagnostic tests include:

- Abdominal x-ray is occasionally used to detect calcified gallstones
- Abdominal ultrasonography is a noninvasive test that is most commonly used to determine the presence of gallstones and acute cholecystitis. A thickened gallbladder is indicative of cholecystitis.
- Computed tomography (CT) visualizes the entire abdomen and can detect the presence of gallstones.
- The **hepatobiliary iminodiacetic acid (HIDA) scan** is a nuclear medicine scan that uses a radioactive tracer to study the production and flow of bile, visualizing the liver, gallbladder, bile ducts, and small intestine.
- **Endoscopic retrograde cholangiopancreatography (ERCP)** allows visualization of the common bile duct where gallstones can be removed. In patients with acalculous cholecystitis who are a high operative risk, a percutaneous drain can be placed. Patients who undergo ERCP should not eat or drink anything the night before the procedure but can take their cardiac and blood pressure medications the morning of the examination with a small amount of water. Patients are sedated for the test and need to have someone drive them home. After the ERCP, the patient goes to the postanesthesia care unit (PACU) to allow time for recovery from the sedation. It is important that the nurse observe the patient after the ERCP for a potential systemic inflammatory response syndrome (SIRS) caused by the manipulation of the bile ducts and potential bacterial translocation.
- Cholecystography is a rarely used diagnostic procedure that is a radiographic test of the gallbladder after the

patient orally takes radiopaque dye, which collects in the gallbladder and is excreted by the liver.

- **Cholangiogram** is commonly used in the operating room to image the biliary tree. A radiopaque dye, usually containing iodine, is injected intravenously, which outlines the bile ducts and gallstones.

Additional diagnostic studies used in the diagnosis of cholecystitis included a complete blood count and liver function tests. Significant findings associated with this diagnosis include:

- Elevated WBC due to inflammation
- Elevated liver enzymes, including AST, ALT, lactate dehydrogenase (LDH), and alkaline phosphatase (ALP), as well as bilirubin because of blockage of bile flow in the bile ducts

### Treatment

Historically, extracorporeal shock wave therapy or **lithotripsy** was commonly used to dissolve gallstones. Patients would sit in a tub of water, and high-energy sound shock waves were directed through the water toward the stones to break them up into smaller pieces that would then pass through the bile duct. This treatment modality was used in conjunction with oral agents to help dissolve the gallstones. Lithotripsy is used for the treatment of small gallstones; however, the current preferred method of intervention for gallstones is laparoscopic surgery, which is one of the most common surgeries performed in the United States (see Surgical Management).

### Medications

Treatment of a patient with acute cholecystitis includes nothing by mouth (NPO) status, IV hydration, correction of electrolyte and fluid imbalances, pain management, and IV antibiotics as indicated. The use of antibiotics in these patients is typically a short course with broad-spectrum medications. Patients are NPO to prevent the release of cholecystokinin, which is activated when eating and causes the gallbladder to contract and release bile, which leads to pain. Morphine is usually contraindicated for pain management because it can cause the sphincter of Oddi to spasm, which results in pain. Narcotics such as meperidine (Demerol) can be used for severe pain management. Acetaminophen or nonsteroidal medications such as ibuprofen or naproxen can also be used for pain management in patients with less severe pain.

In some cases, oral agents are used to dissolve the gallstones; these natural bile acids are provided to reduce the size and number of gallstones. Effective medications include ursodiol, Actigall, and chenodiol, which work best in small-sized stones that have a high cholesterol content. The drawback to some of these medications is that patients may need to take the medications for up to 2 years, which can be very expensive, and if the patient stops taking them, the stones usually reappear. Because treatment is prolonged, many patients are noncompliant with this therapy.

### Diet

Several foods contribute to the formation of gallstones and should be avoided. Fatty foods such as fried foods, ice cream, dairy products, red meats, and heavy alcohol should be restricted because they promote gallstone formation. Patients are advised to choose foods low in saturated fats, including rice, potatoes, pasta, yogurt, fruits, lean meat, and whole grains.

### Surgical Management

Several surgical options for the treatment of patients with cholecystitis are available, and the intervention is dependent on the presentation of the patient and the severity of the clinical manifestations. The standard surgical treatment is a laparoscopic cholecystectomy. If the patient has complications such as a perforated gallbladder or peritonitis, an open surgical procedure may be indicated. Open cholecystectomy may also be indicated if the patient has a history of previous abdominal surgeries or is morbidly obese. If stones are present in the common bile duct, surgeons may place a T-tube, or biliary drainage tube, into the common bile duct to monitor bile drainage. This tube exits the patient's abdomen through the skin and is connected to a closed drainage system. This tube may stay in place for up to 2 weeks after surgery. Bile output should not exceed 500 mL in the first 24 hours.

Laparoscopic cholecystectomy uses several small incisions (up to 1/2 in. long) in the abdominal cavity. Carbon dioxide gas is inserted to create space in the abdomen, and the surgical instruments and a laparoscope (a small thin telescope, camera, and surgical equipment) are placed through the incisions to remove the gallbladder. This procedure involves general anesthesia and can be done on an outpatient basis or may require the patient to stay in the hospital overnight.

During the immediate postoperative period, the patient recovers from anesthesia in the postanesthesia care unit (PACU), where the nurse monitors vital signs, pain, neurological status, nausea and vomiting, and the surgical site for distention, bleeding, or bruising. Once the patient is awake and following commands, clear liquids are given slowly in small amounts to prevent nausea and vomiting. After the first 12 hours of liquids and no nausea, vomiting, or abdominal cramping, patients can gradually introduce small amounts of solid foods and maintain a low-fat diet. Discharge instructions include incision care (keep Band-Aid or dressing on for first 24 hours and then remove), recognizing signs and symptoms of infection, signs of jaundice (yellow eyes or skin), pain medication instruction, constipation prevention, activity level (encourage walking and normal activity within a week, such as driving, working, and light lifting of less than 10 pounds), and no driving while taking narcotics. It is important to teach the patient that it is okay to take a shower after the first 48 hours and get the incision a little wet in the shower, but patients should not let the water pressure flow directly on the incision, which can increase chances of infection at the incision site. The

patient should not soak in a tub, pool, or hot tub for up to 1 week. Pain after a laparoscopic cholecystectomy can occur at the incisions and sometimes in one or both of the shoulders because of irritation of the diaphragm from the carbon dioxide gas given during the surgery.

Postoperative care of the T-tube requires assessment of the characteristics of the drainage (color, consistency, and amount), routine emptying of the contents of the drainage bag, skin care, and routine flushing with appropriate preservative-free solution as ordered. Patient teaching includes information about care, biliary drainage, clinical manifestations of obstruction, color of urine and stool (if bile is being drained outside of the body), and infection.

Open cholecystectomy is the removal of the gallbladder through an open incision in the abdomen and is performed under general anesthesia. This was the most common means of removal of the gallbladder prior to the development of laparoscopy. This procedure is indicated for patients with previous abdominal surgeries because of scarring and adhesions, morbid obesity, or peritonitis. About 5% of laparoscopic procedures are converted to open procedures if there is an injury to a blood vessel, difficulty removing or visualizing the gallbladder, or other reasons as determined by the surgeon during the procedure.

Postoperative care after open cholecystectomy includes monitoring vital signs, pain, neurological status, and the abdomen for signs and symptoms of distention, bleeding, or bruising. Once the patient is passing flatus, clear liquids are introduced, and the diet is advanced to regular if the patient has no nausea or vomiting. Pain management via patient-controlled analgesia or as needed, pulmonary interventions to encourage lung expansion, coughing and deep breathing to prevent pneumonia and atelectasis, and walking are encouraged. Discharge teaching includes signs and symptoms of infection, prevention of constipation, low-fat diet, and activity levels. If a T-tube is present, routine care and teaching of T-tube management are necessary. The patient is typically in the hospital for several days after open cholecystectomy.

## Nursing Management

### Assessment and Analysis

The most common symptom of acute cholecystitis is abdominal pain. Pain can be described as colicky pain, which is intermittent and radiating to the back. Physical examination includes RUQ tenderness, fever, and elevated heart rate. Upon physical examination, the patient may have a positive Murphy's sign, and this is elicited during deep palpation of the abdomen. Pain occurs when the inflamed gallbladder touches the peritoneum during deep inspiration. When this test is performed, it is not unusual for patients to quickly hold their breath or stop breathing when they experience the pain from this test. Patients also have elevated liver enzymes, bilirubin, and WBC because of obstruction and inflammation.

## Nursing Diagnoses

- **Acute pain** related to obstruction and edema related to gallstones
- **Fluid volume deficit** related to nausea, vomiting, and increased insensible fluid loss
- **Imbalanced nutrition, less than body requirements**, related to nausea and vomiting
- **Knowledge deficient** regarding condition, prognosis, treatment regimen, self-care, and discharge needs

## Nursing Interventions

### ■ Assessments

- **Vital signs**  
*Fever and tachycardia may represent inflammation due to gallstones. Elevated respiratory rate may occur because of anxiety and pain, the rate may be shallow and rapid because of pain, and blood pressure may be low as a result of dehydration/inflammatory response.*
- **Serum electrolytes**  
*These measure imbalanced electrolytes due to dehydration from nausea and vomiting and lack of oral intake and include BUN and creatinine (elevated). In the patient with nasogastric tube suctioning, the serum potassium should be monitored closely because this electrolyte is lost with nasogastric suctioning.*
- **Serum WBC**  
*Inflammation leads to an elevated WBC count.*
- **Liver enzymes, bilirubin**  
*Liver enzymes (AST, ALT, LDH, ALP) and bilirubin are elevated because of blockage of bile flow in the bile ducts.*
- **Skin turgor**  
*Decreased skin turgor indicates dehydration.*
- **Pain (onset, duration, exacerbating and relief factors)**  
*Pain can be intermittent and colicky. Pain can be severe epigastric and in the RUQ with radiation to the back, mid-shoulder/scapula, or in the chest. The onset is fast, commonly within 1 hour of eating a high-fat meal, and common at night.*
- **Abdominal assessment: distention, bowel sounds; Murphy's sign**  
*Palpation may reveal rebound tenderness, muscle guarding, or rigid abdominal muscles due to pain.*
- **Stool**  
**Steatorrhea** *(presence of excess fat in stool or oily stools), clay-colored stools due to blockage of bile flow*
- **Daily weight**  
*Provides information in regard to fluid gains or losses*
- **Intake and output**  
*Provide data about fluid volume status and prevent dehydration*
- **Nutritional intake**  
*Determines diet history, fat intake, foods that can contribute to symptoms*

### ■ Actions

- **Maintain NPO status.**  
*NPO status prevents gallbladder contraction that releases bile to break down nutrients; these contractions cause pain because of the inflamed gallbladder.*

- Administer ordered antibiotics.  
*A short course of antibiotics may be given to reduce inflammation and treat infection.*
- Administer ordered bile acid reducers.  
*Bile acid reducers help dissolve gallstones.*
- Administer analgesics as ordered.  
*Analgesics decrease the patient's symptoms of pain. Avoid morphine due to spasm of the sphincter of Oddi.*
- Administer antiemetic as ordered.  
*Antiemetics decrease symptoms of nausea and vomiting, which may occur for a prolonged time due to abdominal pain and obstruction.*
- Promote bedrest in semi-Fowler's position.  
*Avoid lying flat because this makes the pain worse, particularly with peritonitis, by stretching the abdominal muscles when supine. Repositioning helps alleviate abdominal pain and pressure.*
- Nasogastric tube (NGT) to low suction (intermittent or continuous is ordered based on type of tube)  
*An NGT is used to decompress the stomach and remove gastric secretions.*

### Teaching

- Postoperative instructions  
*Discharge teaching includes signs and symptoms of infection, prevention of constipation, low-fat diet, and activity restrictions (encourage walking and normal activity within a week, such as driving, working, and light lifting of less than 10 pounds), and no driving while taking narcotics.*
- T-tube management  
*The patient needs to monitor the insertion site for inflammation and drainage. The T-tube bag should be emptied when one-half to two-thirds full to decrease the pull on the insertion site.*
- The patient should avoid a diet high in saturated fats.  
*Obtaining a diet history can help identify foods that contribute to symptoms. Bile breaks down fats; thus, a diet high in fat requires activation of bile for breakdown and increases pain. Stress small, frequent meals.*
- Disease clinical manifestations, progression, diagnostic procedures, and interventions  
*Patient education about the disease improves overall management and health. It is important that the patient recognize and report symptoms that may indicate relapse or complications, including pain, chills, fever, jaundice, dark urine, and light (clay-colored) stools.*

### Evaluating Care Outcomes

Cholecystitis is a manageable disease process. It is important to educate patients about this disease and its clinical manifestations and help them develop a plan for prevention. Timely and accurate diagnosis facilitates definitive treatment that focuses on pain management and medical and/or surgical management. Absence of pain and vital signs and fluid status within normal limits, as well as normalizing liver enzymes and WBC count are all indicators of recovery from this disease process.

### Connection Check 60.1

The nurse recognizes which as risk factors for cholecystitis? (Select all that apply.)

- A. Obesity
- B. Male
- C. Female
- D. African American descent
- E. European descent

### Connection Check 60.2

The nurse correlates which clinical manifestation with cholecystitis?

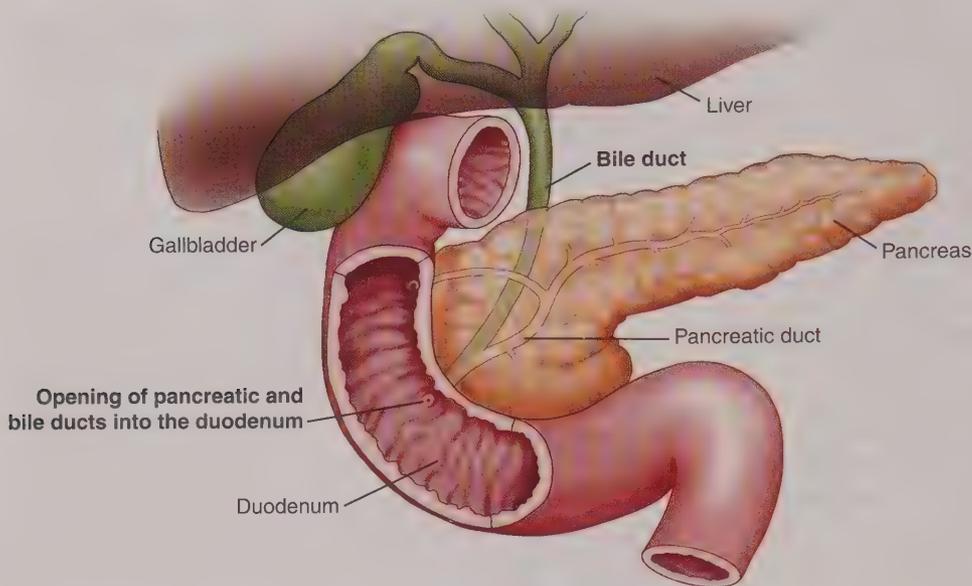

- A. Retroperitoneal pain
- B. Absence of bowel sounds
- C. Diarrhea
- D. RUQ pain

## ACUTE PANCREATITIS

### Epidemiology

Pancreatitis is a disease characterized by inflammation of the pancreas and is classified as acute or chronic. In acute pancreatitis, patients usually present with life-threatening conditions that require hospitalization, frequently in the intensive care unit (ICU). Acute pancreatitis is an inflammation of the pancreas that can be mild to severe and affect people of all ages. Patients with a mild case of pancreatitis have no end-organ dysfunction and have a low mortality rate (<1%). Mild pancreatitis is self-limiting, and 85% of patients fully recover. Patients with severe acute pancreatitis may develop SIRS and end-organ dysfunction. Severe acute pancreatitis has a mortality rate of 15% to 30%. More frequent in males than females, acute pancreatitis occurs over all age spans, and the risk of pancreatitis is two to three times higher among African Americans than Caucasians. Chronic pancreatitis is defined as persistent inflammation that causes scarring and damage to the pancreas and surrounding tissue.

The most prevalent causes of acute pancreatitis are gallstones and alcohol. Alcohol consumption accounts for approximately one-third of all cases of pancreatitis and is more commonly found in men because of the increased frequency of heavy alcohol consumption in males. Gallstone pancreatitis is due to the presence of gallstones obstructing the bile duct or located near the area where the bile duct and pancreatic duct empty into the duodenum (Fig. 60.2), both causing alteration in the flow of bile and pancreatic enzymes and leading to inflammation of the pancreas. Gallstone pancreatitis is more common in women than men, and the incidence increases with every decade of life. Cannabis has recently been identified as a possible risk factor due to toxin release in a small number of reports. Other causes of pancreatitis are presented in Box 60.2.

**FIGURE 60.2** Diagram of pancreatic and bile duct openings. Gallstones obstruct the bile duct or the area near where the bile duct and pancreatic duct empty into the duodenum. They both cause alteration in the flow of bile and pancreatic enzymes, thus leading to inflammation of the pancreas.

### Box 60.2 Causes of Acute Pancreatitis

- Alcohol
- Gallstones
- Trauma
- Medication reactions
- Hypertriglyceridemia
- Hypercalcemia
- Bile duct abnormalities or obstruction (tumor)
- Surgery
- Infectious organisms
- Parasites
- Spider bites
- Scorpion stings
- Idiopathic (unidentified cause)
- Pancreas divisum (congenital anomaly where pancreatic duct is divided into two parts)

### Pathophysiology

Acute pancreatitis is the third-leading cause of gastrointestinal (GI) disorders that require hospitalization, and the cost of care in the United States for this disease and its complications is more than \$2 billion annually. Acute pancreatitis is a reversible process involving inflammation of the pancreas secondary to the release of pancreatic enzymes that “autodigest” the pancreas, peripancreatic tissues, and adjacent areas. **Autodigestion** occurs when the pancreatic enzymes digest the pancreas and surrounding tissue. Acute pancreatitis may occur as an isolated event, or it may be recurrent. The exact mechanism of the release of the pancreatic enzymes is not well known, and pancreatitis has a variety of causes ranging in severity from mild to severe and life threatening.

### Clinical Manifestations

Patients with acute pancreatitis present with sudden onset of epigastric pain that is felt in the upper left quadrant or mid-abdomen and can radiate to the back or shoulder blades. This pain is usually characterized as being deep and very sharp and becomes more intense within minutes of eating foods high in fat content. The pain can be constant and severe and last for several days, and some patients complain of severe pain when lying flat or bending forward. Pain can also be associated with nausea, vomiting, and anorexia. Patients with alcoholic pancreatitis may not have symptoms of pain for several hours or days after binge drinking. The general clinical presentation of patients with pancreatitis includes abdominal fullness from gas or bloating, hiccups, indigestion, fever, tachycardia, and hypotension.

### Management

#### Medical Management

#### Diagnosis

Physical examination reveals a tender abdomen with localized guarding and rebound tenderness. The presence of **Cullen’s sign** (periumbilical bruising) and **Grey Turner’s sign** (flank bruising) are infrequent findings and indicate retroperitoneal hemorrhage. Grey Turner’s and Cullen’s signs usually take 24 to 48 hours to develop and can be a predictor of acute pancreatitis with pancreatic necrosis and retroperitoneal or intra-abdominal bleeding.

Laboratory tests used in the diagnosis of pancreatitis include a metabolic panel, hematology studies, and specific tests of pancreatic enzymes such as serum amylase and serum lipase. **Amylase** is an enzyme that aids in the digestion of carbohydrates, and **lipase** is an enzyme that aids in the digestion of fats. Patients can exhibit elevated BUN, AST, ALT, and WBC (Table 60.1). Elevated BUN indicates

**Table 60.1 Common Laboratory Values Associated With Acute Pancreatitis**

Serum Laboratory Test	Level	Rationale
<b>Albumin</b>	Decreased	Due to poor nutrition
<b>Amylase</b>	Rapid increase	Pancreatic enzyme
<b>AST</b>	Elevated	Common in bile flow obstruction
<b>ALT</b>	Elevated	Common with gallstone pancreatitis
<b>Calcium</b>	Decreased	Due to fat necrosis, hypoalbuminemia, and malnutrition, all common in alcoholic pancreatitis
<b>Direct bilirubin</b>	Elevated	Mostly seen with biliary obstruction
<b>Lipase</b>	Elevated	Pancreatic enzyme
<b>WBC</b>	Elevated	Due to inflammation

ALT, Alanine transaminase; AST, aspartate transaminase; WBC, white blood cell count.

impaired kidney function suggestive of hypovolemia or a hypercatabolic state. Monitoring elevations in BUN early in the course of the disease may provide an indicator of mortality from pancreatitis. Elevated AST indicates damage to liver cells, and elevated ALT is indicative of gallstone pancreatitis. Elevated serum lipase is the most specific test for pancreatitis because lipase is produced only by the pancreas. Patients with gallstone pancreatitis may have elevated serum bilirubin, serum amylase, and serum liver enzymes—AST, ALT, ALP, and LDH—related to gallstones obstructing bile flow. Elevated WBC counts are an indicator of inflammation.

Diagnostic imaging tests for pancreatitis include abdominal CT scans, abdominal magnetic resonance imaging (MRI), and abdominal ultrasound. The purpose of these diagnostic tests is to evaluate for the presence of an inflamed pancreas, gallstones, and bile duct obstruction or distention.

### Connection Check 60.3

The most specific laboratory result in the patient with acute pancreatitis is an elevation in which laboratory value?

- Serum bilirubin
- Serum lipase
- Serum trypsin
- Serum lactase

There are several scoring systems to determine the severity of pancreatitis. Four such scoring mechanisms are the Ranson's criteria, the APACHE II score (Acute Physiology and Chronic Health Evaluation), the Balthazar CT severity index, and the Bedside Index Severity of Acute Pancreatitis (BISAP). Most commonly used is the **Ranson's criteria**, which are a means to measure the severity of illness and the likelihood of mortality in patients with pancreatitis (Table 60.2). The patient is evaluated upon admission and then again within the first 48 hours according to the scoring criteria. If at 48 hours the patient has a score of greater than or equal to 3, severe pancreatitis is likely, and with a score less than 3, severe pancreatitis is unlikely. The mortality rate associated with the score is found in Box 60.3. The higher the overall score, the higher the mortality rate.

The APACHE II score is an illness severity score calculated on the basis of the first 24 hours of ICU stay. The score is based on demographic factors (age, immunosuppression, chronic health status) and physiological factors (fever, mean arterial pressure, heart rate, oxygenation status, serum electrolytes [sodium, potassium, creatinine, hematocrit, and WBC count], and Glasgow Coma Scale score).

Computed tomography with contrast is the standard for the diagnosis of pancreatic necrosis or fluid collections around the pancreas and is used for scoring the severity of pancreatitis. The Balthazar index is calculated from the results of a CT scan and ranges from 0 to 10 on a point system given the extent of the inflammation of the pancreas and surrounding pancreatic tissue and the presence of pancreatic necrosis. The grading of the pancreas is given a letter grade of A through E, representing the range from normal pancreas to inflammatory changes to peripancreatic fluid collections. Necrosis of the pancreas is scored based on the percentage of the pancreas with necrosis with an overall higher percentage correlating with a higher severity of illness and poor outcome.

**Table 60.2 Ranson's Criteria**

At Admission	At 48 Hours
Age greater than 55 years	Hematocrit decrease greater than 10%
WBC greater than $16 \times 10^3/\text{mm}^3$	BUN increase greater than 5 mg/dL after fluid resuscitation
LDH greater than 350 IU/L	Calcium less than 8 mg/dL
AST greater than 250 IU/L	PaO <sub>2</sub> less than 60 mm Hg
Glucose greater than 200 mg/dL	Base deficit greater than 4 mg/dL
	Fluid sequestration greater than 6 L

AST, Aspartate transaminase; BUN, blood urea nitrogen; LDH, lactate dehydrogenase; WBC, white blood cell count.

## Box 60.3 Mortality Associated With Ranson's Score

- Score 0–2: 2% mortality
- Score 3–4: 15% mortality
- Score 5–6: 40% mortality
- Score 7–8: 100% mortality

The BISAP score is calculated based on several patient factors, including age, mental status, BUN, presence of pleural effusions, and SIRS criteria (points for fever range, respiratory status, WBC). A score of 0 to 2 indicates a mortality rate of less than 2%, and 3 to 5 points is associated with a mortality rate of greater than 15%.

### Treatment

Specific interventions for the treatment of acute pancreatitis traditionally include NPO status to prevent the release of pancreatic enzymes responsible for autodigestion of the pancreas; however, evidence of early initiation of enteral feeding helps protect the gastrointestinal mucosal barrier. Patients are given IV hydration and pain medications. IV fluid administration includes several liters of fluid initially followed by a high rate of maintenance fluid at approximately 200 to 300 mL/hr continuously to maintain intravascular volume. Crystalloids, either normal saline or lactated Ringer's, are the most common fluids used, and some evidence suggests that a combination of crystalloids and colloids should be used. If the patient receives several liters of IV fluid, it is imperative to monitor the patient for clinical manifestations of overhydration that can lead to pulmonary edema. If the patient has severe acute pancreatitis with end-organ involvement (heart, lungs, kidneys), the patient needs to be managed in the ICU because of the potential for hypovolemic shock, pulmonary compromise, renal failure, and GI bleeding. Aggressive supportive therapy is crucial to the recovery of these patients because they may require medications to decrease inflammation and surgical procedures to resect areas of necrotic pancreas. In general, IV antibiotics are not given to patients with acute pancreatitis related to fever because the fevers are secondary to inflammation of the pancreas, not infection. If the patient has necrotic pancreatitis, IV antibiotics are indicated (explained later in this chapter). If pancreatitis is caused by gallstones, the patient generally undergoes a cholecystectomy.

The specific cause of pancreatitis (biliary obstruction, alcohol) also determines the medical management. Gallstone-induced pancreatitis leads to the removal of the gallbladder (cholecystectomy) for acute treatment and to prevent recurrence of pancreatitis. Laparoscopic cholecystectomy is performed if the patient is stable and inflammation has resolved. Endoscopic **sphincterotomy** to dislodge gallstones may alternatively be performed. In this procedure, an endoscope is placed into the ducts in the opposite direction of bile flow, and the sphincter or muscles of the

bile and pancreatic ducts are cut to remove gallstones or blockages. This is usually done after an ERCP. If pancreatitis is alcohol induced, it is important to monitor and treat the patient for alcohol withdrawal, which includes agitation, hallucinations, tachycardia, fever, diaphoresis, and possible nausea and vomiting. Treatment may include sedation, hydration, and nutrition.

### Medications

Medications used in the treatment of acute pancreatitis include opioid analgesics for pain, anticholinergics to decrease secretions, histamine blockers, pancreatic enzymes, and antibiotic therapy. Table 60.3 includes a list of common medications for patients with acute pancreatitis.

Prophylactic antibiotics for acute pancreatitis have been controversial for the last five decades. Several randomized controlled trials and retrospective studies have examined the practice of prophylactic antibiotics. Some studies have suggested that there is a lower incidence of peripancreatic infection with the use of antibiotics; however, the routine use of antibiotics as prophylaxis against infection in severe acute pancreatitis is not recommended. Because the mortality associated with acute pancreatitis is primarily due to infectious complications, the use of antibiotics for this disease has been common, but the evidence does not support routine antibiotic use because no difference in outcome was found between patients treated with antibiotics versus those who received a placebo. If antibiotics are utilized, it is important that the antibiotics chosen penetrate the pancreatic tissue to treat the infection.

### Diet

Historically, patients with severe acute pancreatitis were managed with IV fluids and parenteral nutrition, avoiding the use of enteral nutrition in an effort to “rest” the inflamed

**Table 60.3 Approved Agents for Acute Pancreatitis**

Type of Agent	Rationale
<b>Opioid narcotics:</b> <i>morphine sulfate</i>	Treats pain
<b>Anticholinergic agents</b>	Decreases intestinal motility and decrease pancreatic enzyme release
<b>Spasmolytics</b>	Relaxes smooth muscle and relax sphincter of Oddi
<b>H<sub>2</sub> (Histamine) antagonist or proton pump inhibitor</b>	Decreases gastric acid secretions
<b>Pancreatic enzymes</b>	Aids in digestion of fats and proteins; taken with meals
<b>Antibiotics</b>	Treats acute necrotizing pancreatitis
<b>Octreotide</b>	Decreases secretion of enzymes

pancreas and prevent the release of pancreatic enzymes. New guidelines advocate for the initiation of early enteral feeding; however, the optimal timing and formulations require more study. Patients with mild forms of acute pancreatitis usually begin oral intake within a few days of their first onset of pain and do not require parenteral nutrition (see Evidence-Based Practice: Enteral Nutrition in Acute Pancreatitis).

## Evidence-Based Practice

### Enteral Nutrition in Acute Pancreatitis

Patients with acute pancreatitis often require supplemental nutrition during the acute phases of this disease. According to a meta-analysis that suggested that enteral nutrition was related to improved outcomes when compared with parenteral nutrition, a Cochrane Database review was conducted to compare different formulations of enteral nutrition, as well as the effectiveness of probiotics in the management of acute pancreatitis. The review yielded 15 trials that represented 1,376 participants. Although there were no conclusive findings related to different formulations of enteral nutrition or the use of probiotics in relation to outcomes, patients with acute pancreatitis who were treated with enteral nutrition as opposed to no nutritional support did demonstrate improved survival. Further studies are needed to examine differences in outcomes of different enteral nutrition formulations and the efficacy of probiotics.

Poropat, G., Giljaca, V., Hauser, G., & Atimac, D. (2015). Enteral nutrition formulations for acute pancreatitis. *Cochrane Database of Systematic Reviews*, 3, CD010605. doi:10.1002/14651858.CD010605.pub2

## Complications

Necrotizing pancreatitis occurs in approximately 20% of all patients with acute pancreatitis and is associated with a high rate of complications and a high mortality rate of up to 50%. Necrotic pancreatitis may present 1 or more weeks after the initial onset of acute pancreatitis and is diagnosed by CT scan, which shows the presences of air and gas surrounding the pancreas. Necrotizing pancreatitis is caused by activation of pancreatic enzymes that basically “eat through” the tissue of the pancreas (like acid disintegrates nylon) and enter the peritoneal cavity and surrounding tissue, causing extensive peripancreatic tissue breakdown, inflammation, and hemorrhage from the rupture of surrounding blood vessels. Patients with necrotizing pancreatitis can develop sepsis, shock, and multiple-organ failure.

There are two types of pancreatic necrosis, sterile and infected. Sterile pancreatic necrosis describes areas of necrosis that are free of bacteria, and infected pancreatic necrosis relates to necrosis that is caused by bacteria. The

type of necrosis is determined through a needle biopsy and culture. Patients with necrotizing pancreatitis are treated medically on the basis of clinical presentation. Interventions may include drainage or surgical intervention that involves debridement of the necrotic tissue and infected debris via the step-up approach. If the culture is positive, the patient is treated with antibiotics. Common organisms include *Pseudomonas*, *Escherichia coli*, *Klebsiella*, *Enterococcus*, *Proteus*, *Staphylococcus aureus*, and *Candida* species.

Patients with necrotizing pancreatitis usually undergo a surgical procedure that can include pancreatic resection, open abdominal resection with open packing and serial debridements every 2 to 3 days, or **necrosectomy** (resection of necrotic tissue) with lavage or drainage. The currently recommended intervention for this is the step-up approach, which is a minimally invasive approach to the surgical management of this disease that involves percutaneous catheter drainage. This approach eliminates the need for necrosectomy in 35% to 50% of patients when compared with the traditional approach. More recently, an endoscopic step-up approach has been developed and demonstrates promising results (see Evidence-Based Practice: Endoscopic or Surgical Step-Up Approach to Necrotizing Pancreatitis).

## Evidence-Based Practice

### Endoscopic or Surgical Step-Up Approach to Necrotizing Pancreatitis

The surgical step-up approach to management of necrotizing pancreatitis has replaced open surgery over the last decade. In this multicenter, randomized trial, 418 patients were recruited to participate and were assigned to either the surgical or endoscopic step-up approach. The endoscopic approach involved ultrasound-guided transluminal drainage, followed by necrosectomy, as indicated. Although the endoscopic step-up approach did not demonstrate significant differences in reducing major complications or death, the rate of fistulas and length of hospital stay were lower in the endoscopy group. The findings from this study may result in a shift to the endoscopic approach as the preferred treatment.

Van Brunschot, S., Van Grinsen, J., Van Santvoort, H. C., Bakker, O. J., Besselink, M. G., Boermeester, M. A., . . . Fockens, P. (2018). Endoscopic or surgical step-up approach for infected necrotising pancreatitis. *Lancet*, 391, 51–58.

Pancreatic hemorrhage is a rare complication that occurs in 1% to 3% of patients with acute pancreatitis as a result of pancreatic enzymes causing microrupture of the vascular system surrounding the pancreatic bed. Patients experience increased pain, decreased blood pressure, and elevated heart

rate. Abdominal examinations may reveal Grey Turner's sign or Cullen's sign. If an active bleed is diagnosed, patients undergo embolization to stop the hemorrhage.

Pancreatic **pseudocysts** are encapsulated areas of fluid that contain pancreatic enzymes and pancreatic tissue. Pseudocysts usually form within 4 to 6 weeks after an episode of acute pancreatitis and can vary in size and number and usually resolve spontaneously over a period of several weeks. Some patients may require percutaneous drainage. If a pseudocyst becomes infected, it is known as a pancreatic abscess, and the patient requires either percutaneous drainage or necrosectomy (excision of necrotic tissue) to drain or debride the infected fluid collection and surrounding tissue. Patients with infected pseudocysts primarily present with chills, fever, nausea, vomiting, and abdominal pain. It is important to carefully monitor for complications such as rupture and impending shock.

The incidence of pleural effusion in patients with acute pancreatitis is about 20%. A **pleural effusion** is the abnormal accumulation of fluid between the layers of the pleura in the lung and can occur in pancreatitis because of impaired capillary permeability or inflammation. Pleural effusions are typically located in the left lung because of the proximity of the pancreas to the left hemidiaphragm but occasionally can be bilateral. Some patients with pleural effusion may complain of shortness of breath, hiccups, or pleuritic chest pain related to the presence of the pleural effusion. The effusions are filled with exudates (high protein and blood) and have high amylase levels (> 30 times normal) if tested.

## Nursing Management

### Assessment and Analysis

The classic presentation of acute pancreatitis is the sudden onset of acute unbearable abdominal pain. Other common clinical manifestations include:

- Elevated heart rate and respiratory rate, and low blood pressure
- Pain
- Elevated serum lipase, amylase, and glucose values
- Hypocalcemia
- Steatorrhea, clay-colored stools
- Hypovolemia
- Hypoxia
- Pleural effusion
- Clinical manifestations of Adult Respiratory Distress Syndrome (ARDS)
- Multiple organ dysfunction

Abnormal vital signs include tachycardia and hypotension due to intravascular volume depletion. Patients have elevated third-space volume loss due to capillary leak or loss of fluid into the interstitial space and out of the intravascular spaces. This volume loss requires IV fluid resuscitation. If this volume loss is not replenished, patients can develop shock and multiple organ dysfunction. Laboratory analysis shows elevated liver enzymes and bilirubin, along with

elevated white blood count. Calcium levels are low because of the accumulation of fatty acids, which chelate calcium salts, causing soapy deposits in the abdomen. Stools are clay colored due to the blockage of bile into the duodenum.

Hypoxia occurs in patients with pancreatitis because of intrapulmonary shunting caused by the collapse of small alveoli in the dependent airways, whereby blood in the pulmonary system is not ventilated, and no gas exchange occurs. It is typical to see a patient with pancreatitis have a room air PaO<sub>2</sub> less than 75 mm Hg (normal PaO<sub>2</sub> is 80–95 mm Hg). Respiratory insufficiency can lead to acute respiratory distress syndrome (ARDS), a complication that leads to a mortality rate of more than 50%. ARDS is an acute lung injury caused by inflammation of the lungs, causing stiffness and the inability to exchange oxygen.

## Nursing Diagnoses

- **Acute pain** related to inflammation, edema, and distention of the pancreas and surrounding tissue
- **Ineffective breathing pattern** related to pain, pulmonary infiltrates, pleural effusion, and atelectasis
- **Imbalanced nutrition, less than body requirements**, related to decreased food intake and increased metabolic demands

## Nursing Interventions

### ■ Assessments

- **Vital signs**  
*Fever and tachycardia may represent inflammation. An elevated respiratory rate may occur because of anxiety and pain, the rate may be shallow and rapid as a result of pain, and blood pressure may be low because of dehydration and fluid shifts secondary to the inflammatory response.*
- **Oxygen status**  
*The patient's PaO<sub>2</sub> may be decreased because of alveoli collapse and pleural effusion.*
- **Pain location, intensity, duration**  
*Pain located in the RUQ (head of pancreas) or LUQ (tail of pancreas) is related to autodigestion of the pancreas due to leaking of pancreatic enzymes into tissue surrounding the pancreas, leading to edema, distention of the pancreas, and peritoneal irritation. Localized pain may indicate pseudocyst or abscess formation.*
- **Abdominal assessment**  
*Palpation may reveal rebound tenderness, muscle guarding, or rigid abdominal muscles.*
- **Grey Turner's and/or Cullen's signs**  
*Grey Turner's sign is bruising noted on the flank due to leaking of exudate stained with blood into the flank area; Cullen's sign is bruising around the umbilicus. Bruising in these areas indicates hemorrhage, severe inflammation, and tissue damage.*
- **Serum lipase and amylase**  
*Elevated lipase and amylase are due to inflammation of the pancreas, which interrupts its normal structure and function. Serum lipase levels are a useful diagnostic*

biomarker in pancreatitis because levels can remain elevated for up to 2 weeks. Elevated amylase levels that are three times normal are indicative of acute pancreatitis. These levels are elevated within 12 hours of the onset of inflammation, and elevation can last approximately 4 days.

- **Serum glucose**

Glucose elevations due to the digestion of the pancreas, which leads to decreased production and availability of insulin

- **Serum calcium, Trousseau sign, or Chvostek sign**

- **Hypocalcemia:** assess for neuromuscular irritability when calcium levels are low because of the accumulation of fatty acids, which chelate calcium salts, causing soapy deposits in the abdomen.

- **Trousseau sign:** hand spasms with inflation of the blood pressure cuff 20 mm Hg above the patient's systolic blood pressure (SBP) for 3 to 5 minutes. Under these ischemic conditions, the nerves become irritable, and spasms result.

- **Chvostek sign:** facial twitching. Tapping the skin over the facial nerve anterior to the external auditory meatus produces Chvostek sign. In a patient with acute hypocalcemia, ipsilateral contraction of the facial muscles occurs.

- **Stool color**

Steatorrhea, clay-colored stools due to obstruction of bile flow

- **Nutritional intake**

Patients exhibit loss of appetite because of pain; in alcoholic pancreatitis, patients may be malnourished at baseline.

- **Daily weight, monitoring of fluid intake and output**

Daily weights and intake and output monitor fluid volume status and prevent dehydration. Hypovolemia (intravascular) occurs because of third-space losses in the retroperitoneum from autodigestion of the pancreas and capillary leak; these fluid shifts can impact weight, and with significant ascites formation, the weight increases as the fluid retention increases.

- **Actions**

- **Maintain NPO status.**

Maintaining NPO status decreases the secretion of digestive enzymes and prevents the contraction of the gallbladder and the release of cholecystikinin.

- **NGT to low suction, as ordered**

Decompresses stomach, prevents abdominal distention

- **Administer ordered medications.**

- **Administer analgesics.**

Analgesics decrease the patient's symptoms of pain.

- **Administer antiemetics.**

Antiemetics decrease symptoms of nausea and vomiting, which may occur over a prolonged time.

- **Administer histamine blockers.**

Histamine blockers to decrease acid secretion and inhibit pancreatic enzyme activity

- Administer sedatives and anti-anxiety medications. Sedatives and antispasmodics help decrease spasms and subsequent enzyme secretions.

- **Promote bedrest in semi-Fowler's position or fetal position.**

Bedrest decreases the stimulation of pancreatic secretions and resulting pain. The semi-Fowler's position relieves abdominal pressure and tension, and the fetal position is generally most comfortable.

- **Encourage coughing and deep breathing.**

These help to prevent atelectasis and improve oxygenation. Patients commonly have pleural effusions.

- **Teaching**

- **Appropriate diet and intake of small, frequent meals and vitamin supplements**

A diet history can help identify foods that can contribute to symptoms. Oral intake should be limited initially to small amounts (fist-sized) and then slowly advanced as the pain subsides. Decreased pain is an indicator of decreased inflammation. Initial foods to eat after an illness with pancreatitis include carbohydrate-containing foods because they stimulate the pancreas less. Avoid fat- and protein-rich foods, which increase pancreatic enzyme stimulation.

- **Abstain from alcohol.**

Alcohol consumption accounts for approximately one-third of all cases of pancreatitis.

- **Abstain from smoking.**

Smoking is associated with pancreatic cancer and with interfering with the healing needed by the pancreas; smoking can adversely impact the healing process.

- **Disease symptoms, progression, diagnostic procedures, and interventions**

Patient education about the disease improves overall management and health and provides details that the patient needs to report to the healthcare provider.

## Evaluating Care Outcomes

Acute pancreatitis is a serious, often life-threatening disorder that requires vigilant nursing management. Because of the potential for sepsis and hypovolemia, monitoring of fluid and electrolytes, as well as complete blood count, is a priority for evaluating the effectiveness of the treatment plan. Pain management and nutritional status are also indicators of how the disease process is progressing. Positive outcomes of acute pancreatitis include stable vital signs, stable weight, serum electrolytes within normal limits, decreased pain, and decreases in liver enzymes.

Patients diagnosed with acute pancreatitis may be hospitalized for weeks and require transitional care (home care, skilled nursing facility, etc.) that focuses on reestablishing their weight and muscle mass, as well as understanding the disease process and lifestyle changes that may be required (abstaining from alcohol and smoking, dietary restrictions, etc.).

**CASE STUDY: EPISODE 2**

Tony Edwards has been in the hospital for 1 day and was transferred to the medical ICU this morning for worsening symptoms. On physical examination, he is restless and slightly combative. His blood pressure is 91/43 mm Hg, and his heart rate is 100 bpm. He is short of breath, with a respiratory rate of 24. His oxygen saturation is 85% on room air. His temperature is 38.5°C (101.3°F). His abdomen is distended, and he has severe pain. He screams that the staff members are trying to kill him by keeping him in the hospital, and all he wants to do is go back to his friend's house and continue to party. He states that he drinks a "ton of beer" whenever he feels like it and occasionally uses marijuana. His arms and legs are covered with tattoos and some scarring from his former IV drug use. His pupils are reactive and equal, and his sclera are slightly yellow, as is his skin. He states that his urine "looks like really dark iced tea." Tony is diagnosed with acute pancreatitis secondary to his alcoholic binge over the weekend...

**CHRONIC PANCREATITIS****Epidemiology**

The most common cause of chronic pancreatitis is heavy, prolonged alcohol use. Other causes are listed in Box 60.4. Chronic pancreatitis is commonly diagnosed between ages 30 and 40 and is more common in men than women. According to the National Institutes of Health, chronic pancreatitis is the seventh most commonly diagnosed digestive disease in the United States, with an annual cost of more than \$3 billion. Alcohol-related pancreatitis is more common in men, whereas gallstones and autoimmune disorders are more common in women. The prevalence of chronic pancreatitis increases with age, with most patients diagnosed at around age 62. African Americans have a two- to three-times-higher risk of chronic pancreatitis when compared with Caucasians. One of the primary differences between acute and chronic pancreatitis is that the chronic form is not reversible, and over time, both the exocrine and endocrine functions of the pancreas are altered.

**Pathophysiology**

Chronic pancreatitis is inflammation of the pancreas that occurs when digestive enzymes autodigest the pancreas and surrounding tissues for a prolonged period of time. Because of inflammation and scarring, the pancreas is unable to make the digestive enzymes necessary for the digestion of proteins and fats or the hormones necessary to regulate glucose (insulin and glucagon). Fibrosis of the pancreas secondary to the chronic inflammation is associated with chronic pancreatitis and further contributes to the loss of normal pancreatic function.

**Box 60.4 Causes of Chronic Pancreatitis**

- Heavy alcohol use
- Hereditary disorders of the pancreas
- Cystic fibrosis
- Hypertriglyceridemia
- Hyperlipidemia
- Hypercalcemia

**Clinical Manifestations**

Patients with chronic pancreatitis have upper abdominal pain, which can spread to the back and feels worse after eating or drinking. Pain is often constant and prevents the patient from normal daily activities and is often described as recurring epigastric and LUQ pain. The pain is exacerbated by alcohol consumption and overeating. Other clinical manifestations include nausea, vomiting, weight loss, diarrhea, pale or clay-colored stools, and steatorrhea or oily stools. Patients may complain of losing weight despite normal eating patterns. Weight loss occurs because the pancreas is no longer secreting pancreatic enzymes to digest food, leading to decreased absorption of nutrients and malnourishment.

**Management****Medical Management****Diagnosis**

The diagnostic work-up of chronic pancreatitis includes abdominal CT, ultrasound, or ERCP to visualize the pancreas, as well as to verify structural or obstructive changes. Other diagnostic tests include laboratory analysis of amylase and lipase levels, which are usually elevated, as well as elevations of serum alkaline phosphatase and bilirubin that are associated with chronic pancreatitis secondary to obstructive processes. As the disease progresses and impairs endocrine functions of the pancreas, serum glucose levels are monitored because increased levels are associated with chronic pancreatitis due to the lack of insulin.

**Treatment**

Treatment of patients with chronic pancreatitis includes pain management, IV fluid replacement, electrolyte management, nutritional support, and insulin therapy to treat elevated blood glucose levels. Pancreatic enzyme replacement therapy (PERT) is used to treat the malnutrition and malabsorption associated with chronic pancreatitis and provides amylase, lipase, and protease. In many cases, patients with chronic pancreatitis are cared for in the ICU, and GI prophylaxis with histamine blockers or proton pump inhibitors may be prescribed secondary to increased gastric acid secretion. In patients with significant weight loss secondary to this disorder, total parenteral nutrition may be required.

Heavy tobacco use and alcohol consumption are associated with chronic pancreatitis; therefore, patient education includes modification of these risk factors.

### Surgical Management

In some patients, surgical resection may provide symptomatic relief of pain; however, surgical intervention is not always appropriate for patients with chronic pancreatitis, and the risks are high (see Evidence-Based Practice: Comparison of Endoscopy and Surgical Approach in the Treatment of Obstructive Chronic Pancreatitis). Surgical procedures for pain relief include the Puestow procedure, which opens the pancreatic ducts and redirects the flow of pancreatic enzymes into the intestine, or resection of the head of the pancreas. Laparoscopic draining may be indicated in patients with abscesses or pseudocysts. Because of the irreversible nature of chronic pancreatitis, these surgical procedures address issues related to pain, inflammation, and obstruction and are not curative.

## Evidence-Based Practice

### Comparison of Endoscopy and Surgical Approach in the Treatment of Obstructive Chronic Pancreatitis

Patients with chronic pancreatitis often require treatment for the pain caused by obstructions in the pancreas secondary to structural changes and damage to the pancreas. Both endoscopy and surgical interventions have been used to treat the pain. To assess for differences in treatment modalities, a Cochrane Database review was completed. Three trials were identified, two of which compared endoscopy with surgical intervention and included 111 participants and another trial with 32 participants that compared surgical intervention with conservative therapy. Patients who underwent surgical intervention had better pain relief, improved quality of life, and preservation of exocrine function when compared with endoscopy. Additionally, surgical patients demonstrated better pain relief and pancreatic function when compared with patients receiving conservative therapy. Because of the low numbers of participants, additional trials need to be conducted to further compare surgical interventions with both endoscopy and conservative therapy in patients with painful obstructive chronic pancreatitis.

Ahmed, A. U., Pahlplatz, J. M., Nealon, W. H., van Goor, H., Gooszen, H. G., & Boermeester, M. A. (2015). Endoscopic or surgical intervention for painful obstructive chronic pancreatitis. *Cochrane Database of Systematic Reviews*, 3, CD007884. doi:10.1002/14651858.CD007884.pub3

## Nursing Management

### Assessment and Analysis

Chronic pancreatitis is characterized by pain and weight loss and is an irreversible disease process. In addition to constant, burning pain that is characterized by exacerbations of intense, unrelenting pain, other clinical manifestations include:

- Anorexia
- Nausea and vomiting
- Constipation
- Flatulence
- Steatorrhea (fatty stools)
- Elevated amylase, lipase, serum bilirubin, and alkaline phosphatase
- Elevated blood glucose levels

### Nursing Diagnoses

- **Acute pain** related to inflammation and obstruction of the pancreas
- **Imbalanced nutrition, less than body requirements**, due to malabsorption and altered secretion of pancreatic enzymes
- **Hopelessness** related to the chronic, progressive, irreversible nature of chronic pancreatitis

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Pulse rate, respiratory rate, and blood pressure elevations are associated with episodes of pain exacerbations.*
- Serum blood glucose levels  
*With decreased insulin production/release with endocrine dysfunction, serum glucose levels are elevated.*
- Amylase and lipase levels  
*Elevations of these pancreatic enzymes are associated with chronic pancreatitis.*
- Serum bilirubin and alkaline phosphatase  
*Obstruction of the bile ducts leads to increases of both bilirubin and alkaline phosphatase.*
- Weight  
*Because of malabsorption secondary to the altered secretion of pancreatic enzymes, the patient with chronic pancreatitis is at risk of weight loss.*
- Pain  
*Chronic pancreatitis is characterized by persistent, recurring episodes of epigastric and LUQ pain secondary to inflammation and obstruction.*
- Abdomen  
*Tenderness of the abdomen may be observed. Palpation may reveal a mass in the LUQ that may indicate a pseudocyst or abscess.*
- Skin color  
*Jaundice may be observed with obstruction of the bile ducts.*
- Stool  
*Steatorrhea may develop with progressive pancreatic insufficiency, as well as clay-colored stools with bile obstruction.*

### ■ Actions

- Administer pancreatic enzymes (PERT).  
*These medications contain amylase, lipase, and protease to enhance the absorption of nutrients.*
- Provide GI prophylaxis as ordered.  
*Histamine blockers or proton pump inhibitors may be prescribed to treat the increased gastric acid secretion associated with chronic pancreatitis.*
- Provide rest and a calm environment.  
*These interventions decrease strain on the already-diseased pancreas and may decrease the secretion of acids in the stomach, which can exacerbate chronic pancreatitis.*
- Implement pain-relief measures.  
*Pain may be managed with the administration of opioids initially and then with nonopioids when the pain is less intense.*
- Collaborate with a dietitian to ensure adequate nutrition.  
*The patient may require increased caloric intake or parenteral nutrition as a result of alterations in absorption. A low-fat diet is often prescribed because of difficulty breaking down fats, resulting in steatorrhea.*

### ■ Teaching

- Avoid alcohol.  
*Alcohol further exacerbates the dysfunction of the pancreas.*
- Do not chew pancreatic enzymes.  
*These medications are available as extended-release or enteric-coated formulations, so they need to be swallowed whole to receive a therapeutic dose.*
- Limit fat in the diet.  
*Malabsorption of fat is associated with chronic pancreatitis, and fat is limited in the diet, particularly in patients with steatorrhea.*
- Avoid intake of irritating foods/beverages (coffee, caffeine).  
*This may increase gastric distress.*
- Referral to support groups such as Alcoholics Anonymous or Al-Anon  
*Chronic pancreatitis is a progressive, irreversible disease, and avoiding the use of alcohol minimizes further damage to the pancreas. Additionally, participation in support groups may be therapeutic and may provide suggestions and recommendations for dealing with this chronic disorder.*

### Evaluating Care Outcomes

Chronic pancreatitis is a progressive, irreversible disease that results in pain, malabsorption, and weight loss. Effectiveness of disease management is related to pain management and minimizing weight loss secondary to the administration of opioid and nonopioid medications. Additionally, a decrease in steatorrhea is associated with the actions of pancreatic enzyme replacement. Patient and family involvement are important in minimizing the exacerbations of chronic pancreatitis by avoiding alcohol intake and seeking out support groups to deal with this incurable disease.

## PANCREATIC CANCER

### Epidemiology

Pancreatic cancer is the fourth most common cause of cancer-related deaths in the United States. In 2017, the American Cancer Society reported that over 50,000 people were diagnosed with pancreatic cancer. Approximately 23% of patients survive to 1 year after diagnosis, and only 5% survive to 5 years. Almost 80% of patients with cancer of the pancreas have unresectable tumors because the diagnosis occurs late in the disease process.

There is no reliable screening test for the early detection of pancreatic cancer, and clinical manifestations are usually vague and similar to those of other GI disorders. The 5-year survival rate for early surgical resection of a small pancreatic tumor that has no lymph node involvement can reach 40%, but this is uncommon because patients are usually diagnosed late in the disease process due to the vagueness of the clinical presentation. The majority of pancreatic cancers are adenocarcinomas and develop in the exocrine portion of the pancreas. An adenocarcinoma is a malignant tumor that grows on the epithelial cells of an organ. The most common pancreatic cancer is ductal adenocarcinoma (75%–93%), most frequently found in the head of the pancreas. Adenocarcinomas are fast growing and spread to other local organs, primarily the stomach, duodenum, gallbladder, liver, and intestines. Metastasis occurs through the invasion of the lymph and vascular systems and can spread to the lung, peritoneum, and spleen. Other types of pancreatic cancers include those that occur in the endocrine tissues of the pancreas, and these tumors produce hormones and are named according to the hormones they produce, such as insulinoma (insulin-producing tumor) and glucagonoma (glucagon-producing tumor).

The exact cause of pancreatic cancer is not known, but there is a high association with behaviors such as cigarette smoking (smokers are twice as likely as nonsmokers to develop pancreatic cancer); diets high in fat; and consumption of meat, fried foods, refined sugars, and nitrates, all of which are modifiable risk factors. There is also a higher risk of pancreatic cancer in patients with diabetes, chronic pancreatitis, or a family history of pancreatic cancer and people of Ashkenazi Jewish descent. Some evidence suggests that patients with diabetes mellitus that is diagnosed later in life (after age 50) are at increased risk for pancreatic cancer.

The risk for pancreatic cancer increases with age, and it is commonly diagnosed in people over the age of 60 years. People of African American descent are more likely to develop pancreatic cancer than people of European descent, and men are more likely to develop pancreatic cancer than women. Because cigarette smoking doubles the risk of pancreatic cancer and is associated with diagnosis at an early age, it is important to teach the patient to quit smoking because this is one of the leading preventable causes of pancreatic cancer. Some occupational exposure to toxins such as gasoline derivatives and other chemicals may predispose a patient to the risk of pancreatic cancer.

## Pathophysiology

Pancreatic tumors may be primary or metastatic, usually originating in the lung, breast, thyroid, kidneys, or skin. Because of the rapid growth of adenocarcinomas in the pancreas, both exocrine and endocrine functions deteriorate as the tumor invades the pancreatic tissue. Pancreatic tumor, because of the proximity of other GI organs, may metastasize to the stomach, duodenum, gallbladder, and intestine. Cancer that invades the tail and body of the pancreas may metastasize to the liver via the splenic vein, and the patient may present with an abdominal mass and hepatomegaly.

## Clinical Manifestations

The clinical presentation of the patient is directly related to the degree of pancreatic damage secondary to tumor growth and, as described earlier, may not manifest until significant damage has occurred. Pain, jaundice (associated with obstruction of the bile duct), fatigue, and weight loss are the most frequently observed clinical manifestations. The pain is typically described as dull pain in the epigastric area and back.

## Management

### Medical Management

#### Diagnosis

The clinical evaluation of pancreatic cancer includes an ultrasound, CT scan, MRI, and/or an ERCP to determine the presence of a mass. The definitive diagnosis for pancreatic cancer is through histopathology. Tissue samples are collected by a fine-needle biopsy or excisional biopsy through a laparotomy. Patients may also undergo angiography to determine the involvement of vessels surrounding the pancreas. Once diagnosed, the tumor is staged according to the size, extent, lymph node involvement, and metastases, and the course of treatment is determined.

#### Laboratory Values

There is no single blood test available for the early diagnosis of pancreatic cancer, but several routine laboratory results may be abnormal. Although these tests are not specifically diagnostic for pancreatic cancer, they include elevated amylase, elevated total and direct bilirubin, and elevated liver enzymes. Fecal fat, trypsinogen, **trypsin** (an enzyme that aids in digestion of proteins), and lipase may indicate how the pancreas is functioning and the need for pancreatic enzyme supplementation.

#### Treatment

Several clinical trials have been performed to test and develop a vaccine that is used to treat patients who have pancreatic cancer, but no vaccine is available to prevent pancreatic cancer. The current evidence for the use of adjuvant therapy recommends combined chemotherapy and radiation. External beam radiation to the tumor and surrounding tissue over a 6-week period concurrent with 5-fluorouracil chemotherapy for up to 4 months help to improve long-term survival.

## Surgical Management

The stage of the cancer and the location of the tumor determine whether surgical intervention is an option. Surgical resection is potentially curable; however, only a small percentage of patients qualify for surgical resection because of the latent nature of the clinical presentation. If the cancer has spread to distant lymph nodes or there is metastasis to the liver, the cancer is generally unresectable. Patients may undergo surgery to relieve symptoms (palliative surgery), but excision of the tumor is not possible. A celiac nerve block can be performed to decrease the pain associated with the tumor's compression of the celiac nerves surrounding the aorta. If a patient has a localized tumor, several surgical interventions are possible. If the tumor is located in the head, neck, or uncinate process of the pancreas, the patient can undergo the **Whipple procedure** or **pancreaticoduodenectomy** (Fig. 60.3).

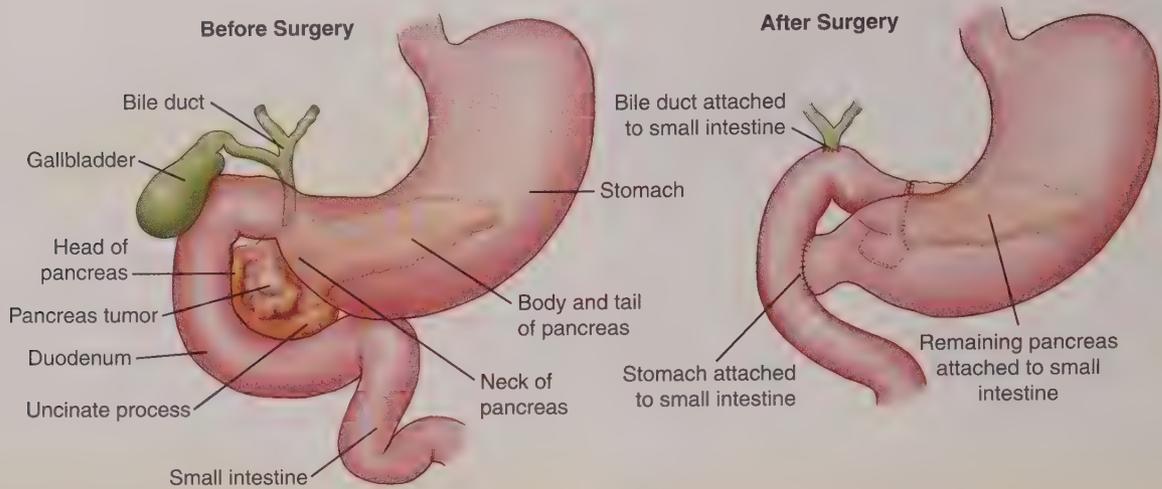

There are several modifications of this procedure, but in general, the head of the pancreas, distal stomach, spleen, gallbladder, common bile duct, portions of the duodenum, proximal jejunum, and lymph nodes are resected. If the tumor is in the body or tail of the pancreas (Fig. 60.4), the patient undergoes a distal pancreatectomy (removal of the tail and part of the body of the pancreas) and splenectomy. A **pancreaticojejunostomy** (anastomosis of the pancreas to the jejunum), **hepaticojejunostomy** (anastomosis of the hepatic duct to the jejunum), or **gastrojejunostomy** (anastomosis of the stomach to the jejunum) may also be done to reconstruct the GI tract. A **vagotomy** (surgical resection of the vagus nerve) is done to decrease acid secretion in the stomach and decrease peptic ulcer formation.

Postoperatively, patients who undergo these procedures should be monitored for exocrine insufficiency (lack of digestive enzymes to properly digest food) and insulin-dependent diabetes mellitus. In addition, patients will have an NGT that is not to be manipulated (see Safety Alert). Pain management via PCA, pulmonary interventions to encourage lung expansion, coughing and deep breathing to prevent pneumonia and atelectasis, and abdominal assessment are all postoperative standards of care.

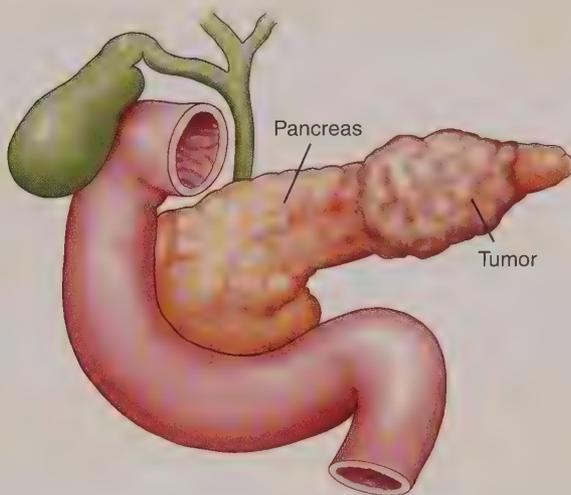

### **Safety Alert** After a Whipple procedure or pancreaticoduodenectomy, NGTs are maintained postoperatively to decompress the stomach, prevent bloating, and remove gastric acid secretions to minimize pressure on the surgical site. These NGTs are placed intraoperatively and are not to be manipulated in any way. A **DO NOT MANIPULATE NGT** sign is placed on the wall above the patient's head. These NGTs are not to be repositioned, irrigated, or checked for placement because these actions can cause a breakdown of the anastomotic site. If a patient removes the NGT, it is not to be replaced by the nursing staff. A member of the surgical team is to be notified.

After a Whipple procedure or pancreaticoduodenectomy, NGTs are maintained postoperatively to decompress the stomach, prevent bloating, and remove gastric acid secretions to minimize pressure on the surgical site. These NGTs are placed intraoperatively and are not to be manipulated in any way. A **DO NOT MANIPULATE NGT** sign is placed on the wall above the patient's head. These NGTs are not to be repositioned, irrigated, or checked for placement because these actions can cause a breakdown of the anastomotic site. **FIGURE 60.3** Pre- and post-Whipple procedure. In the post-Whipple procedure, note that the head of the pancreas, distal stomach, spleen, gallbladder, common bile duct, portions of the duodenum, proximal jejunum, and lymph nodes have been resected.

**FIGURE 60.4** Pancreatic tumor. Pancreatic tumors often develop in the body or tail of the pancreas.

### Connection Check 60.4

The nurse receives a patient from the operating room after he undergoes a Whipple procedure. The nurse recognizes that this procedure is indicated for the patient who has which disorder?

- Acute pancreatitis
- Peritonitis
- Cholecystitis
- Pancreatic cancer

### Nursing Management

#### Assessment and Analysis

Patients with pancreatic cancer present with nonspecific clinical manifestations that can be attributed to a variety of GI disturbances. Pain, jaundice, fatigue, anorexia, and

weight loss are primary clinical manifestations, with vague, nonspecific abdominal and epigastric pain common. Pain is described as dull and intermittent that sometimes increases in intensity with eating and movement. Jaundice, which occurs in 80% of patients, develops in a pattern that is first seen in the mucous membranes, then the palms of the hands and eventually becomes generalized. Patients may complain of pale, greasy stools, which is attributed to a tumor that blocks digestive enzyme release. Other clinical manifestations include pruritus starting with the palms of the hands and then generalized and dark-amber urine due to the accumulation of bilirubin.

### Nursing Diagnoses

- **Pain: acute or chronic** related to the pressure caused by the pancreatic mass
- **Imbalanced nutrition:** less than body requirements related to malabsorption and anorexia
- **Anxiety** related to the cancer diagnosis

### Nursing Interventions

#### Assessments

- **Vital signs**  
*Tachycardia may be related to fever and pain. Elevated blood pressure may be related to pain and anxiety. Fever may be related to infection due to blocked bile ducts.*
- **Fluid intake and output**  
*Daily intake and output monitor fluid volume status and prevent dehydration. With the development of ascites, there may be a fluid shift from the intravascular space.*
- **Serum glucose**  
*Elevated because of impaired insulin secretion due to tumor or due to removal of pancreas, which secretes insulin*
- **Weight**  
*Weight loss due to anorexia due to presence of tumor and malabsorption*

- **Muscle mass**

*Cachexia (weight loss) secondary to loss of muscle mass is common because of decreased appetite and altered protein metabolism.*

- **Pain location, intensity, duration**

*It is important to note the location, intensity, and duration of pain that is caused by the pancreatic tumor compressing surrounding organs and nerves. Pain may radiate to the back because of the compression of nerves.*

- **Abdomen**

*Distention and enlargement of the abdomen are common in advanced disease because of the presence of ascites.*

- **Skin color**

*Jaundice due to tumor obstruction of bile flow*

- **Pruritus**

*Accumulation of bile salts under the skin causes itching.*

- **Postoperative assessment**

*Postoperatively monitor vital signs, pain, glucose, NGT output, abdominal assessment, and surgical site.*

### ■ **Actions**

- **Provide intravenous fluids.**

*Hypovolemia occurs because of third-space losses in the retroperitoneum from autodigestion of the pancreas and capillary leak.*

- **Maintain NPO status.**

*Maintain NPO status until the return of GI function postoperatively, then slowly introduce a diet with clear liquids, and then advance to a regular diet to decrease strain on the surgical site.*

- **NGT to low suction**

*Decompresses stomach because postoperative abdominal distention and decreased GI tract motility can place strain on the surgical anastomosis*

- **NEVER manipulate NGTs.**

*NGTs are placed by the surgeon, and manipulation can increase the risk of anastomotic breakdown.*

- **Administer insulin.**

*Pancreatic cancer affects the ability of the pancreas to produce and secrete insulin, leading to hyperglycemia.*

- **Encourage coughing and deep breathing and the use of an incentive spirometer or flutter valve every hour while awake.**

*Prevents atelectasis, improves oxygenation, prevents postoperative pneumonia*

- **Administer analgesics and antiemetics as ordered.**

*Pain management postoperatively for incisional pain and discomfort; preoperative pain management for pain caused by tumor compression*

- **Nutritional supplements**

*These help to improve calorie input, prevent weight loss, and promote postoperative surgical wound healing. These include high-calorie, high-protein supplements.*

### ■ **Teaching**

- **Postoperative care: what to expect after surgery, pain management**

*Informs the patient and improves compliance with prescribed interventions*

- **Medication regimens**

*It is important for the patient to be knowledgeable of the mechanism of actions as well as the side effects of the ordered medications. Pain medications may increase the risk of constipation and increase pressure and discomfort in the abdominal cavity.*

- **Diet and nutrition**

*Nutritional supplements are prescribed to increase calorie intake to maintain weight and promote healing after surgery. Megestrol acetate (Megace) may be given as an appetite stimulant.*

- **Signs and symptoms of hyperglycemia and hypoglycemia**

*With compression and damage to the pancreas, the production and secretion of insulin and glucagon may be impaired, leading to hyperglycemia or hypoglycemia.*

- **Disease symptoms, progression, diagnostic procedures, and interventions**

*Patient education about the disease and disease progression improves symptom management and increases compliance with the prescribed interventions.*

- **Coping skills, palliative care, and support groups (Box 60.5)**

*Support groups and networks provide additional information for patient and family.*

### Evaluating Care Outcomes

The diagnosis of pancreatic cancer generally occurs in a late stage of the disease, and often the patient does not have a prolonged life expectancy. With patients who are surgical candidates, it is imperative they are aware of the postoperative requirements and restrictions. Because a diagnosis of pancreatic cancer carries a devastating prognosis, it is important for the healthcare providers to direct the patient to and encourage the use of support systems and self-help books. Encouraging the patient to be knowledgeable about the disease, treatment, interventions, and restrictions is important.

### Box 60.5 Complementary Alternative Medicine for Pancreatic Cancer

No alternative treatments are effective for the treatment of pancreatic cancer. There are alternative therapies a patient might want to consider to help with the management of the signs and symptoms of the disease. These include activities or therapies that help with coping, including exercise, relaxation techniques, art therapy, and meditation. It is important to teach the patient with a terminal illness to develop his or her immediate support system with friends and family members and encourage talking about the diagnosis and relying on surrounding support systems. Support groups may be encouraged, and self-education about the disease and end-of-life care or hospice should be addressed.

### Connection Check 60.5

The nurse assesses for which finding in a patient with a positive Cullen's sign?

- Periumbilical bruising
- Rebound tenderness
- RUQ pain with radiation to shoulder
- Flank bruising

### Connection Check 60.6

The nurse should question the administration of which medication in the patient admitted with cholecystitis?

- Acetaminophen
- Demerol
- Ibuprofen
- Morphine

## Making Connections

### CASE STUDY: WRAP-UP

Tony's condition continues to worsen. His abdominal pain is excruciating, he is delirious, and he develops hypovolemic shock with a blood pressure of 80/40 mm Hg and heart rate of 125 bpm. Because of the hypovolemic shock, fluid resuscitation is started in an attempt to increase his blood pressure.

Diagnostic tests reveal:

- Chest x-ray indicating left pleural effusions, atelectasis
- Electrocardiogram revealing sinus tachycardia
- Elevated serum lipase and amylase

Tony is intubated and placed on a mechanical ventilator and started on broad-spectrum antibiotics for the treatment of acute pancreatitis and hypovolemic shock. He is closely monitored for necrotizing pancreatitis and sepsis.

#### Case Study Questions

- Tony's pain continues to worsen. What is the rationale for the healthcare provider to more likely prescribe meperidine (Demerol) for pain instead of morphine?
  - Meperidine can be given intravenously or intramuscularly.
  - Morphine is not absorbed in the pancreas.
  - Morphine causes spasms in the sphincter of Oddi.
  - Meperidine is better tolerated in patients with substance abuse.

- What laboratory finding is the primary diagnostic indicator for pancreatitis?
  - Elevated blood urea nitrogen (BUN)
  - Elevated serum lipase
  - Elevated aspartate aminotransferase (AST)
  - Elevated lactate dehydrogenase (LDH)
- In reviewing the prescriptions for Tony's acute pancreatitis, what order would the nurse anticipate?
  - Maintenance of NPO status
  - Oral fluid restriction
  - Low-fat diet
  - Regular diet
- During the physical examination of Tony, what clinical manifestation correlates with his diagnosis?
  - Constipation
  - Steatorrhea
  - Clear lung sounds throughout all lung fields
  - Diarrhea
- Tony is ready for discharge. What should be included in his discharge teaching about pancreatitis?
  - Education about alcohol restriction
  - Education about smoking cessation
  - Education about a low-carbohydrate diet
  - Education about vaccines

## CHAPTER SUMMARY

Disorders of the gallbladder and pancreas are common and lead to admissions to acute care facilities. Cholecystitis, inflammation of the gallbladder, is most typically caused by obstruction of the bile duct by gallstones. The clinical presentation of cholecystitis includes acute right upper quadrant pain, often accompanied by clay-colored stool and darkened urine secondary to elevated serum bilirubin. Cholecystectomy is often required, as well as diet modifications.

Pancreatitis may be acute or chronic and may lead to serious complications. Acute pancreatitis may result in actual autodigestion of the pancreas and is associated with complications such as necrotizing pancreatitis and sepsis. Patients with acute pancreatitis present with a sudden onset of epigastric pain in the upper left quadrant or mid-abdomen, often accompanied by radiation to the back or shoulder blades. Pain is worsened within minutes of eating foods high in fat content and can be constant and severe

and last for several days. Some patients complain of severe pain when lying flat or bending forward. Pain can also be associated with nausea and vomiting and anorexia. Medical management includes bowel rest, fluid administration, and monitoring for complications. Chronic pancreatitis is a progressive, irreversible disease that results in pain, malabsorption, and weight loss. Effectiveness of disease management is related to pain management and minimizing weight loss secondary to the administration of opioid and nonopioid medications. Avoiding alcohol intake and seeking out

support groups to deal with this incurable disease are key aspects of the care of patients with this disorder.

Pancreatic cancer is often considered a terminal disease secondary to late diagnosis. The clinical presentation typically includes nonspecific symptoms such as pain, jaundice, and anorexia. Abdominal and epigastric pain is common, vague, and sometimes nonspecific. Surgical interventions are indicated in the absence of metastatic disease. If there is evidence of metastatic disease, medical management is primarily symptomatic and palliative.

## Promoting Health in Patients With Renal Disorders

### Chapter 61

## Assessment of Renal and Urinary Function

*Sarah Tarr*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the renal and urinary systems
2. Discussing the function of the renal and urinary systems
3. Describing the procedure for completing a history and physical assessment of the renal and urinary systems
4. Correlating relevant diagnostic examinations with renal and urinary system function
5. Explaining nursing considerations for diagnostic studies relevant to renal and urinary system function
6. Discussing changes in renal and urinary system function associated with aging

#### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Infection
- Medication
- pH Regulation
- Urinary Elimination

#### ESSENTIAL TERMS

Afferent arterioles  
Antidiuretic hormone (ADH)  
Anuria  
Bladder  
Bowman's capsule  
Bruit  
Collecting tubule  
Continenence  
Creatinine  
Distal convoluted tubule (DCT)  
Dysuria  
Efferent arterioles  
Glomerular filtrate  
Glomerular filtration rate (GFR)  
Glomerulus  
Kidney  
Loop of Henle  
Major calyces  
Micturition  
Minor calyx  
Nephron  
Nocturia  
Oliguria  
Papillae  
Polyuria  
Proximal convoluted tubule (PCT)  
Pyramids  
Renal pelvis  
Renin  
Ureter  
Urethra

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Reginald Jones is a 72-year-old African American male patient who presents to his healthcare provider with complaints of recent weight gain, swelling in his hands and feet, voiding only small amounts of urine, and fatigue. His wife accompanies him and reports that he is “just not himself” and “sometimes seems dazed.” Mr. Jones has a history of depression and borderline hypertension, which at this time are not being treated with any medications. His last visit to a healthcare provider was more than 2 years ago. Mr. Jones and his wife are concerned about these recent changes and his overall health...

## OVERVIEW OF ANATOMY AND PHYSIOLOGY

The renal system is composed of the two kidneys. The urinary system is composed of two ureters, the urinary bladder, and the urethra. The two systems work together to help maintain homeostasis in the human body. For example, urine is formed as blood is filtered through the kidneys. The bladder then provides storage, and the ureters and urethra act as passages for urine to exit the body; thus, the function of excreting wastes from the body is complete.

The kidneys perform the following functions essential to the maintenance of homeostasis in the human body: (1) excretion of wastes, (2) regulation of fluid and electrolyte

balance, (3) regulation of acid-base balance, (4) regulation of blood pressure, (5) secretion of erythropoietin for red blood cell (RBC) production, and (6) activation of vitamin D. The urinary system provides for the storage and passage of urine, promoting **continence** and facilitating voiding. This chapter will first examine the anatomy and physiology of the kidneys and then examine the anatomy and physiology of the urinary system structures.

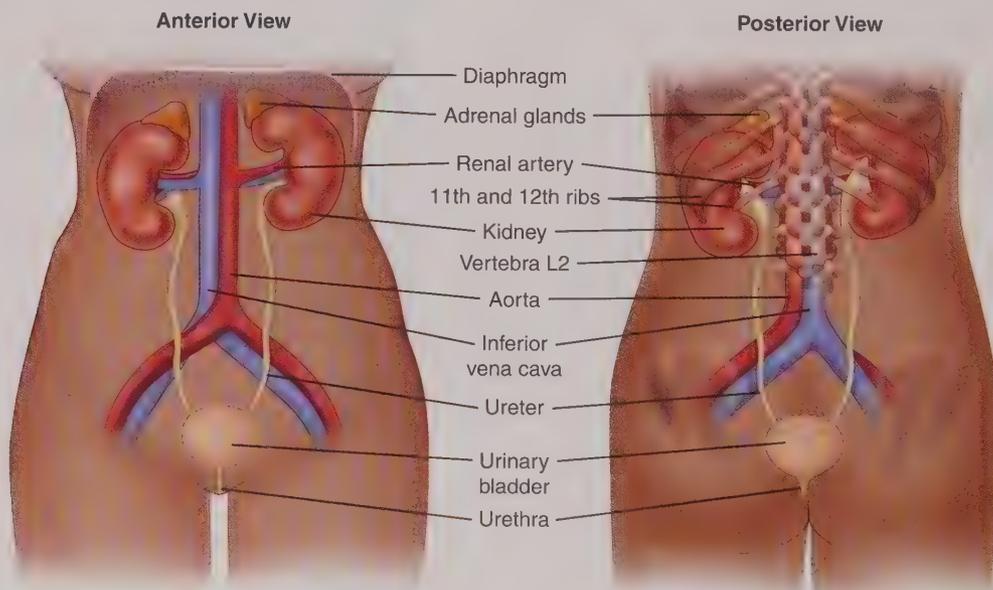

## Renal Anatomy

### Kidney Gross Anatomy

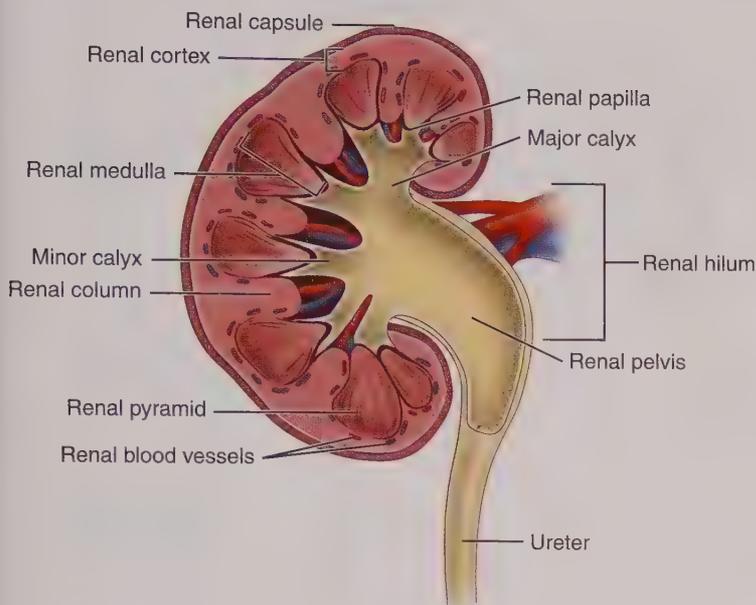

The **kidneys** are bean-shaped organs located retroperitoneally (behind the abdominal contents), one on each side of the spinal column (Fig. 61.1). The kidneys are held in place by connective tissue known as the renal fascia. The left kidney is typically located slightly higher than the right kidney because of the position of the liver. Each kidney is approximately 4 to 5 in. (10 to 12 cm) long, 2 to 3 in. (5 to 7 cm) wide, and 1 in. (2.5 cm) thick, and each weighs approximately 4 to 6 oz. An adrenal gland, an endocrine organ, sits atop each kidney (see Chapter 40).

Each kidney is surrounded by multiple layers of subcutaneous and connective tissue that provide support and protection. The outermost layer of the kidney is termed the **renal capsule** (Fig. 61.2). This thin, fibrous tissue serves to protect the organ and absorb shock. The capsule covers the distal surface of the kidney and extends to the medial portion of the kidney, termed the **hilum**. The hilum is the indented part of the kidney and is the location at which the renal artery and nerves enter the organ and the renal vein and ureters exit.

The inner tissue of the kidney, the **parenchyma**, lies beneath the renal capsule and contains the functional layers of the organ. When the parenchyma is viewed as a cross

**FIGURE 61.1** The renal and urinary systems: anterior and posterior views.

**FIGURE 61.2** Gross anatomy of the kidney.

section, the tissue layer lying directly beneath the renal capsule is the cortex. The medulla is the innermost layer of tissue and is composed of multiple **pyramids**. Each kidney contains approximately 12 to 18 pyramids. Each pyramid is separated by tissue known as renal columns.

The narrow tips of the renal pyramids are the **papillae**. The papillae empty urine into the calyces, cuplike collection structures. A small cluster of these structures is known as a **minor calyx**. Minor calyces widen moving toward the hilum and merge to form **major calyces**, which empty into the larger collection sac known as the **renal pelvis**. The renal pelvis can store only a small volume of urine, approximately 3 to 5 mL. The renal pelvis narrows to become the ureters. Urine flows through the gross structures of the kidney via the following route: from the papillae of the pyramids into the minor calyces, the major calyces, the renal pelvis, and the ureters en route to the bladder.

### Kidney Microscopic Anatomy

A **nephron** is the functional unit of the kidney. Approximately 800,000 to 1.2 million nephrons are contained within each kidney. It is here that the work of filtering the blood to remove wastes and produce urine occurs. Nearly 80% of nephrons in the kidneys are known as cortical nephrons, meaning they are short in length and are fully contained within the cortex region of the organ. The remaining 20% of nephrons are juxtamedullary nephrons and contain structures that lie deep within the medulla of the kidney.

Each nephron is composed of the following: a **glomerulus**, a **Bowman's capsule**, and a tubular system (Fig. 61.3). A glomerulus is a collection of semipermeable capillaries responsible for filtering blood. The Bowman's capsule is the structure surrounding each glomerulus. The tubular system is composed of the **proximal convoluted tubule (PCT)**, the **loop of Henle**, the **distal convoluted tubules (DCTs)**, and a **collecting tubule**. The PCT emerges from the

Bowman's capsule and winds until straightening into the loop of Henle. The loop of Henle is composed of a descending and an ascending limb, each of which is responsible for reabsorbing different substances in the process of urine formation. The DCT is a continuation of the ascending limb of the loop of Henle that thickens and continues twisting until it widens further into a collecting tubule.

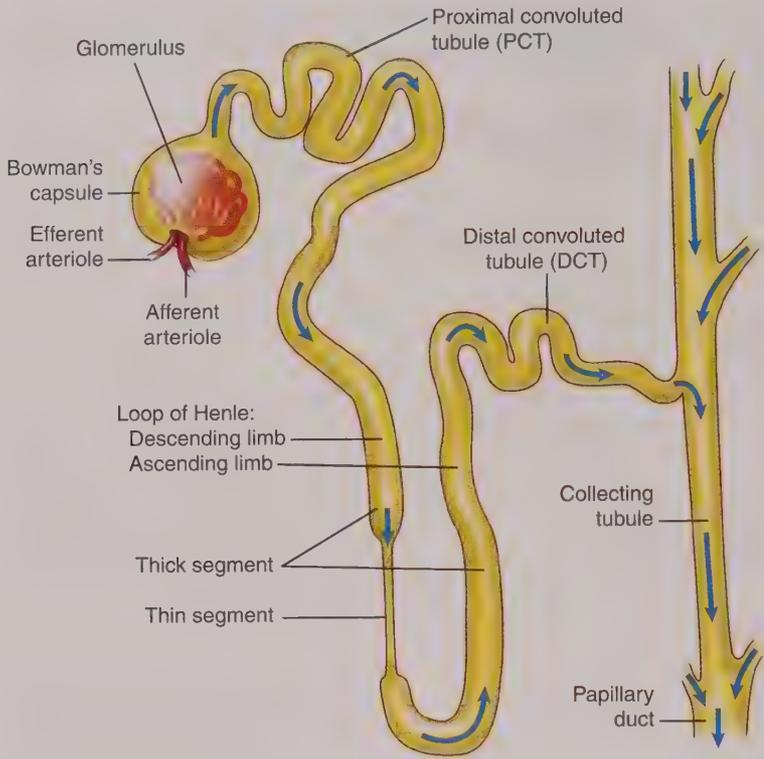

### Blood Supply

The kidneys receive 20% to 25% of the total cardiac output, a flow rate of approximately 1,200 mL of blood per minute. The renal artery, a branch of the abdominal aorta, enters each kidney at the hilum and delivers blood to the kidney. As the renal artery enters the kidney, it branches into several segmental arteries, which then branch into interlobar arteries. The interlobar arteries travel through the renal columns between the pyramids, moving outward toward the renal cortex tissue. As the interlobar arteries approach the renal cortex, they divide, forming arcuate arteries and then cortical radiate arteries.

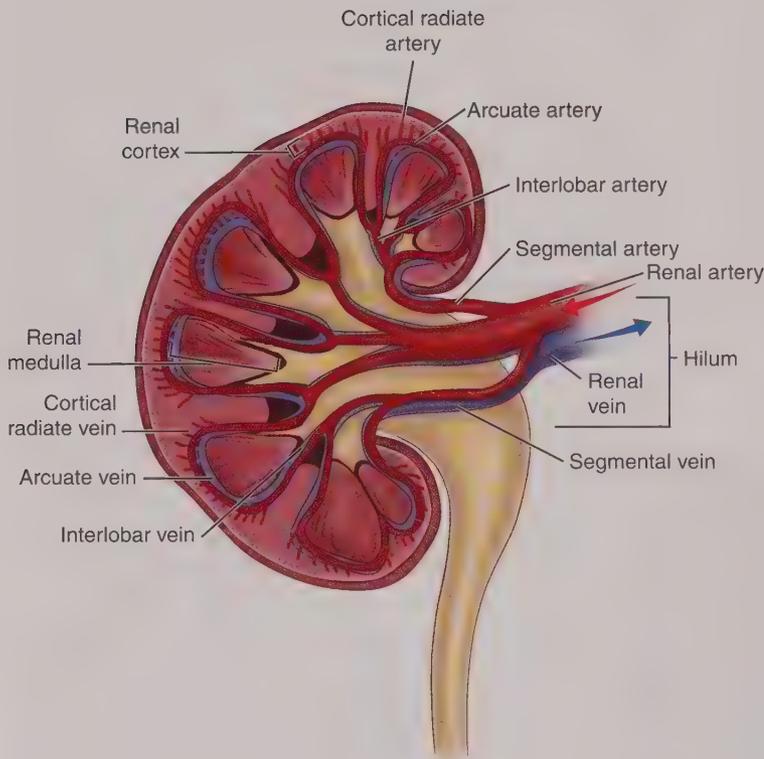

The branches formed off these cortical radiate arteries are the **afferent arterioles**. The afferent arterioles form a collection of capillaries that direct blood flow to the glomeruli of the nephrons, where the process of urine formation begins. Capillaries within the glomeruli then merge into the **efferent arterioles** to transport blood away from the glomeruli and into the peritubular capillaries. This collection of capillaries drains blood into the venous system. The renal vein then carries blood away from the kidneys and drains into the inferior vena cava (see Figs. 61.3 and 61.4).

### Renal Physiology

The kidneys perform several functions essential to the maintenance of homeostasis in the human body: (1) urine formation and the excretion of wastes, (2) regulatory functions such

**FIGURE 61.3** Anatomy of a nephron.

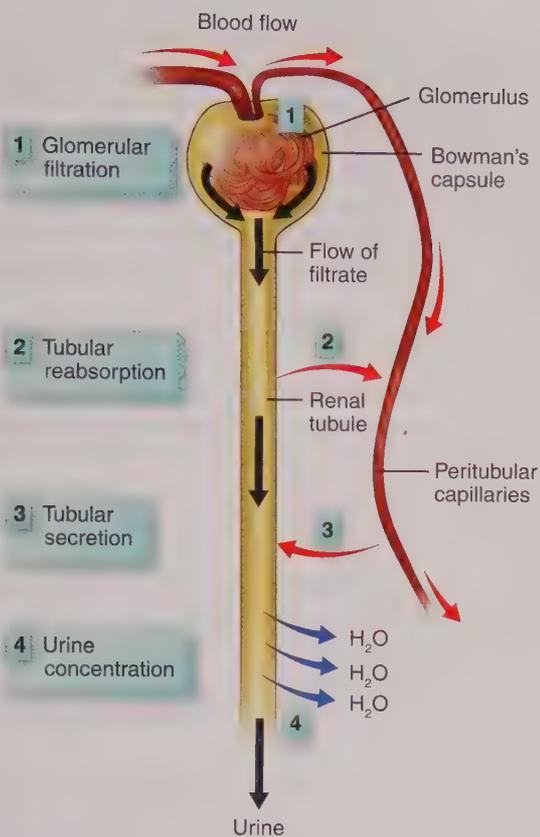

**FIGURE 61.4** Renal circulation. The renal artery delivers blood to the kidney. As the renal artery enters the kidney, it branches into segmental arteries, then into interlobar arteries. The interlobar arteries travel through the renal columns between the pyramids, moving outward toward the renal cortex tissue. As the interlobar arteries approach the renal cortex, they divide, forming arcuate arteries and then cortical radiate arteries.

as regulation of fluid and electrolyte balance and acid-base balance, and (3) hormonal functions such as renin production that helps regulate blood pressure, secretion of erythropoietin for RBC production, activation of vitamin D, and the production and release of bradykinin and prostaglandins (PGs).

### Urine Formation

Urine is formed through the continuous processes of filtration, reabsorption, secretion, and concentration (Fig. 61.5). Each of these processes is discussed in the following subsections.

**FIGURE 61.5** Steps of urine formation.

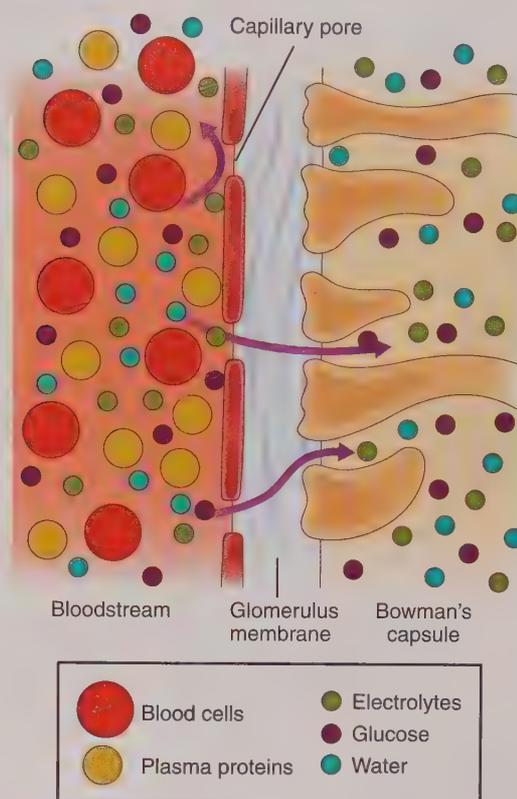

## Glomerular Filtration

Glomerular filtration begins as blood is filtered across the semipermeable membrane of the glomerulus (Fig. 61.6). The membrane filters particles primarily by their size. The capillary pores do not normally allow large particles such as plasma proteins and blood cells to pass through the membrane. However, in conditions that increase the capillary membrane permeability (i.e., diabetes mellitus and renal failure), plasma proteins and blood cells may escape through the membrane and into the urine.

When blood enters the capillaries of the glomerulus, **glomerular filtrate** is formed via hydrostatic pressure, which forces electrolytes, water, and small particles such as urea nitrogen, **creatinine**, and glucose from the blood across the glomerular membrane and into the Bowman's capsule. The glomerular filtrate or ultrafiltrate then flows from the Bowman's capsule into the PCT, where it is termed *tubular filtrate*.

The amount of blood filtered by the glomeruli in a set amount of time is the **glomerular filtration rate (GFR)**. The normal GFR is approximately 125 mL/min. This rate of filtration results in an average of 180 L of filtrate per day! Although a large volume of filtrate is produced, the reabsorption that occurs beyond the glomerulus returns much of this volume to the body. In a healthy adult, approximately 1 to 3 L of filtrate is actually excreted as urine each day.

The rate of glomerular filtration is dependent on several factors, including systemic blood pressure, blood flow, and

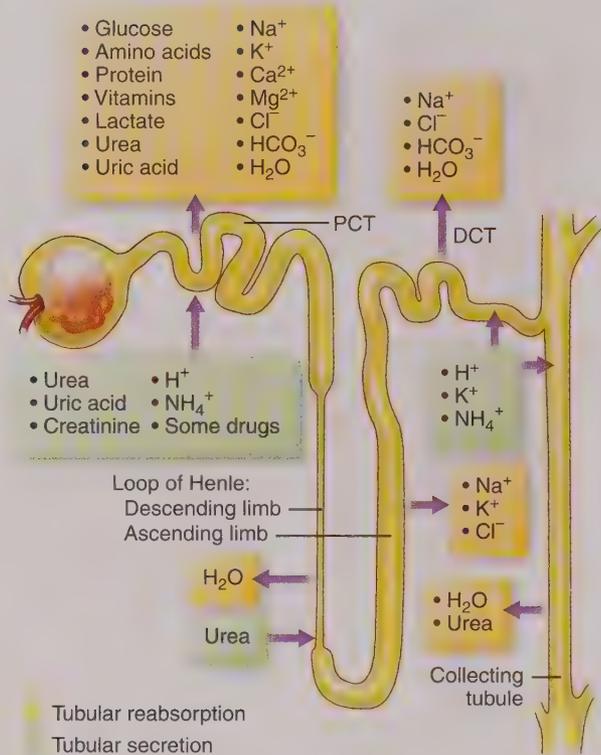

**FIGURE 61.6** The glomerular filtration membrane. As blood enters the capillaries of the glomerulus, glomerular filtrate is formed via hydrostatic pressure. It moves across the glomerular membrane and into the Bowman's capsule. The filtrate contains electrolytes, water, and small particles such as urea nitrogen, creatinine, and glucose.

volume. The kidneys have some ability to change the pressure within the glomerular capillaries through the dilation and constriction of the afferent arterioles that direct blood into the glomerulus and the efferent arterioles that guide blood away from the glomerulus. The constriction of the afferent arterioles or dilation of the efferent arterioles results in decreased pressure within the glomerular capillaries and a decreased filtration rate. Dilation of the afferent arterioles or constriction of the efferent arterioles results in the opposite, increased glomerular capillary pressure and an increased filtration rate. This regulatory mechanism enables the kidneys to maintain a constant GFR despite global changes in blood pressure. This is a powerful compensatory mechanism, but it cannot typically compensate for systolic blood pressures below 70 mm Hg. Pressures at or below that level result in a decreased GFR.

## Tubular Reabsorption

Tubular reabsorption is the second phase of urine production. It is the movement of water and solutes from the tubular filtrate back into the blood (Fig. 61.7). These processes occur throughout the length of the tubular system and are accomplished through both active and passive transport. Different from glomerular filtration, which occurs nonselectively based on particle size, the kidneys allow for selective reabsorption of certain substances to occur within the tubular

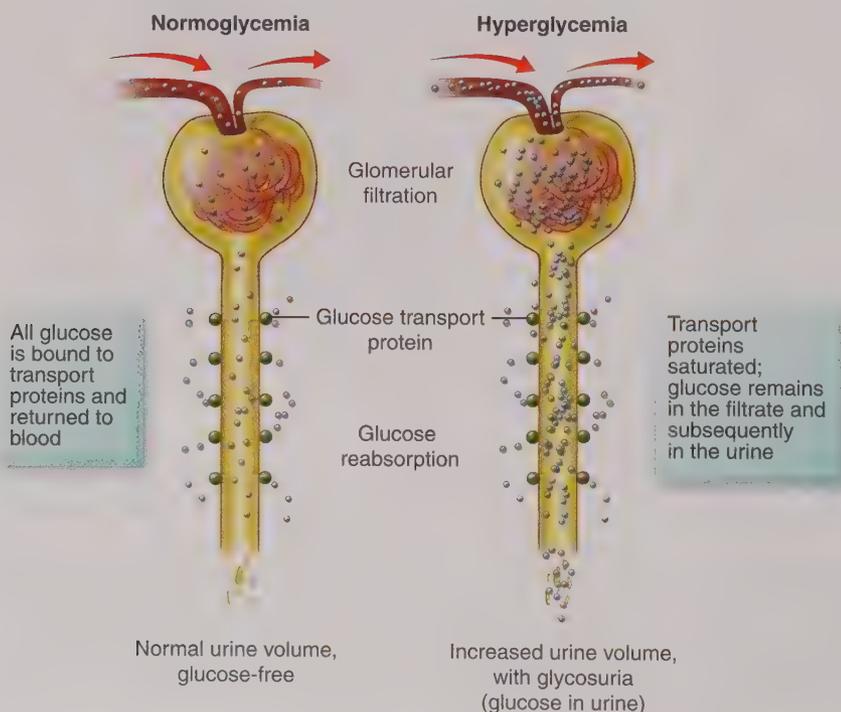

**FIGURE 61.7** Tubular reabsorption and tubular secretion of solutes throughout the renal tubule.

system. To avoid dehydration, up to 99% of the glomerular filtrate is reabsorbed and returned to the blood, mainly in the PCT. The PCT is responsible for reabsorbing approximately 65% of the glomerular filtrate. Reabsorption of water can also occur in the DCT depending on the

membrane permeability. The hormones **antidiuretic hormone (ADH)** and aldosterone control the permeability of the DCT membrane. Antidiuretic hormone, also known as vasopressin, is discussed in great detail later regarding the kidneys' role in the regulation of water balance. Aldosterone is a hormone secreted from the adrenal cortex that increases the reabsorption of sodium in the DCT. Because water follows sodium, the reabsorption of water is also increased.

Solute is also selectively reabsorbed from the tubular filtrate and returned to the blood. The reabsorption rate of specific electrolytes depends on the level of that electrolyte in the blood. The reabsorption of a solute such as bicarbonate is dependent on the current serum pH. A more thorough discussion of the kidneys' role in regulating water, electrolyte, and pH balance appears in the later section on regulatory function.

Glucose is another solute reabsorbed by the kidneys and returned to the blood via tubular reabsorption (Fig. 61.8). Transport proteins within the PCT move glucose from the filtrate back into the blood. There is a maximum amount of glucose the kidneys can reabsorb. This is termed the *renal threshold* or *transport maximum* for glucose reabsorption. The typical value associated with the renal threshold for glucose is 220 mg/dL, meaning that at blood glucose levels of 220 mg/dL or less, all glucose is bound to the transport proteins and returned and reabsorbed in the blood. At higher levels, the transport proteins become saturated, resulting in the presence of glucose in the filtrate and subsequently in the urine. A patient with uncontrolled or undiagnosed diabetes mellitus will therefore at times test positive for glucose in the urine, termed *glycosuria*.

**FIGURE 61.8** Renal threshold for glucose transport. A serum glucose over 220 mg/dL results in incomplete reabsorption and resulting glycosuria.

## Tubular Secretion

Tubular secretion is the third phase of urine formation and is the movement of solutes from the blood into the filtrate. Substances move from the capillaries into the renal tubule cells and then into the urine to be excreted from the body. Substances secreted in this fashion include potassium ions ( $K^+$ ) and hydrogen ions ( $H^+$ ). Both are secreted back into the filtrate in quantities necessary to maintain stable electrolyte and blood pH levels. This is discussed in more detail later in the chapter and is illustrated in Figure 61.7.

## Urine Concentration

Following tubular secretion, the urine must be concentrated prior to its excretion from the body. Without the kidneys' ability to concentrate the urine, the body would quickly experience dehydration due to significantly large volume losses. The loop of Henle plays a significant role in this final step of urine formation. The descending portion of the loop is permeable to water and is responsible for reabsorbing the additional water required to concentrate the urine. The role of the kidneys in maintaining a homeostatic balance of water within the body is discussed further in the next section.

## Regulatory Function

### Water Balance

Water accounts for approximately 50% to 60% of the body weight of the average adult. Two-thirds of this water is found in the intracellular fluid (ICF), whereas the majority of the remaining water is found outside the cells in the extracellular fluid (ECF). Water found in the ECF is distributed throughout the plasma, lymph, and interstitial fluid (tissue fluid). Small quantities of water (2%) are also found in the cerebrospinal fluid (CSF), the gastrointestinal (GI) tract, the respiratory tract, and the vitreous humor of the eye. The kidneys are the primary organs responsible for maintaining water balance within the body.

For this fluid balance to be maintained, the kidneys must ensure that the volume of water taken into the body is equal to the volume of water lost from the body (Fig. 61.9). Water is taken into the body through consumed liquids and foods. Water is also present in the body as a product of metabolism. Water losses occur through perspiration (water from sweat glands), urination, defecation, cutaneous transpiration (water loss through the epidermis), and exhalation.

Osmolality is a measure of the concentration of solutes, including electrolytes and ions, contained in the blood. Typically, the osmolality of the fluid inside the cells and the fluid outside the cells is nearly equal because water is allowed to pass freely along the cell membrane. When less water is taken into the body, serum osmolality increases because the solutes are more concentrated as a result of the decrease in water content. Likewise, when excess water is taken into the body, serum osmolality decreases because the excess water dilutes the concentration of solutes.

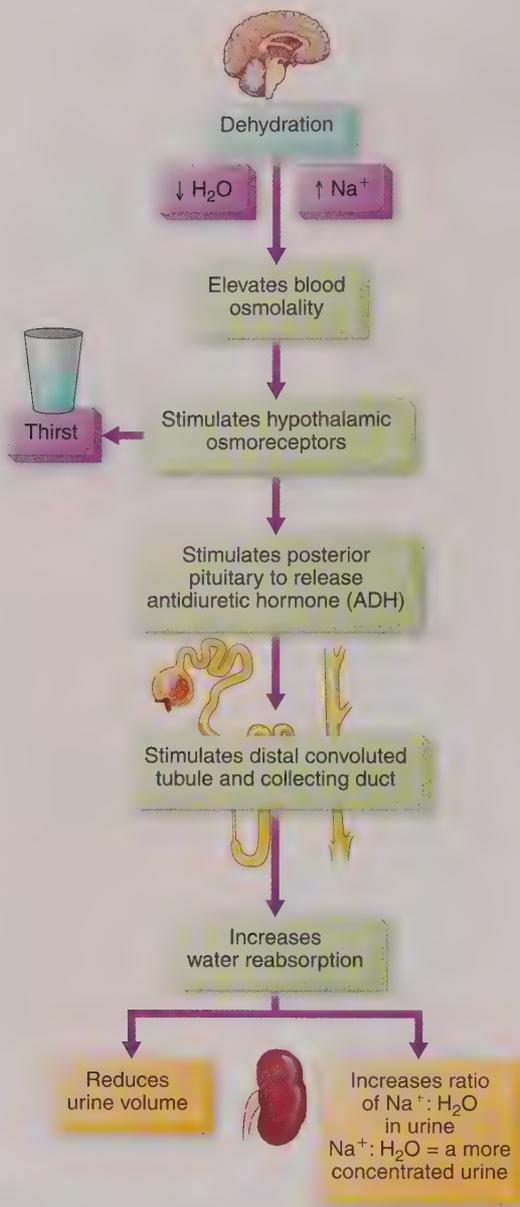

When serum osmolality is altered, several mechanisms are activated to restore homeostasis. The hypothalamus is

**FIGURE 61.9** Normal mechanisms of fluid intake and output.

capable of detecting changes in the osmolality of blood. When serum osmolality increases because of dehydration, the brain is stimulated to produce the sensation of thirst. In addition, increased osmolality triggers the release of ADH from the posterior pituitary gland. Antidiuretic hormone regulates water balance by altering the permeability of the tubular membrane, making it more permeable to water and resulting in the increased absorption of water. These mechanisms, along with the production of more-concentrated urine, result in a decrease in serum osmolality. The action of ADH is illustrated in Figure 61.10.

Conversely, when excess water is taken into the body, osmolality decreases, and the secretion of ADH is suppressed. The kidneys then produce more dilute urine to rid the body of excess water and to restore serum osmolality. These mechanisms of regulating water balance enable the kidneys to control the volume and concentration of urine independently from fluid intake. Therefore, the kidneys are able to prevent dehydration when fluid intake is low and prevent volume overload when fluid intake is excessive. The

**FIGURE 61.10** Action of antidiuretic hormone (ADH).

role of the kidneys in maintaining water balance is invaluable. When the kidneys lose this regulatory capacity, homeostasis is altered, and all body systems are affected. Complete loss of this regulatory function can result in death.

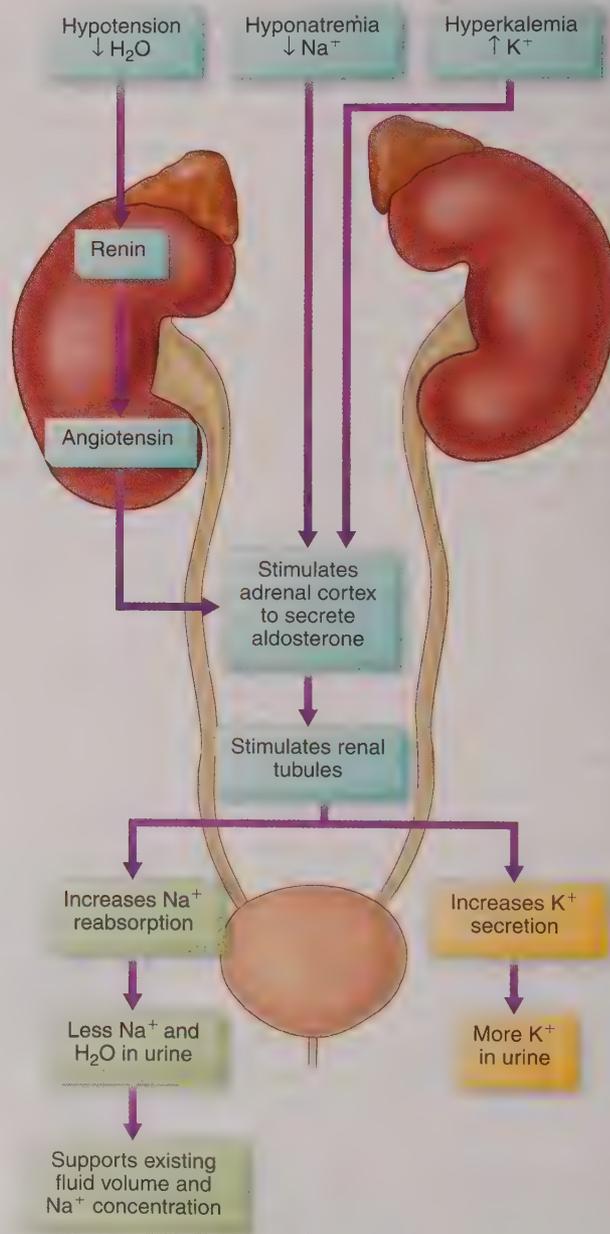

### Electrolyte Balance

The kidneys also control the composition of the blood by reabsorbing and secreting electrolytes to maintain levels within normal ranges. The PCT is responsible for reabsorbing up to 80% of the electrolytes contained in the filtrate. Figure 61.7 illustrates the locations throughout the tubule at which various solutes, including electrolytes, are reabsorbed and secreted.

The rate of reabsorption and secretion of each electrolyte is dependent on the concentration of that electrolyte in the serum. To explain, when a higher-than-normal electrolyte

level is detected, the kidneys act by increasing the secretion of this electrolyte. Likewise, when a specific electrolyte level is lower than normal, the kidneys increase the reabsorption of that electrolyte to restore homeostasis.

As an example, the release of the hormone aldosterone from the adrenal cortex is stimulated when serum levels of sodium are decreased (hyponatremia), causing increased reabsorption of sodium (Na<sup>+</sup>) in the distal tubule (Fig. 61.11). As a result, sodium is reabsorbed, increasing serum sodium levels. Water is also reabsorbed. Aldosterone is also secreted in instances of elevated potassium (hyperkalemia), resulting in the excretion of K<sup>+</sup>. This is one mechanism by which the kidneys exert control of specific electrolyte levels. The rates of reabsorption and secretion of other electrolytes, including

**FIGURE 61.11** Action of aldosterone secretion.

calcium and phosphate, are also partially controlled by hormonal action on the kidney. Both calcium and phosphate are reabsorbed mainly in the PCT. Their reabsorption and secretion are regulated by parathyroid hormone and calcitonin. These hormones are discussed in detail in Chapter 40.

### Acid-Base Balance

To maintain homeostasis, the pH of the blood must constantly remain between 7.35 and 7.45. A serum pH ( $H^+$  levels) less than 7.35 is termed *acidosis*, and a serum pH greater than 7.45 is termed *alkalosis*. Three bodily mechanisms work to maintain normal serum pH levels: an acid-base buffer system, regulation by the respiratory system, and regulation by the renal system. The role of the kidneys in regulating the acid-base balance is invaluable because cells within the body cannot survive and function properly when pH is not maintained within the normal range.

In instances of acidosis, the kidney tubules excrete  $H^+$  and reabsorb bicarbonate ions ( $HCO_3^-$ ) to increase serum pH to a normal level. In cases of alkalosis, the kidney tubules reabsorb  $H^+$  and excrete  $HCO_3^-$  to decrease pH to a normal level. Although the renal regulation of pH balance is the last mechanism to activate when the serum pH is

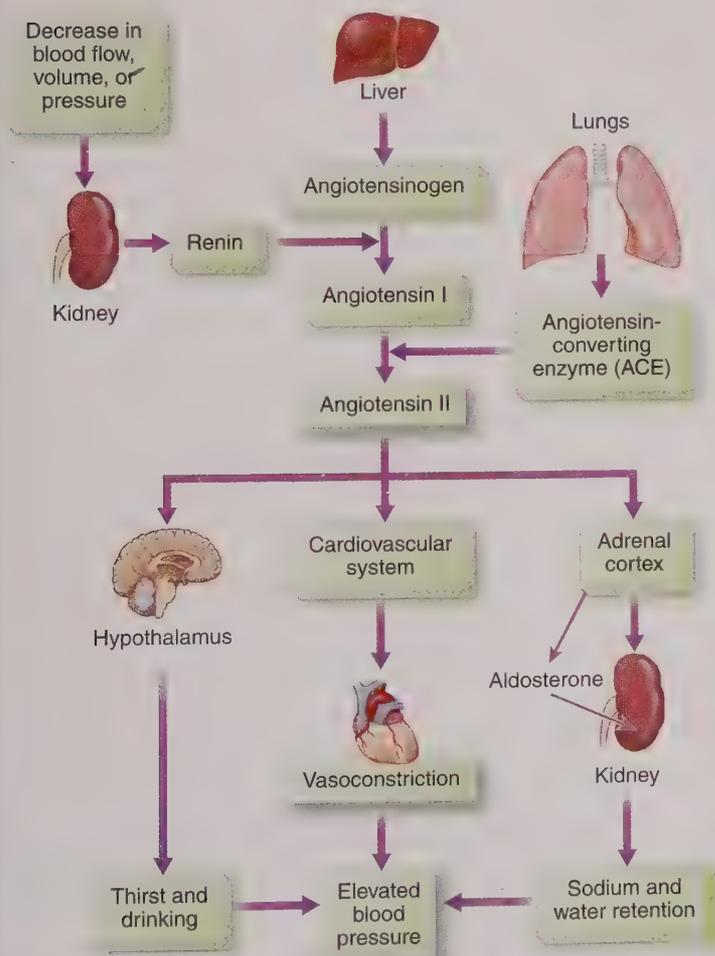

altered, its response exerts the most control in restoring the pH to a normal level; the kidneys are the only organs with the capability to fully excrete  $H^+$  from the body.

### Hormonal Function

In addition to producing urine and regulating water, electrolyte, and acid-base balance, the kidneys are responsible for producing hormones, including renin, erythropoietin, activated vitamin D, bradykinin, and PGs.

### Renin

**Renin** aids in blood pressure regulation within the body. It is produced and released when receptors in the kidneys sense a decrease in blood flow, volume, or pressure. Renin is also released when decreased levels of sodium in the renal blood supply are detected. Upon its release, renin interacts with angiotensinogen released from the liver to produce angiotensin I, which, with the aid of angiotensin-converting enzyme (ACE) secreted from the lungs, results in the formation of angiotensin II (Fig. 61.12). Angiotensin II constricts blood vessels, resulting in increased blood pressure. In addition, angiotensin II stimulates the adrenal glands to release aldosterone. Aldosterone causes increased sodium reabsorption and subsequent water reabsorption in the DCT.

**FIGURE 61.12** Renin-angiotensin-aldosterone system (RAAS).

This regulatory mechanism is termed the *renin-angiotensin-aldosterone system*. Angiotensin II also stimulates the hypothalamus to stimulate thirst.

### Erythropoietin

Erythropoietin is a hormone produced exclusively by the kidneys in response to decreased renal blood flow and hypoxia. Erythropoietin stimulates the bone marrow to produce RBCs. In cases of renal impairment and failure, erythropoietin is produced in insufficient quantities, and a resulting anemia occurs.

### Vitamin D

Although obtained through diet and exposure to ultraviolet radiation, vitamin D must be activated in order to be useful to the body. The steps required for activation begin in the liver, where vitamin D is converted to calcidiol, then continues in the kidneys, where calcidiol is converted to its active form, 1,25-dihydroxycholecalciferol or calcitriol. The activated form of vitamin D is required for calcium to be absorbed in the GI tract. A patient with renal impairment can have deficiencies in activated vitamin D and, as a result, decreased serum calcium levels. Because of the inverse relationship of calcium and phosphate, serum phosphate is typically increased in patients with renal impairment (discussed in detail in Chapter 62).

### Prostaglandins

Prostaglandins are hormones produced by various tissues of the body. They typically affect the tissues surrounding their site of production. The kidneys specifically produce prostaglandin E<sub>2</sub> and prostacyclin. These PGs function within the kidneys to trigger vasodilation, resulting in increased blood flow to the kidneys and increased sodium and water excretion. Prostaglandins synthesized in the kidneys may also play a role in lowering systemic blood pressure as a result of decreasing vascular resistance. As the quantity of functional kidney tissue decreases in renal failure, the production of PGs also decreases. The absence of the vasodilating effects of PGs may be a contributing factor to the development of hypertension often associated with renal failure.

### Bradykinin

Bradykinin is a hormone released by the kidneys in response to the presence of PGs, ADH, and angiotensin II. It increases the permeability of the capillary membrane to certain solutes and dilates the afferent arteriole to ensure adequate reabsorption of solutes and blood flow to the kidneys.

## Connection Check 61.1

The nurse expects to observe which of the following altered laboratory values in a patient diagnosed with renal failure?

- Decreased calcium
- Increased calcium
- Decreased phosphorus
- Increased hematocrit

## Urinary System Structures

### Ureters

A **ureter** is a small, hollow, muscular tube through which urine travels from the renal pelvis of the kidney to the bladder. Each ureter is approximately 10 to 12 in. (25.4 to 30.5 cm) long, and one is associated with each kidney. The ureter is composed of three layers: an inner mucous membrane, a middle layer of smooth muscle, and an outer layer of fibrous tissue. The narrowing where each ureter joins the renal pelvis is known as the ureteropelvic junction. Each ureter joins the bladder on its posterior side at the ureterovesical junction. Because these areas represent locations of narrowing in the ureter lumen, they are common sites for the obstruction of urine flow related to urinary stones, or calculi.

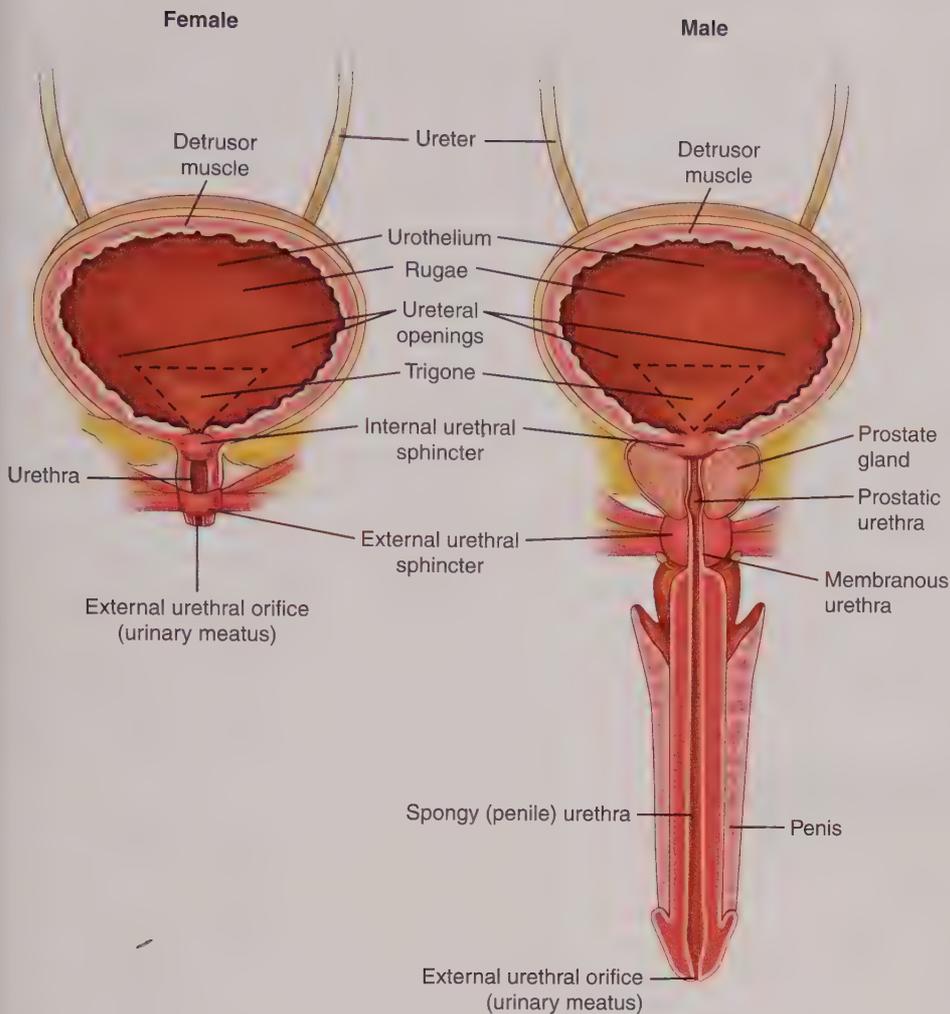

Urine moves one way through the ureters and into the bladder as a result of the peristaltic contractions of the smooth muscle fibers of the ureters. These contractions occur as stretch receptors within the renal pelvis detect increased urine volume. Urine is prevented from backflowing into the kidneys when the pressure in the bladder increases (i.e., with coughing or voiding) because the muscles of the bladder and urethra contract to close off the lumen.

### Bladder

The **bladder** is a muscular reservoir for storing urine until it is excreted from the body. The bladder lies directly posterior to the symphysis pubis. It is positioned anterior to the rectum and in women is anterior to the vagina and inferior to the uterus. When the bladder contains urine, it appears as a sac; yet when empty, it appears as stacked folds within the pelvic cavity. The bladder is fixed to the abdominal wall by a ligament emerging from the umbilicus; therefore, as the bladder fills with urine, it expands upward toward the umbilicus. The total capacity of the bladder varies from person to person but is typically 600 to 1,000 mL of urine.

The bladder is composed of three layers: the outer lining, the middle smooth muscle (detrusor), and the inner epithelium (urothelium) (Fig. 61.13). The detrusor consists of layers of smooth muscle that distend as the bladder fills and contract when the bladder empties. The urothelium is composed of transitional epithelial tissue unique to the urinary system. When the bladder is empty, the lining contains folds known as rugae. As the bladder fills and the lining stretches, these rugae disappear. The urothelium resists the absorption of urine, which ensures that urine stays within the urinary tract. The urothelium also secretes a unique substance that resists bacterial colonization. The trigone is the smooth, triangular-shaped region at the base of the bladder between the entrance points of the ureters and the urethra. This is a common location of bladder infections.

The bladder allows for continence and facilitates voiding. Continence is the ability to voluntarily control the emptying

**FIGURE 61.13** Layers and anatomy of the bladder and urethra.

of the bladder. **Micturition**, voiding, is the act of releasing urine from the body. Micturition is a learned response coordinated by the brain and the spinal nerves that innervate the bladder.

As the bladder fills with urine, stretch receptors in the bladder are stimulated, sending impulses to the sacral spinal cord (S2 to S4) and the brain, triggering the urge to void. If the time to void is suitable, the brain transmits signals to nerves along the thoracolumbar (T11 to L2) and sacral spine to relax the muscles of the bladder neck, sphincter, and pelvic floor. As these muscles relax, the bladder contracts, and urine is released from the body.

If the time to void is not suitable, inhibitor impulses in the brain are stimulated. Signals are transmitted to the thoracolumbar and sacral spinal nerves to contract the muscles of the sphincter and pelvic floor, resisting increasing bladder pressure. The contraction of these muscles temporarily inhibits voiding. Typically, the urge to urinate occurs when the bladder is distended with 200 to 250 mL of urine. The average adult voids five to six times each day.

Medical conditions or trauma involving the brain, spinal cord, or nerves innervating the muscles of the bladder, sphincter, or pelvic floor can affect the normal functioning

of the bladder. This can result in a lack of continence, also called *incontinence*, and/or difficulty voiding. Such conditions include multiple sclerosis, paraplegia, quadriplegia, spina bifida, and diabetes mellitus. Medications affecting nerve pathways can also alter the functioning of the bladder. Classes of medications known to have the potential to affect bladder function include opioid pain medications, some antihypertensives, certain antidepressants, some antiemetics, and antihistamines.

### Urethra

The **urethra** is a narrow muscular passage extending from the neck of the bladder to the urinary meatus, the opening at the end of the urethra through which urine exits the body. The length of the urethra varies in males and females. The average length of the male urethra is 8 to 10 in. (20.3 to 25.4 cm) long. The male urethra extends from the bladder neck through the prostate gland and continues for the length of the penis. The average female urethra is only 1 to 2 in. (2.5 to 5.1 cm) long. The short length of the female urethra allows for bacteria to more easily invade the urinary tract, explaining the increased incidence of urinary tract infections (UTIs) in females when compared with males.

The internal urethral sphincter is formed by the thickening of the detrusor muscle around the top of the urethra as it exits the bladder. The smooth muscle of this sphincter contracts, maintaining closure of the urethra to ensure that urine remains in the bladder until the time of voiding. Control of the internal urethral sphincter is involuntary. The external urethral sphincter encircles the urethra as it enters the pelvic floor. Because it is composed of skeletal muscle fibers, control of the external urethral sphincter is voluntary.

### Connection Check 61.2

The nurse is caring for an older adult with intermittent urinary incontinence. The nurse recognizes that the incontinence is a result of which structure failing to contract to keep urine in the bladder until micturition?

- A. The detrusor muscle
- B. The external urethral sphincter
- C. The urethra
- D. The internal urethral sphincter

### CASE STUDY: EPISODE 2

Mr. Jones has presented with complaints of decreased appetite, fatigue, 10-lb weight gain over 2 months, changes in mental status, and urinating “only small amounts of urine.” Vital signs reveal that Mr. Jones is hypertensive, and his laboratory values reveal elevated BUN, creatinine, potassium, phosphorus, and decreased calcium. A physical assessment reveals a lethargic gentleman with obvious pallor and peripheral edema in his extremities.

The provider orders a renal ultrasound and a computed tomography (CT) scan to assess for obstructions within the urinary tract. Both the ultrasound and the CT scan are negative for masses or obstructions, leading the provider to diagnose Mr. Jones with renal insufficiency likely related to uncontrolled hypertension...

## ASSESSMENT

### History Collection

#### Demographics and Personal Data

Collecting a subjective patient history is a critical component of assessing the functioning of any body system. When the renal and urinary systems are evaluated, essential demographic data to be collected include gender, age, race, socioeconomic status, occupational history, and dietary and personal habits.

Because of the variations in the anatomy of the male and female urinary systems, each gender is predisposed to unique complications that should be considered and

assessed. Females are more susceptible to develop UTIs than males because of the short length of the female urethra. The presence of the prostate gland in males introduces the potential for complications, including prostatitis, benign prostatic hypertrophy (BPH) or nonmalignant enlargement of the prostate gland, and prostate cancer.

Changes in the urinary system and its function occur with increasing age. Aging adults are more prone to experience problems with urination, including incontinence, urgency, frequency, nocturia, and urinary retention. Therefore, a thorough assessment of urinary elimination patterns of this patient population is essential. Aging also increases the risk of developing bladder cancer. For a further discussion of age-related changes in the renal and urinary systems, see the section titled “Age-Related Changes.”

Race should also be considered because evidence has revealed an increased incidence of hypertension and diabetes mellitus in the African American population. According to the National Kidney Foundation, one out of three African American adults over the age of 65 is affected by hypertension, and more than 3 million African Americans have diabetes. Both hypertension and diabetes are precursors to the development of renal dysfunction.

Socioeconomic status should also be assessed when evaluating renal function. Research has revealed relationships among those with low socioeconomic status, low levels of education, and lack of access to healthcare and the development of chronic conditions that increase the risk of renal complications. Low socioeconomic status has also been linked with a higher incidence of bladder cancer. This may be due in part to the associations of low socioeconomic status with occupational exposure to specific chemicals and to an increased rate of smoking, factors that increase the risk of developing bladder cancer. Occupational history should be assessed because some occupations result in exposure to chemicals known to be damaging to the kidneys. Exposure to chemicals such as aromatic amines and hydrocarbons is known to increase the risk of bladder cancer. Individuals employed as textile workers, hairdressers, painters, and manufacturers of rubber and leather products have a high incidence of bladder cancer.

A thorough review of dietary intake should occur. Consumption of foods high in protein, dairy products, and salt may lead to an increased development of renal calculi. Inadequate fluid intake also increases the risk of developing UTIs, renal calculi, and even renal failure. A dietary review may also reveal changes in appetite and taste sensation that are sometimes present in patients with renal failure.

Smoking history should be assessed because smoking is the primary risk factor for the development of bladder cancer. Smokers have more than a five-fold increase in the risk of developing bladder cancer when compared with nonsmokers. Educating patients regarding the need for smoking cessation and providing them with strategies for

cessation are essential responsibilities of the healthcare team, including the nurse.

### Personal and Family Health History

Patients should be questioned about their overall health status. Alterations in the functioning of the renal and urinary systems can produce systemic effects. Complaints of fatigue, changes in weight, excessive thirst, and signs of fluid retention are symptoms that warrant further investigation of the functioning of the renal and urinary systems. As mentioned previously, chronic conditions such as diabetes and hypertension can compromise blood flow to and through the kidneys, resulting in renal complications. The patient should be asked about a personal history of such conditions. A personal history of neurological deficits, urological cancers, frequent UTIs, and trauma to the urinary tract should also be assessed. Because conditions such as diabetes and hypertension have a hereditary component, it is vital to assess the family history of the patient for the presence of these conditions. The family history should also be reviewed for the presence of kidney disease, urological failure, and frequent UTIs.

Because the urinary and reproductive systems are closely related, a brief sexual and reproductive history should be collected. Alterations in urinary function do not specifically alter the functioning of the reproductive system but can affect the level of self-confidence required for sexual relationships. The patient with urinary system alterations such as frequency or incontinence may find it difficult to feel pleasure in a sexual relationship because of embarrassment, fear, and lack of self-confidence. Nurses should be prepared to provide education regarding management of the urinary system alteration and to support the patient to pursue the desired sexual relationship.

### Medication Use

It is essential to collect a thorough history of a patient's current and past use of over-the-counter (OTC) medications, prescription medications, vitamins, and herbal supplements. Many classes of medications are known to affect the normal functioning of the urinary system. Medications such as diuretics increase the quantity and frequency of urine output. Medications, including some chemotherapeutic agents, phenazopyridine (Pyridium), and nitrofurantoin (Macrochantin), are known to alter the color of urine. Classes of medications used to treat neurological and musculoskeletal disorders can affect the normal functioning of the muscles and nerves controlling bladder contraction and relaxation. This may lead to urinary incontinence, urinary retention, and other difficulties in voiding.

Many classes of medications are also known to be toxic to the kidneys. Such medications are termed *nephrotoxic*. See the Safety Alert for a partial list of substances with nephrotoxic potential. A patient prescribed these medications must be closely monitored for complications related to nephrotoxicity.

### Safety Alert Potential Nephrotoxic Substances

#### Antibiotics

Acyclovir (Zovirax)  
Amikacin (Amikin)  
Amphotericin B (Amphocin)  
Bacitracin (BACiIM)  
Cephalosporins  
Gentamicin (Garamycin)  
Kanamycin (Kantrex)  
Neomycin (Neo-Fradin)  
Penicillins  
Rifampin (Rifadin)  
Streptomycin  
Sulfonamides  
Tetracycline (Vibramycin)  
Tobramycin (Tobrex)  
Vancomycin (Vancocin)

#### Analgesics

Cyclooxygenase-2 (COX-2) inhibitors  
Nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., aspirin, ibuprofen)  
Salicylates

#### Other Medications

Antiretrovirals  
ACE inhibitors  
Benzodiazepines  
Contrast media  
Cyclosporine (Sandimmune)  
Diuretics  
Lithium (Lithobid)  
Methotrexate (Rheumatrex)  
Tacrolimus (Prograf)

#### Substances

Cocaine  
Gold  
Heroin  
Lead  
Mercury

### Renal and Urinary Assessment

When specifically assessing the renal and urinary systems, question the patient regarding any changes in the appearance (clarity and color) or odor of urine, the pattern of urination, and the ability to voluntarily control voiding. A change in the color of urine may be a result of medications, overhydration, dehydration, or the presence of blood in the urine (hematuria). Urine typically smells slightly of ammonia. Changes in the odor of urine may be caused by medications, hydration status, or the presence of infectious organisms.

A patient's pattern of urination should be thoroughly assessed in regard to frequency, flow, and amount. The

average adult voids five to six times per day and does not regularly need to void overnight. Urinary frequency refers to the sensation of needing to void more than normal but voiding only small amounts of urine each time. **Nocturia** describes the increased need to urinate at night. The patient should also be questioned regarding any changes in the flow of urination. **Dysuria**, pain or discomfort with urination, may indicate an obstruction or infection. Difficulty starting the flow of urine despite the sensation to void, termed *hesitancy*, may be indicative of age-related changes in the male prostate gland.

Patients typically do not know the normal quantity of their urine output. However, they can usually convey if there have been increases or decreases in the amount of urine output. Any change in the volume of urine output warrants further investigation. **Anuria** is a total urine output of less than 100 mL in 24 hours. **Oliguria** is a decreased amount of urine output, 100 to 400 mL in 24 hours. **Polyuria**

describes excess quantities of urine output. The significance of these and other urinary system abnormalities is presented in Table 61.1.

The mode by which a patient voids must also be assessed. Most patients void spontaneously; however, some patients may eliminate urine via self-catheterization or indwelling drainage devices as a result of previous alterations in the functioning of the renal and/or urinary system or other body systems. Patients requiring the use of such devices to void are at an increased risk of developing UTIs and should be closely monitored for signs and symptoms of infection.

Patients should also be questioned regarding their ability to voluntarily control voiding. Changes in the ability to voluntarily control micturition can occur with age and during pregnancy, postpartum, and postoperative recovery. A patient may report incontinence, urgency, retention, and/or hesitancy. See Table 61.1 for a description and the clinical significance of such subjective complaints.

**Table 61.1 Renal and Urinary System Assessment Abnormalities**

Finding	Definition	Clinical Significance of Abnormal Finding
<b>Anuria</b>	Less than 100-mL urine output/24 hr	End-stage renal disease, acute renal failure, urinary tract obstruction
<b>Dysuria</b>	Difficulty or pain with urination	Urinary tract infection, cystitis (bladder infection)
<b>Enuresis</b>	Involuntary urination at night	Lower urinary tract disorder
<b>Frequency</b>	Increase in incidence of voiding, usually urinating only small amounts with each void	Bladder inflammation, excessive fluid intake, urinary retention
<b>Hematuria</b>	Presence of blood in the urine	Cystitis or other inflammation in the urinary tract, calculi, cancers of the urinary tract, renal disease, bleeding disorders, medications such as anticoagulants
<b>Hesitancy</b>	Difficulty starting the flow of urine	Urethral obstruction, enlargement of the prostate gland (benign or malignant)
<b>Incontinence</b>	Inability to voluntarily control micturition	Bladder infections, trauma to the external sphincter, neurogenic bladder, trauma to the nerve innervating the urinary tract structures
<b>Nocturia</b>	Frequent urination at night	Heart failure, renal disease, bladder obstruction, consumption of excessive fluids late at night
<b>Oliguria</b>	Decreased urine output; less than 400-mL urine output/24 hr	Shock, end-stage renal disease, acute kidney injury, severe dehydration, blood transfusion reaction
<b>Polyuria</b>	Increased urine output; greater than 2,000-mL urine output/24 hr	Excessive fluid intake, diabetes insipidus, diabetes mellitus, diuretic medications, diuresis phase of chronic renal failure
<b>Renal colic</b>	Pain radiating to the perineal or groin area	Ureter spasm during passage of calculi, ureter obstruction
<b>Retention</b>	Inability to completely empty the bladder of urine	Normal finding briefly after childbirth, pelvic surgery, and removal of indwelling catheter  Prolonged/abnormal related to neurogenic bladder, obstruction or stricture of the urethra
<b>Urgency</b>	Sudden onset of the urge to void immediately	Medications, pelvic organ prolapse, cystitis, UTI

## Physical Examination

Following the collection of subjective data, a physical examination of the patient should occur. In addition to the specific assessment of the renal and urinary systems, physical assessment data of all body systems should also be collected. Vital signs and weight provide valuable baseline information on overall health status. A patient's mental status and level of consciousness should be noted because cognitive changes may reflect renal dysfunction. Auscultation of the lungs is also vital in assessing the body's overall fluid status.

When the renal system is assessed, the location of the kidneys can be estimated using the costovertebral angle (CVA) as a landmark. The CVA is formed by the lower border of the 12th rib and the spine. When assessing the renal and urinary systems, begin with inspection. Auscultation should follow and precedes palpation and percussion because these techniques amplify bowel sounds and diminish abdominal vascular sounds.

### Inspection

Because alterations in the renal and urinary systems affect all other body systems, begin with an inspection of the skin, oral mucosa, abdomen, and extremities. Depending on subjective reports by the patient, an inspection of the urethral meatus may also be necessary. When inspecting, assess for the presence of the following abnormal changes:

**Skin:** poor skin turgor, rough texture, pallor, yellow-gray color, flank bruising

**Mouth:** ammonia breath odor, stomatitis (inflammation and ulceration of oral mucosa)

**Abdomen:** uneven contour, unilateral lower abdominal mass, striae (stretch marks)

**Extremities:** edema

**Urethral meatus:** bloody or purulent discharge, skin lesions or rashes, obvious tissue trauma

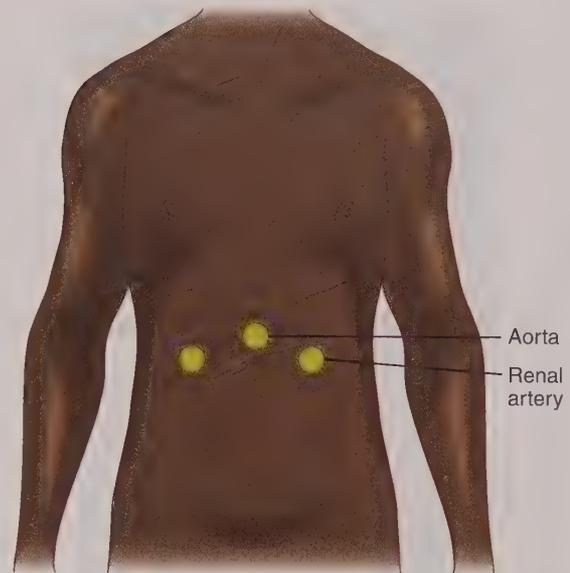

### Auscultation

With the patient supine, auscultate over the abdominal aorta and each renal artery with the bell of the stethoscope (Fig. 61.14). When auscultating, listen for a **bruit** (a turbulent or whooshing sound produced by an increase in the volume of blood traveling through a vessel or a decrease in the diameter of a blood vessel). The presence of a bruit indicates altered blood flow to the kidneys and warrants further investigation.

### Palpation

With the patient in the supine position, lightly palpate in all four abdominal quadrants. Instruct the patient to report any discomfort or tenderness upon palpation. The bladder is typically not palpable unless distended with urine. If filled with urine, the bladder is sensitive to palpation and feels round and firm.

To palpate the kidneys, position one hand under the patient's flank between the rib cage and the iliac crest (Fig. 61.15). Position the other hand over the abdomen,

**FIGURE 61.14** Auscultation of renal vessels. If a bruit is heard, it may indicate altered blood flow to the kidneys.

**FIGURE 61.15** Palpation of the kidneys; position one hand under the patient's flank between the rib cage and the iliac crest. Position the other hand over the abdomen, just below the rib cage. Ask the patient to take a deep breath, and use your lower hand to raise the flank while the upper hand palpates.

just below the rib cage. Ask the patient to take a deep breath and use the lower hand to raise the flank while the upper hand palpates. The lower pole of the right kidneys is occasionally palpable in some patients. The left kidney is positioned deeper than the right and is typically not palpable.

### Percussion

While the patient remains supine, percuss over the symphysis pubis upward toward the umbilicus. Dullness is the sound elicited over a distended bladder. A bladder containing little to no urine produces no sound upon percussion.

Assess for flank tenderness utilizing fist percussion over each kidney at the CVA (Fig. 61.16). Have the patient return to a sitting position and position yourself behind the patient. Place one hand flat over the CVA. Form a fist with the other hand and strike it against the dorsal surface of the flattened hand. This blow to the flank area should not elicit pain or tenderness. If the patient reports pain or tenderness, it is suggestive of kidney inflammation or infection.

**FIGURE 61.16** Percussing for costovertebral angle tenderness. Pain or tenderness is suggestive of kidney inflammation or infection.

### Connection Check 61.3

The nurse is assessing a patient for a routine physical examination. Which of the following are *normal* findings when assessing the renal and urinary systems? (*Select all that apply.*)

- A. Inability to palpate the kidneys
- B. CVA tenderness upon percussion
- C. Absence of a renal artery bruit
- D. Purulent drainage from the urinary meatus
- E. Tympanic sounds over an empty bladder upon percussion

## DIAGNOSTIC STUDIES

A variety of diagnostic studies can be utilized to further assess the structure and function of the kidneys and urinary system. Such studies are classified as blood tests, urine tests, and radiographical tests. We present several diagnostic studies of each class throughout the following sections.

### Laboratory Studies

#### Blood Tests

Blood tests are routinely performed to assess kidney function. The most commonly utilized blood tests include serum creatinine, BUN, and BUN/creatinine ratio. Additional values that reflect the functioning of the kidneys include uric acid and bicarbonate. Electrolyte values including sodium, potassium, phosphorus, and calcium are also monitored as a reflection of kidney function.

The patient should be educated regarding the indication for the blood test and should be informed of the results and their significance. There is no specific patient preparation required for these blood tests. Obtaining a sample of blood for the tests involves little risk to the patient. Abnormal results should be closely monitored.

#### Serum Creatinine

Creatinine is the end product of protein and muscle breakdown in the body. Creatinine is filtered by the kidneys and excreted into the urine. No commonly occurring medical condition other than renal dysfunction causes an increase in the serum creatinine, making it the most reliable indicator of kidney function, specifically reflecting glomerular function.

The normal range for serum creatinine in adults is 0.5 to 1.2 mg/dL. Males typically have slightly higher levels than females because of their larger muscle mass. Muscle mass and the resulting amount of creatinine produced in the body decrease with age; however, creatinine clearance also decreases, resulting in relatively stable creatinine levels in healthy aging adults. A patient with little muscle mass may present with slightly decreased creatinine levels.

An increase in the serum creatinine level does not occur until approximately 50% of the kidneys' function has been lost. Hence, any increase in the serum creatinine indicates impairment in the renal system and warrants immediate investigation and intervention. An increased creatinine level can be attributed to causes such as acute and/or chronic kidney injury or disease, cancer, diabetic nephropathy, shock, congestive heart failure, and consumption of a high-protein diet. A decreased creatinine level can be attributed to the loss of muscle mass or certain medications, including some classes of antibiotics (e.g., aminoglycosides and cephalosporins) and lithium carbonate.

#### Blood Urea Nitrogen

Urea nitrogen is a by-product of protein metabolism that occurs in the liver. The kidneys are responsible for filtering it from the blood. Serum BUN is a measure of the renal excretion of urea nitrogen.

The normal range for BUN in adults is 8 to 21 mg/dL. Increased BUN can occur not only in cases of renal dysfunction but also with liver disease, dehydration, infection, consumption of a high-protein diet, GI bleeding, steroid use, and trauma. Decreased BUN can be indicative of severe liver damage, malnutrition, consumption of a low-protein diet, or fluid volume excess. An elevated BUN is not diagnostic of renal dysfunction but certainly indicates it as a possibility. The hydration status of the patient should also be considered when interpreting the results of serum BUN. Serum creatinine should also be assessed in a patient with an elevated BUN.

#### Blood Urea Nitrogen/Creatinine Ratio

A BUN/creatinine ratio can be utilized to assess if the cause of elevated BUN is renal or nonrenal in nature. The normal ratio of BUN to creatinine is in the range of 10:1 to 20:1. In cases of hypovolemia or hypotension, the serum BUN

ises more quickly than the serum creatinine level. This results in an increased ratio of BUN to creatinine. Likewise, a decreased ratio can occur in instances of fluid volume excess. When both the BUN and creatinine levels are increased and the ratio remains normal, renal dysfunction is likely.

### Uric Acid

Purines are compounds that naturally occur in cells of the body and are also taken into the body in dietary sources (e.g., organ meats, anchovies, sardines, shellfish, asparagus, beans, mushrooms, spinach). Uric acid is formed as a by-product of purine metabolism. Excess uric acid is then excreted into the urine. Uric acid values are dependent upon kidney function, the rate of purine metabolism, and dietary intake of foods containing purines.

Normal uric acid values for adults are in the range of 3.5 to 8 mg/dL. Values greater than 12 mg/dL are critical and warrant immediate intervention. Excess uric acid is termed *hyperuricemia*. It can result in the development of gout— inflammatory arthritis that is caused by uric acid crystals in the joints and in severe cases can cause renal damage. Increased uric acid can occur as a result of renal failure, multiple myeloma, malnutrition, leukemia, lymphoma, metastatic cancers, and alcoholism. Some medications, including acetaminophen (Tylenol), furosemide (Lasix), and aspirin, are also known to cause hyperuricemia when used long term.

Decreased uric acid can occur as a result of burns, pregnancy, folic acid anemia, and Wilson's disease. Medications such as allopurinol (Zyloprim), Rasburicase (Elitek), azathioprine (Imuran), and warfarin (Coumadin) are known to decrease uric acid levels.

### Bicarbonate

Bicarbonate values are typically reported as a component of arterial blood gas results. Bicarbonate ions ( $\text{HCO}_3^-$ ) are alkaline and serve as buffers in the bloodstream to maintain pH in the normal range of 7.35 to 7.45. The kidneys regulate the concentration of  $\text{HCO}_3^-$  in the blood by altering the rate of excretion and production of the ions on the basis of serum pH. Because the ions are alkaline, an increase in the amount of bicarbonate ions increases the serum pH, resulting in metabolic alkalosis. Likewise, a decrease in the amount of  $\text{HCO}_3^-$  lowers the serum pH, resulting in a state of metabolic acidosis.

The normal range for bicarbonate in adults is 22 to 26 mEq/L. Increases in bicarbonate levels can occur as a result of severe vomiting or gastric suctioning, excess loss of potassium, or excess administration of bicarbonate. A decrease in bicarbonate levels can occur in renal failure as the kidneys lose their ability to produce  $\text{HCO}_3^-$  to buffer the blood. Decreased bicarbonate levels can also occur as a result of diabetic ketoacidosis, severe diarrhea, malnutrition, and burns.

### Electrolytes

The serum concentrations of several electrolytes are regulated in part by the kidneys. Therefore, these electrolyte values can be examined as a reflection of the functioning of the kidneys.

Sodium ( $\text{Na}^+$ ) is the primary cation in the ECF. Sodium exhibits water-retaining effects. In adults, the normal range for sodium is 135 to 145 mEq/L. In the late stages of renal failure, a patient's sodium balance can be altered as fluids accumulate in the body because of the kidneys' decreasing ability to filter and excrete properly.

The kidneys are responsible for excreting the majority of the body's  $\text{K}^+$  and maintaining it in the narrow range of 3.5 to 5.0 mEq/L. Potassium is typically one of the first electrolyte values to reflect an alteration in kidney function. As kidney function declines, potassium values typically increase above the normal level, termed *hyperkalemia*. Hyperkalemia can lead to cardiac dysrhythmias and therefore requires immediate recognition and intervention.

Phosphorus ( $\text{PO}_4$ ) is the primary anion in the ICF. The significant majority of phosphorus in the body exists as phosphate and is found along with calcium in the bones and teeth. Phosphorus and calcium are inversely related, meaning that as one increases, the other decreases. The normal range for phosphorus in adults is 2.5 to 4.5 mEq/L. Because the kidneys are responsible for excreting phosphorus from the body, as kidney function decreases, the phosphorus levels increase. This is known as hyperphosphatemia.

Calcium is the main mineral in teeth and bones. As noted earlier, in cases of declining kidney function, calcium levels decrease (hypocalcemia) as phosphate levels increase. The normal range for calcium in adults is 8.2 to 10.2 mg/dL. Hypocalcemia also occurs as kidney function declines because the kidneys are unable to produce quantities of vitamin D sufficient for calcium to be absorbed from the GI tract.

### Urine Tests

Various urine tests can be utilized to assess the functioning of the renal and urinary systems. The most commonly performed urine tests include bedside urine dipsticks, urinalysis, culture and sensitivity, composite urine collection, creatinine clearance, and urine cytology.

#### Bedside Urine Dipsticks

Urine can be tested at the bedside to assess the specific gravity; the pH; and the presence of protein, glucose, bilirubin, blood, and ketones. This testing method can provide the healthcare team with current information that may be needed to direct immediate treatment decisions for a patient. Commercially available dipsticks include a color-coded chart corresponding to a grading scale to be used when interpreting results. To yield accurate results, a fresh sample should be used for testing, and the dipsticks should be stored in a dry, sealed container. Follow institution policy and manufacturer guidelines for performing dipstick testing and reporting results.

#### Urinalysis

A urinalysis provides an overall examination of urine to provide baseline data or to monitor specific characteristics of the urine. The most precise urinalysis results are obtained by collecting urine from the patient's first void of the day.

To obtain accurate urinalysis results, the sample should be sent to the laboratory within 1 hour of collection. If not analyzed within an hour, RBCs hemolyze, bacteria multiply, casts disintegrate, and the pH becomes increasingly alkaline. Although not ideal, if the sample cannot be sent to the laboratory within 1 hour, it should be refrigerated until it can be sent.

Urinalysis results include data on multiple characteristics and components of the urine. These characteristics and components are briefly examined in the following subsections. The normal range of findings and the significance of abnormal findings in adults are outlined in Table 61.2.

### Color, Turbidity, and Odor

Some basic information about the urine can be gleaned simply by observing the urine. Urine should appear yellow in color because of the pigment urochrome. The range of the yellow color varies depending on hydration status. Urine should appear clear, without turbidity (cloudiness). Normal urine smells faintly like ammonia but should not smell foul.

### Specific Gravity

The specific gravity is a measure of the concentration of solutes contained in the urine. It reflects the ability of the kidneys to concentrate and dilute the urine effectively.

**Table 61.2 Normal Urinalysis Results and Significance of Abnormal Findings**

Component	Normal Findings for Adults	Clinical Significance of Abnormal Findings
<b>Color</b>	Pale yellow	<i>Clear or pale</i> indicates dilute urine related to excess fluid intake. <i>Dark amber</i> indicates concentrated urine related to dehydration and presence of bilirubin. <i>Red/brown</i> indicates blood, myoglobin, or bilirubin in urine. <i>Other colors</i> may occur as a result of foods or medications.
<b>Turbidity</b>	Clear	<i>Cloudy</i> indicates the presence of bacteria, pus related to infection, or sediment.
<b>Odor</b>	Faint odor of ammonia	<i>Foul</i> indicates the presence of bacteria related to infection, dehydration, or the effects of some foods and medications.
<b>Specific gravity</b>	1.005–1.030	<i>Increase</i> indicates diabetes mellitus, dehydration, or fever. <i>Decrease</i> indicates renal insufficiency, diabetes insipidus, or diuretic use.
<b>Osmolality</b>	250–900 mOsm/kg (24-hr collection)	<i>Increase</i> indicates diabetes mellitus, dehydration, or fever. <i>Decrease</i> indicates renal insufficiency, diabetes insipidus, or diuretic use.
<b>pH</b>	4.5–8	<i>Altered</i> indicates changes in renal function, infection, or certain medications and can also be related to the freshness of the sample.
<b>Protein</b>	2–8 mg/dL	<i>Increase</i> indicates stress, strenuous exercise, fever, septicemia, lead, mercury, or high-protein diet. <i>Persistently increased</i> indicates acute or chronic renal disease.
<b>Glucose</b>	Negative	<i>Presence</i> indicates undiagnosed or uncontrolled diabetes mellitus or decreased renal threshold for glucose.
<b>Ketones</b>	Negative	<i>Presence</i> indicates diabetic ketoacidosis, high-protein diet, or anorexia nervosa.
<b>Bilirubin</b>	Negative	<i>Presence</i> indicates hepatic biliary obstruction or liver disease.
<b>Red blood cells (RBCs)</b>	0–4/ (hpf)	<i>Slight increase</i> is normal with presence of an indwelling urinary catheter or during menstruation. <i>Significant increase</i> indicates bleeding disorders, cystitis, tumor, calculi, or trauma.
<b>White blood cells (WBCs)</b>	0–5/hpf	<i>Increase</i> indicates presence of inflammation, urinary infection, or fever.
<b>Casts</b>	Few or none	<i>Increase</i> indicates the presence of bacteria, kidney disease, or urinary calculi.
<b>Bacteria</b>	Less than 1,000 colonies/mL	<i>Increase</i> indicates possibility of UTI or contamination during sample collection.

hpf, High-powered field; UTI, urinary tract infection.

### Osmolality

Osmolality provides further information regarding the concentration of solutes in the urine. It is a more precise measure of the kidneys' ability to concentrate and dilute the urine than specific gravity.

### pH

The normal range for urine pH is wide and is affected by many factors. A pH value of 7.0 is neutral, so less than 7.0 is acidic, and a pH value greater than 7.0 is alkaline.

### Protein

Proteins are not typically contained in the urine because they are large and are not permitted to cross intact glomerular membranes. The presence of protein in the urine is termed *proteinuria*. Transient conditions such as infection and inflammation increase the permeability of the glomerular membrane, allowing some protein molecules to enter the urine. When proteinuria is identified in such cases, subsequent urinalyses should be obtained after resolution of the infection or inflammation to ensure that the urine is then negative for proteins. Proteinuria that persists indicates abnormalities in glomerular filtration and requires further assessment.

### Glucose

Glucose does not appear in the urine until the renal threshold has been reached at serum glucose levels of approximately 200 mg/dL. At glucose levels less than 220 mg/dL, the PCT of the nephron can reabsorb glucose, and none is present in the urine.

### Ketones

The partial metabolism of fatty acids in the body produces ketones. Normally, there are no ketones contained in the urine. In situations when fat is burned as energy in place of glucose, as in diabetes, ketones are produced and are present in the urine.

### Bilirubin

Bilirubin is formed during the breakdown of hemoglobin and is not typically present in the urine. Bilirubin in the urine, bilirubinuria, causes the urine to appear dark amber to brown in color.

### Red Blood Cells

Red blood cells are not normally present in the urine and are indicative of bleeding within the renal and/or urinary system. The presence and number of RBCs are assessed using microscopic examination.

### White Blood Cells

Small numbers of white blood cells (WBCs) can be present in urine samples because of perineal contamination during voiding. The presence and number of WBCs are assessed using microscopic examination.

### Casts

Casts are molds formed around the outside of particles such as RBCs, WCBs, proteins, or bacteria. They are not present in the absence of these particles. Casts are often described by the particle they surround (e.g., RBC cast, WBC cast). Casts are also assessed by microscopic examination.

### Bacteria

Urine can easily be contaminated during collection, so the presence of bacteria in a urinalysis does not definitely confirm a UTI. If urinalysis results indicate an increased presence of bacteria, a urine culture should be obtained to confirm the diagnosis and to isolate the infectious organism.

### Culture and Sensitivity

Culturing urine is useful to identify the number and type(s) of bacteria present. Sensitivity testing involves combining bacteria isolated in the urine with various classes of antibiotic medications to determine which are most effective at stopping the multiplication of the bacteria. Culture and sensitivity testing provides healthcare professionals with data useful when planning the best course of treatment for UTIs. Careful medication selection is crucial because medication resistance has become an increasing problem in managing UTIs and many other infections.

Urine to be tested for culture and sensitivity should be collected using a clean-catch technique (Box 61.1) and should be placed in a sterile specimen container. This ensures that the bacteria identified are not present because of contamination of the urine sample. It typically takes 48 to 72 hours to isolate any bacteria present. Bacteria commonly

## Box 61.1 Patient Education: Collecting a Clean-Catch Urine Sample

*Clean-catch urine samples are required for urine cultures to ensure that any bacteria found in the urine are not there as a result of contamination. Patients should be instructed to complete the following steps to provide a clean-catch sample:*

1. Wash hands.
2. Remove cap from sterile specimen container, ensuring not to touch the inside of the lid or container.
3. Males: Use enclosed towelette(s) to wipe the head of the penis.  
Females: Spread the labia with one hand and use the other hand to wipe from front to back with the enclosed towelette(s).
4. Begin urinating a small amount into the toilet. Without stopping the flow of urine, place the cup into the stream of urine and collect enough urine to fill the cup. Finish urinating into the toilet.
5. Securely attach the cap onto the sterile container, ensuring not to touch the inside of the lid or container.

isolated in culture samples include *Escherichia coli*, enterococci, *Klebsiella*, and streptococci.

### Composite Urine Collection

Composite urine collection involves collecting all urine voided for a defined period of time ranging between 2 and 24 hours. Such specimens can be used to measure the quantity of specific components of the urine including electrolytes, minerals, creatinine, protein, and glucose. Collection begins by discarding the first voided urine of the time period. All other urine should be saved, and the sample should be refrigerated or kept on ice for the duration of collection. At the completion of the collection period, the patient is asked to void, and the final urine should be added to the sample. All urine must be saved to ensure the accuracy of the results.

### Creatinine Clearance

Creatinine clearance testing of the urine is a type of composite urine collection. This test is a reliable indicator of GFR. Creatinine clearance measures the amount of creatinine excreted from the body during a defined time period. Urine is typically collected for 24 hours, but shorter collection periods may also be ordered. A blood sample testing for creatinine is required and can be obtained at any point during the urine collection period. The urine and blood samples are compared, and the creatinine clearance is calculated using one of several established mathematical formulas. Creatinine clearance is sometimes used to ensure adequate dosing of medications. The normal range for creatinine clearance in adults is 88 to 137 mL/min. Values are generally slightly lower in females than males. Decreased creatinine clearance occurs as a result of renal impairment and as a result of muscle wasting.

### Urine Cytology

Urine collected for cytological examination is used to identify any abnormal cells present in the urine. Abnormal cells are often present in the urine with bladder cancer. For this reason, examination of the urine is used as a diagnostic tool and a treatment marker in patients with bladder cancer. A urine sample other than the first void of the day should be collected and sent to the laboratory for microscopic analysis within 1 hour of collection.

### Imaging Studies

A variety of radiographical studies are available to examine the renal and urinary systems. Regardless of the study, nursing responsibilities include patient education, patient preparation, and monitoring for complications during and after the study. The patient should be educated on indications for the study, preparation for the study, what to expect during the study, possible complications, and any required follow-up care.

Many radiographical studies require the patient to complete bowel preparation the evening prior to the procedure. This eliminates feces and flatus in the bowel so that the view

of the urinary tract is not obstructed by a distended colon. Agents commonly used for bowel preparation include enemas, magnesium citrate, bisacodyl (Dulcolax), and castor oil. Bowel preparation agents such as Fleet enemas and magnesium citrate should be used cautiously in patients with known renal dysfunction. Patients may also be instructed to take in nothing by mouth (NPO status) for an ordered period of time prior to the procedure.

### Bedside Sonography

Portable ultrasound scanners provide a noninvasive means of estimating the volume of urine contained in the bladder. This technology can be used to assess for the presence of urine remaining in the bladder after voiding (postvoid residual) or to determine if there is a need for intermittent catheterization in a patient who is not independently voiding. This study can be completed at the bedside independently by the nurse. It requires no preparation of the patient and results in no discomfort or risk to the patient.

Conductive gel is placed over the symphysis pubis, and the probe is positioned above the pubic bone, pointing downward toward the coccyx. Bedside scanners are typically equipped with icons that indicate the accuracy of the probe placement. The scanner displays the estimated volume of urine contained in the bladder. For the most accurate results, the scan should be completed twice, and the results should be averaged. Large volumes of urine in the bladder following voiding or in a patient who is unable to spontaneously void indicate the need for catheterization.

### X-ray

An x-ray of the kidneys, ureters, and bladder (KUB) is a simple abdominal x-ray taken with the patient lying in the supine position. It reveals the size and anatomy of the renal and urinary system structures and can also reveal masses, obstructions, and calculi within the kidneys and urinary tract. The test requires no preparation of the patient and results in no discomfort or significant risk to the patient. If possible, x-rays should be avoided during pregnancy.

### Intravenous Urography

Intravenous urography is also termed *IV pyelography*. This test requires the administration of radiographical dye (contrast) via an IV line with the patient in the supine position. The contrast is circulated within the venous blood and upon reaching the kidneys is filtered by the glomeruli and is then excreted in the urine. Following the injection of dye, x-rays are performed at specific time intervals. A final x-ray is taken after the patient voids to measure the volume of any residual urine in the bladder. Intravenous urography reveals the size and anatomy of the KUB as well as any tumors, cysts, calculi, and obstructions within the urinary tract.

### Nursing Implications

#### Preprocedure

- Instruct the patient to complete bowel preparation the evening prior to the procedure and to remain NPO for approximately 8 hours prior. Before the procedure, the

nurse should confirm that the patient has completed the bowel preparation as ordered and has remained NPO for the prescribed time.

- Instruct the patient that the study lasts approximately 30 to 45 minutes and results in no discomfort. The patient should be told that he or she may feel a brief flushing sensation of the body and a salty taste in the mouth during the injection of the contrast.
- Ensure signed informed consent has been obtained after education regarding the indication and potential risks of the procedure
- Assess the patient's baseline serum creatinine prior to the study because of the nephrotoxic potential of the contrast. Caution should occur when utilizing contrast in patients of increased age and those with known renal dysfunction.
- Question the patient regarding any allergies to the contrast dye to be injected during the procedure. See the Safety Alert for patients receiving IV contrast.

#### Postprocedure

- Instruct the patient to increase fluid intake following the study to ensure adequate excretion of the contrast.
- Monitor the patient for changes in urine output, irritation at the IV site, and delayed signs of reaction to the contrast (e.g., rash, dyspnea, tachycardia). If there is a concern for changes in renal function related to the contrast, subsequent serum creatinine laboratory tests may be ordered.

#### Safety Alert Nursing considerations for patients receiving IV contrast for radiographical studies:

- Confirm the presence of signed informed consent.
- Assess patient for a history of allergies to contrast, iodine, and shellfish.
  - Patients with a history of these allergies may be premedicated with steroids.
- Confirm the presence of emergency medications and equipment at the bedside.
- Review baseline serum creatinine as evidence of renal function.
- Review patient history for the presence of renal dysfunction.
- Educate the patient regarding the flushing sensation and salty taste he or she may notice during contrast administration.
- Ensure the patency of the IV.
- Assess the patient for signs of a delayed reaction to contrast (e.g., rash, dyspnea, tachycardia)
- Ensure that the patient increases fluid intake following the study.
- If warranted, monitor subsequent serum creatinine laboratory values.

#### Renal Ultrasound

A renal ultrasound can be utilized to identify masses, cysts, and obstructions within the kidneys. Conductive gel is applied to the patient's skin, and an external probe is moved across the abdomen. Ultrasound images are produced as sound waves enter the body and are reflected back. The patient is exposed to no radiation, and the technology is noninvasive, making it a safe procedure with no risk to the patient. Ultrasound can be used to determine kidney size. Kidneys that are smaller than normal may be reflective of chronic kidney disease, and kidneys that are larger than normal may be reflective of a polycystic process or an obstruction. Ultrasound technology can also be used to differentiate between renal cysts and tumors. The patient may be ordered to drink up to 24 oz of fluid 1 hour prior to the study without voiding until completion of the ultrasound. No other preparation of the patient is required. There is no specific monitoring required during or following the study.

#### Computed Tomography

A CT scan produces three-dimensional images of the renal and urinary system structures as well as the surrounding tissues. Although not commonly a first-line diagnostic test, a CT scan may be used to further examine findings from studies such as x-rays or ultrasounds. Unlike ultrasounds, CT scans are capable of detecting slight variances in densities, providing more specific diagnostic results related to kidney size, tumors or other masses, renal vessels, and obstruction.

#### Nursing Implications

##### Preprocedure

- Instruct the patient to remain NPO for several hours prior to the procedure if required by the institution.
- Ensure signed informed consent has been obtained after education regarding the indication and potential risks of the procedure. Patient education includes the requirement to lay completely still while the scanner rotates around the body. If the patient is anxious or unable to follow such instructions, sedation or anxiolytic agents may be required. The scan lasts approximately 10 to 15 minutes.
- Assess allergies and baseline renal function because CT scans can be performed with or without IV contrast. Contrast may be withheld in a patient with known renal dysfunction.

#### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) varies from x-rays and CT scans in its use of magnetic forces rather than ionizing radiation to produce images for diagnostic testing. Magnetic resonance imaging is known for its ability to reveal contrasts between soft tissues of the body. For this reason, it is useful in examining the tissue of the kidneys to assess for abnormalities.

## Nursing Implications

### Preprocedure

- Educate the patient:
  - The procedure is painless but can last for up to 90 minutes.
  - Remove any metal objects, including jewelry, removable metal dental devices, hearing aids, glasses, and body piercings.
  - The machinery used for MRI is a cylinder surrounded by a large magnet. The patient lies on a moveable examination table and is slowly guided through the cylinder.
  - A patient with known claustrophobia or a patient who is unable to lie still for other reasons may require sedation or anxiolytic medications prior to the MRI. Open MRI equipment is available for use in patients who are claustrophobic, obese, or unable to lie still for other reasons.
- Ensure signed informed consent has been obtained after education regarding the indication and potential risks of the procedure.
- Assess for the presence of pacemakers and some other types of implanted medical devices because MRI is contraindicated in patients with these devices present.
- Assess allergies and baseline renal function because MRI is infrequently performed with IV contrast.

### Cystography and Urethrography

Diagnostic tests utilizing cystography are termed *cystograms*. For this procedure, contrast dye is injected into the bladder via a urinary catheter or a cystoscope, and a thin, lighted instrument is inserted into the urethra and slowly advanced into the bladder. Cystography can be used to assess the bladder for abnormalities, including calculi and masses. It can also be used to examine the bladder if trauma is suspected. A similar test can be performed to assess for trauma to the urethra and is termed a *urethrogram*. A specific type of this diagnostic test, a voiding cystourethrogram (VCUG) can also be performed to determine if vesicoureteral reflux is present. A VCUG requires the patient to void after the bladder is filled with contrast while x-rays are taken. If reflux is present, urine is backflowing from the bladder into the ureters and/or kidneys, increasing the patient's risk of developing kidney infections.

## Nursing Implications

### Preprocedure

- Educate the patient regarding the indication and risks of the procedure. The insertion and use of the urinary catheter or cystoscope should be thoroughly explained.
- Ensure that informed consent has been obtained.
- Assess for allergies to contrast, iodine, and shellfish. Because the contrast does not enter the bloodstream, there is no danger of nephrotoxicity.

### Postprocedure

- Monitor the patient for signs and symptoms of infection because the instrumentation used increases the risk of infection.
- Educate the patient on signs and symptoms of infection and adequacy of urine output once discharged.

### Arteriography

Arteriography, or angiography, involves visualizing the renal vasculature to assess for strictures, bleeding, renovascular hypertension, and other vascular abnormalities. An arteriogram requires placement of a catheter into the femoral artery. The catheter is then advanced to the level of the renal arteries, and IV contrast is injected to highlight any vascular abnormalities.

## Nursing Implications

### Preprocedure

- Educate the patient regarding the indication of the study and its potential risks; also, educate the patient about the bowel preparation that should occur the evening prior to the angiogram and the need to remain NPO after midnight.
- Ensure that signed informed consent has been obtained.
- Assess for allergies to contrast, iodine, and shellfish. See the related Safety Alert for further nursing considerations related to the use of IV contrast for radiographical studies.

### Postprocedure

- Apply manual pressure to the femoral site following removal of the femoral catheter until the bleeding has stopped. A pressure dressing should then be placed over the site, and the nurse should assess the site frequently per institutional policy for bleeding.
- Monitor vital signs frequently.
- Monitor color, temperature, and pulses distal to the femoral site every 30 to 60 minutes to assess for signs of the development of a thrombus or hematoma, which can occlude distal blood flow.
- Instruct the patient to lie with the affected leg straight for the prescribed time, usually 8 to 12 hours.

### Renography (Kidney Scan)

A kidney scan is an additional diagnostic test that can be utilized to assess renal blood flow. A radionuclide is injected intravenously and is absorbed by the kidney tissue. An external probe is then placed over the kidney to detect radiation emissions. Images of the kidney are produced by these emissions. The study is useful in determining kidney size, general blood flow through the kidneys, glomerular and tubular filtration, and urinary excretion. Signed informed consent should be obtained following patient education about the indications and risks of the study. A kidney scan requires no specific patient preparation or monitoring during or after the procedure.

## Connection Check 61.4

The nurse understands that an abnormal VUCG indicates which of the following?

- A. The presence of a mass in the bladder
- B. An increased risk of kidney infection
- C. Incomplete emptying of the bladder
- D. Decreased creatinine clearance

### Renal Biopsy

A renal biopsy involves removing a tissue sample via a small percutaneous (through the skin and other tissue) site using CT or ultrasound guidance while the patient is sedated and lying in the prone position. Renal biopsies are useful in ruling out malignant processes and diagnosing renal abnormalities that have not been successfully diagnosed with other diagnostic tests.

### Nursing Implications

#### Preprocedure

- Educate the patient regarding the procedure and its associated risks.
- Ensure that a signed informed consent has been obtained.
- Ensure that the patient has been NPO for 4 to 6 hours prior to the procedure and has stopped taking aspirin, warfarin (Coumadin), and other agents that may affect the ability of the blood to clot normally prior to the procedure.
- Send a type and screen and coagulation laboratory values, including a platelet count, prothrombin time, and activated partial thromboplastin time, to the laboratory prior to the study because of the risk of bleeding.
- Obtain baseline vital signs and monitor vital signs frequently during the biopsy.

#### Postprocedure

- Apply manual pressure to the site until bleeding has stopped. A pressure dressing should then be applied, and the nurse should monitor the site frequently per institutional policy for bleeding.
- Assess hematocrit and hemoglobin levels postprocedure because bleeding can sometimes occur internally with no external indications. Signs of internal bleeding include flank pain, decreased urine output, decreased blood pressure, and other signs of hypovolemia and shock.
- Assure the patient remains on bedrest for up to 24 hours following the renal biopsy.
- Educate the patient regarding the following:
  - Some local discomfort may occur at the site of the biopsy, but pain radiating to the abdomen and flank should be reported.

- Increase fluid intake following the biopsy to prevent clot formation in the urinary tract, which could obstruct the flow of urine.
- The most common complication following a renal biopsy is hematuria. This typically resolves within 48 to 72 hours following the procedure. Inform the patient that within this time period, hematuria is an expected finding, but notify the healthcare provider of hematuria occurring beyond 72 hours after the procedure. The patient should also be told to notify the provider of the presence of clots in the urine or any difficulties with voiding.
- Avoid heavy lifting for 1 week following the procedure.
- Do not resume taking anticoagulant medications until instructed by the healthcare provider.

### Cystoscopy

Cystoscopy is a surgical procedure utilized to diagnose and/or treat bladder problems. A cystoscope is a tubular, lighted device that is inserted through the urethra while the patient is sedated and in the lithotomy position. As a diagnostic tool, it can be used to assess for bladder trauma, urethral trauma, or urinary tract obstructions. Cystoscopy can also be used to remove an enlarged prostate gland, bladder tumors, or renal calculi. Cystoscopy can be performed utilizing local or general anesthesia.

### Nursing Implications

#### Preprocedure

- Educate the patient regarding the indication of the study and its potential risks; also, educate the patient about the bowel preparation that should occur the evening prior to the cystoscopy and the need to remain NPO after midnight.
- Ensure that signed informed consent has been obtained.
- Assess baseline vital signs before the administration of anesthesia and at frequent intervals throughout and immediately following the procedure.

#### Postprocedure

- Assess urine volume to ensure adequate output.
- Educate the patient regarding the following:
  - Expected findings following cystoscopy include urinary frequency and pink-tinged urine. Gross bleeding and/or clots in the urine are not normal and should be reported to the healthcare provider.
  - Mild analgesics and topical measures such as warm, moist heat and sitz baths may be used to manage the discomfort following the procedure.
  - Monitor for signs and symptoms of infection (e.g., fever, chills, dysuria) and report these to the healthcare provider immediately should they occur.

### Connection Check 61.5

The nurse is caring for a patient receiving IV contrast for a renal CT scan. Nursing responsibilities related to the administration of IV contrast include which of the following? (Select all that apply.)

- A. To assess for allergies to contrast, iodine, and seafood prior to the study
- B. To educate the patient to increase fluid intake following the study
- C. To obtain an order for NPO status following the study
- D. To ensure that IV contrast is administered only through a central line
- E. To assess the patient's baseline creatinine value prior to the study

### AGE-RELATED CHANGES

The renal and urinary systems undergo many changes with increasing age. Both systems experience anatomical and physiological changes that are reflected as changes in subjective and objective assessment findings and laboratory results (see Geriatric/Gerontological Considerations). Although baseline renal function may remain stable with age, the kidneys are less tolerant of insult. Therefore, damage to the kidneys caused by disease processes or medications can be much more significant in the geriatric population.

### Geriatric/Gerontological Considerations

#### Renal and Urinary System Age-Related Changes and Assessment Findings

- Kidneys decrease in size → Kidneys less palpable on examination
- Number of nephrons decreases, nephrons lose functioning, glomerular membrane thickens → ↓GFR, ↑BUN and creatinine
- Blood flow to kidneys decreases → ↓GFR, ↑BUN and creatinine
- Changes in loop of Henle → Decreased ability to concentrate urine, decreased effect of ADH and aldosterone, urinary frequency, risk for dehydration
- Loss of muscle tone and elasticity → Risk for urinary incontinence
- Decreased bladder capacity → Urinary frequency, urgency, incontinence
- Enlargement of prostate gland → Urinary hesitancy, frequency, straining, slow urine stream, urinary retention

ADH, Antidiuretic hormone; BUN, blood urea nitrogen; GFR, glomerular filtration rate.

The kidneys decrease in mass by up to 10% each decade starting at approximately age 50. The number of glomeruli also begins to decline around the age of 50. The decreased number of glomeruli coupled with the thickening of the glomerular membrane results in decreased filtering capacity. It is estimated that by the seventh decade of life, between 30% and 50% of glomeruli have lost their function. This is typically manifested as a decrease in GFR and sometimes an increase in BUN and creatinine levels. By approximately age 65, the GFR of an otherwise healthy adult is 65 mL/min, half of the normal value for GFR. The GFR decreases more rapidly in adults with chronic conditions that affect the kidneys, such as diabetes mellitus and hypertension. The decrease in GFR affects the speed at which the kidneys are able to eliminate medications from the body. Therefore, GFR is an important consideration when planning the dosage and administration schedules of many medications in the geriatric population.

Blood flow to the kidneys also decreases with age. This decrease in blood flow is intensified in the presence of alterations in the vascular system such as atherosclerosis and hypertension, which are often associated with aging. Decreased blood flow to the kidneys also contributes to the decrease in the GFR.

Changes in the functioning of the loop of Henle and the kidney tubules coupled with a decrease in the effectiveness of ADH and aldosterone result in a decreased ability to concentrate the urine. Consequentially, the aging adult produces less-concentrated urine and experiences more frequent urination. These factors explain the common finding of nocturnal polyuria in the geriatric population. The total water content of the body also decreases with age. The decreased effect of ADH and the production of less concentrated urine place the aging adult at an increased risk for dehydration.

The structures of the urinary system also undergo changes related to increasing age. In females, the bladder, vagina, and pelvic floor muscles lose tone and elasticity, which contributes to an increased occurrence of urinary incontinence. This can be further intensified in women who previously lost muscle tone and elasticity during pregnancy and childbirth.

The capacity of the bladder in both sexes decreases with age by up to 50%. This results in the need for more frequent urination and increased occurrence of urinary urgency and, at times, urinary incontinence.

A majority of men experience changes in their urination patterns related to enlargement of the prostate gland. Enlargement of the prostate gland not related to a malignant process such as cancer is termed *benign prostatic hypertrophy* (BPH). Benign prostatic hypertrophy causes the urethra to be compressed and results in urinary hesitancy, frequency, straining to urinate, slow urine stream, and urinary retention (BPH is discussed in Chapter 66).

As a whole, aging adults experience a higher incidence of UTIs. Urinary tract infections are the most common bacterial infection in the geriatric population. In women,

the increased incidence can be partially attributed to age-related changes in the pH of vaginal secretions that make the environment more conducive to bacterial growth. In men, alterations in the flow of urine related to BPH can alter the ability of bacteria to be eliminated efficiently from the urinary tract. The increased occurrence of urinary retention in both sexes results in higher-than-normal postvoid residuals, which may also explain the increased incidence of UTIs in the geriatric population.

### Connection Check 61.6

The nurse caring for an 86-year-old female patient who presents with nocturnal polyuria incorporates which priority nursing diagnosis into the plan of care?

- Risk for deficient fluid volume
- Risk for sleep deprivation
- Risk for excess fluid volume
- Risk for urge urinary incontinence

## Making Connections

### CASE STUDY: WRAP-UP

At the completion of a thorough health history, physical assessment, and collection of laboratory studies, the following pertinent data have been collected:

- 72-year-old African American male
  - Decreased appetite, fatigue, 10-lb weight gain over 2 months, changes in mental status, urinates “only small amounts of urine”
  - Personal medical history: “borderline hypertension”
  - BP 188/92 mm Hg, HR 94 bpm, R 22, T 98.2°F (36.8°C), O<sub>2</sub> saturation 94% on room air
  - Follows commands, yet appears lethargic; +2 nonpitting, bilateral pedal edema; pallor with poor skin turgor
  - Creatinine: 1.8 mg/dL
  - BUN: 40 mg/dL
  - BUN/creatinine ratio: 15:1
  - Potassium: 5.5 mEq/L
  - Phosphorus: 3.9 mEq/L
  - Calcium: 8.2 mg/dL
- Mr. Jones is admitted to a medical unit for further monitoring and treatment of hypertension and his newly diagnosed renal insufficiency.

### Case Study Questions

- The nurse has received the following provider orders for Mr. Jones, who was recently admitted to the medical unit. Which order should the nurse plan to implement first?
  - Administer 40 mg furosemide Lasix daily.
  - Implement fluid restriction less than 1,500 mL/24 hr.
  - Monitor urine specific gravity with each void.
  - Instruct patient to follow a low-sodium diet.
- The provider orders a basic metabolic panel to be drawn 12 hours after Mr. Jones's admission. When the results are reported, the nurse recognizes that which of the following laboratory values should be reported to the provider most urgently?
  - Creatinine 1.9 mg/dL
  - Calcium 8.0 mg/dL
  - Potassium 5.7 mEq/L
  - Phosphorus 4.2 mEq/L
- The nurse caring for Mr. Jones should implement which of the following priority nursing interventions? Select all that apply.
  - Strict monitoring of intake and output
  - Frequent monitoring of vital signs
  - Administer supplemental oxygen
  - Safety/fall precautions
  - Obtain daily weights
- The nurse caring for Mr. Jones incorporates which of the following priority nursing diagnoses into the plan of care?
  - Risk for falls
  - Risk for imbalanced fluid volume
  - Impaired urinary elimination
  - Readiness for enhanced knowledge
- Which statement by Mr. Jones indicates that the discharge teaching by the nurse has been effective?
  - “I should carefully monitor and record my weight each day.”
  - “If I am feeling well, I do not have to take my blood pressure medications regularly.”
  - “If I have aches and pains, I should take over-the-counter Motrin.”
  - “I should try to increase the amount of potassium I take in by eating at least one banana every day.”

## CHAPTER SUMMARY

The renal system is composed of two kidneys. The functions of the renal system include removing wastes from the bloodstream, regulating blood pressure and red blood cell production, activating vitamin D, and maintaining the balance of fluids, electrolytes, and acids and bases.

Each kidney contains nearly a million nephrons, which are the functional units of the kidneys. Through the continuous processes of filtration, reabsorption, secretion, and concentration, nephrons move wastes from the blood into the urine while maintaining a careful balance of fluids and electrolytes.

The urinary system is composed of two ureters, the urethra, and the urinary bladder. The function of the urinary system is to store urine and to allow for the excretion of urine from the body. Micturition occurs as a result of the coordination of signals from the brain and spinal nerves that innervate the bladder. Continence is the learned ability to control urination and can be affected by medications, trauma, and comorbid conditions.

Assessment of the renal and urinary systems should include the collection of a subjective health history and an objective physical examination. Data related to gender, age, race, socioeconomic status, occupational history, past medical history, and dietary and personal habits should be obtained from a health history. A physical examination should occur following the sequence of inspection, auscultation, palpation, and percussion.

A variety of laboratory and diagnostic tests can be utilized to evaluate the structure and function of the renal and urinary systems. Serum laboratory values, including creatinine, BUN, and electrolytes, can be obtained to assess the function of the renal system. Urine tests can also be used to evaluate renal function. Radiographical studies, including ultrasounds, x-rays, and computed tomography scans, can be used to evaluate the structure of the kidneys, ureters, bladder, and renal vasculature.

The kidneys and urinary system structures undergo changes with increasing age. The size of the kidneys and the number of nephrons decrease with aging, resulting in slowed kidney function. Females may experience a loss of muscle tone of the urinary system and its supportive structures, causing an increased risk of urinary incontinence. Males may experience enlargement of the prostate gland and associated urinary frequency, hesitancy, and urinary retention. Patients of advanced age are also at an increased risk of experiencing dehydration and developing UTIs.

Nursing roles in caring for clients with potential alterations in the renal and urinary systems include monitoring vital signs and intake and output data, collecting a health history and physical examination, evaluating laboratory results, and monitoring the client during and following radiographical procedures. The nurse also has a responsibility in assisting clients to maintain normal functioning of the renal and urinary systems by teaching healthy dietary and lifestyle habits in addition to the need for preventive healthcare screenings.

# Chapter 62

## Coordinating Care for Patients With Renal Disorders

*Vinciya Pandian*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of renal disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Polycystic kidney disease
  - b. Pyelonephritis
  - c. Glomerulonephritis
  - d. Renal cancer
  - e. Renal trauma
  - f. Acute kidney injury
  - g. Chronic kidney disease
3. Describing the diagnostic results used to confirm the diagnoses of renal disorders
4. Discussing the medical management of:
  - a. Polycystic kidney disease
  - b. Pyelonephritis
  - c. Glomerulonephritis
  - d. Renal cancer
  - e. Renal trauma
  - f. Acute kidney injury
  - g. Chronic kidney disease
5. Comparing and contrasting acute and chronic renal failure
6. Developing a comprehensive plan of nursing care for patients with renal disorders
7. Designing a plan of care that includes pharmacological, dietary, and lifestyle considerations for patients with renal failure
8. Describing the indications, management, and complications associated with renal replacement therapies
9. Describing the indications, management, and complications associated with renal transplantation

### ESSENTIAL TERMS

Acute kidney injury (AKI)  
Arteriovenous (AV) fistula  
Arteriovenous (AV) graft  
Chronic kidney disease (CKD)  
Cold ischemia time  
Continuous renal replacement therapies (CRRTs)  
End-stage renal disease (ESRD)  
Glomerular filtration rate (GFR)  
Glomeruli  
Glomerulonephritis  
Hemodialysis (HD)  
Nephron  
Oliguria  
Peritoneal dialysis  
Polycystic kidney disease (PKD)  
Renal cancer  
Renal replacement therapies (RRTs)  
Renal transplantation  
Renal trauma

### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Infection
- Medication
- pH Regulation
- Urinary Elimination

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Doris Flood is a 35-year-old woman who presents to the clinic with complaints of abdominal and left flank pain. She is currently not on any medications except for a multivitamin daily. Ms. Flood complains of increased frequency of voiding, an urgency to void, and the presence of cloudy urine. She also complains that she has noticed abdominal distention over the last year. Vital signs reveal a temperature of 101°F (38.3°C) (orally) and a blood pressure of 180/100 mm Hg...

## INTRODUCTION

The kidneys play a critical role in the overall function of the body. The kidneys remove waste, help maintain fluid and electrolyte balance, and help regulate the acid-base balance of the body. Adequate functioning of the kidneys is essential to an individual's health and well-being. Patients with compromised renal function may present with a variety of clinical manifestations. If the kidneys are not functioning properly and adequate treatment is not implemented promptly, acute illness occurs, and death is inevitable. This chapter discusses specific disorders of the kidneys and renal system.

## POLYCYSTIC KIDNEY DISEASE

### Epidemiology

Polycystic kidney disease (PKD) is one of the most common genetic disorders in the world, affecting approximately 1 in 600,000 people in the United States and 12.5 million people worldwide. Polycystic kidney disease represents about 10% to 15% of chronic renal disorders. It is a progressive

kidney disorder causing excessive growth of fluid-filled cysts in the kidneys, often leading to complications over time. There are two forms of PKD, childhood and adult. Polycystic kidney disease in infancy and childhood is less common. It is caused by an autosomal-recessive disorder, and its course is rapid and progressive, leading to severe lung and liver dysfunction and **end-stage renal disease (ESRD)**, causing death during infancy or childhood. The adult form is autosomal-dominant polycystic kidney disease (ADPKD), which is relatively common. It affects 1 in 540,000 people in the United States and has a 50% chance of genetic inheritance. Autosomal-dominant polycystic kidney disease is a multisystemic disorder characterized by cysts that are not limited to the kidneys but may also be present in the liver, spleen, and pancreas. Adult PKD lies dormant for many years and usually appears between the ages of 30 and 40 years. The prevalence of PKD is the same for men and women and involves both kidneys.

### Connection Check 62.1

The nurse recognizes that genetic counseling is appropriate for which patient?

- A child with frequent urinary tract infections
- An adult with frequent urinary tract infection
- An adult with autosomal-dominant polycystic kidney disease
- An adult with metastatic renal cancer

### Pathophysiology

Polycystic kidney disease is a genetic disorder that manifests in the cortex and medulla of both kidneys and appears as large, thin-walled, fluid-filled cysts ranging from millimeters to centimeters in diameter (Fig. 62.1). Cysts develop as a result of a repeated cell-division process within the renal tubule known as a cystogenic process that occurs many times over the life of the patient with PKD. Progressive expansion causes emerging cysts to separate from the parent tubule, leaving an isolated sac. The cysts become large and compress the

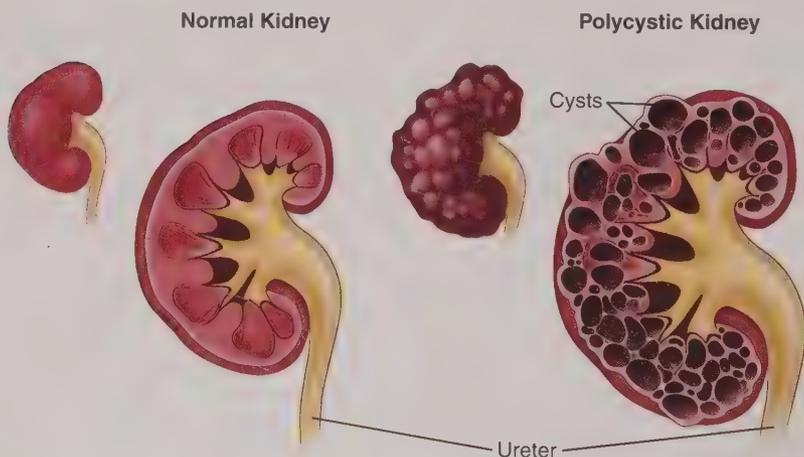

FIGURE 62.1 Polycystic kidney disease.

surrounding tissue, destroying the underlying renal tissue. The compression of the underlying tissue reduces the blood flow and subsequent nutrient supply to the renal tissues, which are highly sensitive to reduced blood and nutrients.

## Clinical Manifestations

Polycystic kidney disease generally has no clinical manifestations in the early stages. The symptoms become apparent as the cysts enlarge. The first symptom to appear is hypertension as a result of damage to the surrounding renal structures caused by the enlargement of the cysts. Hematuria also occurs because of the rupture of the cysts. The patient may complain of lower back or flank pain, headaches, or pain in the abdominal area. The patient also may initially manifest clinical manifestations of urinary tract infection (UTI), increase in urinary frequency, or urinary calculi (stones) that cause severe pain as a result of obstruction to urinary flow. Physical examination on palpation may reveal bilaterally enlarged kidneys, increased abdominal girth, and costovertebral angle tenderness. The disease progresses to ESRD in about 50% of patients by age 60. The remaining 50% of patients have mild to moderate symptoms and generally die from complications such as infection or impaired renal function.

## Management

### Medical Management

#### Diagnosis

The diagnosis of PKD is generally made based on clinical manifestations and patient and family history. Laboratory tests such as urinalysis reveal blood (hematuria) or bacteria in the urine. Definitive diagnosis is determined by abdominal ultrasound, magnetic resonance imaging (MRI), IV pyelogram (IVP), or computed tomography (CT) scan. Diagnostic imaging can reveal other complications related to PKD, such as cysts on the liver and other abdominal organs. A renal ultrasound, a less invasive and less expensive method of diagnosing PKD, can also assist in the visualization of cysts.

### Connection Check 62.2

The nurse understands that which diagnostic study is most specific in identifying PKD?

- Abdominal x-ray
- Serum creatinine level
- Urinalysis
- Computed tomography scan

### Treatment

PKD frequently progresses to ESRD because of the renal impairment caused by the cysts. The enlarged cysts obstruct and compress surrounding tissue, causing a reduction in renal circulation. The impairment of renal circulation causes renal failure, resulting in decreased clearance of

wastes and inadequate fluid, electrolyte, and acid-base balance. Patients who progress to severe PKD will require treatment consistent with that of ESRD: **hemodialysis (HD)** or **peritoneal dialysis**.

Other treatment goals for PKD include managing UTIs, pain, and hypertension. Managing UTIs requires regular checkups and immediate treatment as the clinical manifestations of infection become evident. Antibiotics are necessary to control the spread of infection up to the kidney. Pain can be managed with nonnarcotic pain medications such as acetaminophen and opiate narcotic pain medications such as morphine. Severe pain may require nephrectomy as a palliative measure. Hypertension is managed with medications such as angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers. Lifestyle changes such as proper diet, exercise, and smoking cessation are also recommended. All treatments described are intended to manage symptoms. **Renal transplant** may be considered as the only curative measure.

### Complications

Common complications of PKD include severe hypertension, renal calculi, recurrent UTIs, hematuria, and heart-valve abnormalities. People with PKD are also at high risk for developing life-threatening aneurysms in the aorta or cerebral circulation. Additionally, PKD can lead to the development of cysts in the liver and the gastrointestinal tract. The cysts that form in the liver destroy surrounding tissues and impair the normal functioning of the liver in degrading waste products of digestion. The cysts in the intestines can cause diverticulosis or an outpouching of the intestines. The most common complication of PKD is renal failure and is characterized by the inability of the kidneys to remove waste products and excess fluid from the circulation. Renal failure is discussed in detail later in this chapter.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations observed in patients with PKD typically appear as a result of the enlargement and rupture of the cyst. Typical findings of PKD include:

- Hypertension
- Hematuria
- Pain or heaviness in the back, abdomen, or flank area
- Headaches
- UTI
- Urinary calculi
- Palpable, bilaterally enlarged kidneys

#### Nursing Diagnoses

- **Excess fluid volume** related to the inability of the kidneys to excrete fluid and excessive fluid intake
- **Risk for infection** related to alteration in urinary elimination pattern
- **Ineffective therapeutic regimen management** related to lack of knowledge regarding the disease process

## Nursing Interventions

### ■ Assessments

#### ● Vital signs

*Increased temperature may be present because of infection. Hypertension is present because of changes in the renal tissue caused by the cysts. Increased heart rate may be present as a result of infection and pain.*

#### ● Oxygenation

*Anemia associated with chronic kidney disease may impair oxygen exchange at the cellular level, which results in lower oxygen saturation.*

#### ● Daily weight

*An increase in sodium and water retention may result in weight gain.*

#### ● Laboratory values

##### • Hemoglobin/hematocrit

*Anemia is associated with chronic renal disease because of the decreased production of erythropoietin, a protein produced in the kidneys necessary for red blood cell (RBC) production.*

##### • Plasma creatinine level/blood urea nitrogen

*Impairment in renal function may affect the renal clearance of waste products. Evidence of impairment in renal clearance is seen as an elevation in serum creatinine and BUN levels.*

##### • Plasma sodium level

*Patients with PKD may retain sodium, which causes fluid retention and predisposes the patients to hypertension, fluid overload, and heart failure.*

##### • Plasma potassium level

*Patients with PKD may have an elevated potassium level as a result of the impaired renal elimination of potassium.*

##### • Plasma calcium level

*Patients with PKD may have low calcium levels because of renal damage impairing the conversion of vitamin D to its active form, which allows the GI absorption of calcium from the diet.*

##### • Plasma phosphorus level

*Patients with PKD may have elevated phosphorus levels because of impaired renal clearance of phosphates.*

##### • Urinalysis/urine cultures

*Patients with PKD are at high risk for UTIs due to the compression of the tissue by the cysts impairing elimination. Careful monitoring of the clinical manifestations of a UTI is necessary to ensure prompt treatment and avoid the ascension of the infection to the renal structures.*

### ■ Actions

#### ● Diet modification consistent with impaired renal function, specifically low potassium, phosphorus, protein, and sodium

*Diet modification is essential to prevent severe complications from eating foods high in protein, potassium, and phosphorus that the kidneys cannot excrete adequately. Excess sodium intake can cause fluid retention.*

#### ● Fluid restriction

*Fluid restriction is important in the care of the patient with PKD and renal failure. Excess fluid intake may*

*not be excreted, and fluid overload and heart failure may occur.*

- Administer antihypertensive agents as ordered. *Uncontrolled hypertension is a significant complication of PKD because of the damage to the renal tissue by the enlarged cyst that compresses the surrounding tissue, reducing perfusion to the tissues. Complying with prescribed antihypertensive agents is required for patients with PKD to reduce elevated blood pressure, which is a risk factor for heart disease and stroke.*
